Recently, a new recombinant VWF (rVWF) concentrate was approved in Europe and North America for use in adults diagnosed with VWD.[109] In contrast to traditional plasma-derived products, the rVWF preparation is FVIII-free, and thus, may be independently administered if baseline FVIII:C is adequate (>40%). Whether administered alone or co-administered with recombinant FVIII, rVWF is cleared with a significantly longer half-life than its plasma-derived counterpart. UL-VWF multimers which are lacking in plasma-derived products due to the proteolytic activity of ADAMTS13, are present in the recombinant product. These UL-VWF multimers are susceptible to endogenous ADAMTS13 and are rapidly proteolyzed into LMW forms. While phase 3 studies have demonstrated the hemostatic efficacy and safety of rVWF in the context of on-demand treatment and perioperative management,[110–112] ongoing studies are evaluating long-term use of rVWF for prophylaxis as well as its use in pediatric patients. Undoubtedly, rVWF represents an important advance in the treatment options for VWD.

Prophylaxis

Short-term prophylaxis with a combination of an antifibrinolytic, DDAVP, and/or VWF/FVIII concentrates, in anticipation of a defined bleeding challenge, such as surgery, is the standard of care in the treatment of VWD.[98] The role of long-term continuous prophylaxis, defined as primary if initiated before long-term sequelae have developed (e.g., joint damage), or secondary if initiated after the development of chronic changes, is less established in VWD than it is in severe hemophilia. Individuals with severe cases of VWD, particularly type 3 VWD and certain patients with severe type 1 or type 2 VWD, may experience recurrent joint bleeds, as well as severe and frequently recurrent nasal/oral, GI, or menstrual bleeding. The resultant anemia, hospitalizations, and absences from school or work may have a significant impact on quality of life. Several cohort studies, including the VWD International Prophylaxis (VIP) study, and case studies suggest that both primary and secondary long-term prophylaxis improve quality of life, alleviate anemia, reduce hospitalizations, and prevent chronic joint disease.[113] Complications are unusual aside from rare cases of VWF inhibitor formation (approximately 3% of type 3 VWD patients). There still, however, remains no international consensus regarding the specific indications, schedules, and dosing of prophylactic regimens.

Pediatric Issues

Prenatal diagnosis for pregnancies at increased risk (generally only for type 3 VWD) is possible by analysis of DNA extracted from fetal cells obtained by chorionic villus sampling at 11 to 13 weeks of gestation or amniocentesis at 15 to 18 weeks of gestation. The disease-causing allele(s) of an affected family member must be identified before prenatal testing. Preimplantation genetic diagnosis may be available for families in which the disease-causing variant(s) have been identified.

The diagnosis and care of infants and children with VWD requires special consideration. An accurate assessment of hemorrhagic symptoms is a key component in the diagnosis of VWD, but it often presents a significant challenge in the pediatric population. Because young children may have been exposed to few hemostatic challenges and may be prepubertal, the bleeding history may be unimpressive. The effect this negative bleeding history may have on perceived risk for bleeding is highlighted in two of the previously published bleeding scores, which assign a negative value to a lack of bleeding symptoms, and are based on the accumulation of bleeding symptoms or complications. Finally, the initial diagnostic assessment of an infant is complicated by the fact that VWF levels are higher in the neonatal period. Consequently, phenotypic testing of VWD should be delayed until later in childhood (see Fig. 133.6).

DDAVP should be avoided in children younger than the age of two because of the potential difficulty in restricting fluids. Infant males should be circumcised only after consultation with a pediatric hemostasis specialist. Typically, only patients with type 3 VWD experience spontaneous musculoskeletal bleeding, such as that seen in patients with severe hemophilia, and should be considered for long-term prophylaxis with VWF/FVIII concentrates, as discussed in the preceding section (see box on Assessment of a Neonate).[114]

ASSESSMENT OF A NEONATE

A baby boy was born to a mother with known type 2B VWD. On the day of birth, investigations demonstrated the following: VWF:Ag 78 IU/dL, VWF:RCo 61 IU/dL, and FVIII:C 69 IU/dL (unclear whether these were done on the mother or the baby). The mother was informed that the results were all within the normal range and that her newborn infant was not affected by type 2B VWD. When he was approximately 18 months of age, the mother noted excessive mucocutaneous bleeding. Blood work at that time demonstrated: VWF:Ag 50 IU/dL, VWF:RCo 20 IU/dL, and FVIII:C 51 IU/dL. Multimer analysis revealed a lack of high-molecular-weight multimers. Finally, genotyping revealed that the boy was heterozygous for the same variant, p.Arg1306Trp, that his mother carried.

This case illustrates several important points. Neonatal levels of VWF are increased over baseline; if investigations are performed, they should be interpreted using appropriate reference ranges. Alternatively, if a phenotypic diagnosis is being sought, it is preferable to postpone investigations, decreasing the likelihood of pretest analytical variables, such as difficulty in collecting an appropriate blood sample from a neonate, and the difficulties with interpretation of the results. Finally, in cases in which the *VWF* variant is known, genotyping is diagnostic and also the most straightforward.

CHAPTER 134

HEMOPHILIA A AND B

Manuel Carcao, Keith Gomez, Davide Matino, and Glenn F. Pierce

Hemophilia is the most common, severe inherited bleeding disorder recognized in humans. The X-linked mode of inheritance has been appreciated since biblical times, and the previous occurrence of the disease in the European royal family has added further interest in this condition.

Hemophilia is subdivided into hemophilia A and B; the former being a deficiency or absence of factor (F) VIII while the latter is a deficiency or absence of FIX. Both are single-gene disorders. Ultimately both disorders result in a similar bleeding pattern whose severity is generally proportional to the amount of active factor VIII (FVIII) or FIX that the person produces. As both types of hemophilia result in deficiency of a coagulation protein, for the past more than half-century treatment has involved replacement of the missing protein (either FVIII or FIX) either episodically (on demand) to treat bleeds or prophylactically to prevent them. In the last 5 to 10 years, the management of both hemophilia A and B has transformed with the availability of coagulation protein replacement products with longer half-lives and with the introduction of emicizumab, a FVIII mimetic.

Additionally, clinical trials on novel therapies that aim at rebalancing coagulation in patients with hemophilia by targeting natural anticoagulants are ongoing and progress in gene therapy over the last decade is poised to provide a cure for hemophilic patients with imminent licensing of gene therapy products.

Therefore, the management of hemophilia is rapidly evolving.

EPIDEMIOLOGY

The prevalence of hemophilia is expected to be the same in all populations globally, apart from rare clusters of mild-moderate disease in areas where founder variants have been propagated (e.g., mild hemophilia A in Twillingate, Newfoundland; mild/moderate hemophilia B in Old Order Amish, United States).[1,2] In many parts of the developing world, the true prevalence of the condition is unknown because of inadequate diagnostic facilities, but from experience in the developed world, it can be assumed that the incidence of hemophilia A and hemophilia B in males at birth is approximately one in 4000 (slightly higher than the previous estimate of one in 5000) and one in 20,000, respectively.[3,4]

Due to the X-linked recessive mode of inheritance, most affected subjects are male. However, for every male with hemophilia there are likely two carrier females (including, in most cases, the mother of the affected male as well as potentially some sisters of the male and his daughters). In addition to mothers and sisters of boys with hemophilia there are likely many other women who are carriers but are never diagnosed because they are not related to any male with hemophilia. Hence the hemophilia carrier state is almost certainly much more common than hemophilia in males. Most carriers without affected sons/brothers will likely never be investigated, as most (particularly women with non-O blood type) will not experience significant bleeding because their FVIII or FIX levels are in the normal range or, if their FVIII levels are low, will be misdiagnosed as having von Willebrand disease (VWD) rather than being carriers of hemophilia.[5] For further discussion on hemophilia carrier detection see the box on Hemophilia Carrier Detection and Prenatal Diagnosis. Even though most carrier females have clotting factor levels in a normal range, some hemophilia carrier women have levels low enough to cause mild, moderate, or even severe disease due to lyonization (X-linked inactivation). A new nomenclature reclassifies these women as having mild, moderate, or severe hemophilia in a similar manner to hemophilic males.[6]

HEMOPHILIA CARRIER DETECTION AND PRENATAL DIAGNOSIS

The X-linked recessive nature of hemophilia results in most affected subjects being males. Females, however, carry and transmit the hemophilic trait and can sometimes also have clinical manifestations of the disease. Female carriers of hemophilia rarely have factor levels low enough to cause moderate or severe hemophilia; however, this can occur under the genetic circumstances listed in Table 134.1.

There are four ways in which hemophilia carriers can be identified. The first three apply to women with a high a priori likelihood of being a carrier based on a positive family history of hemophilia while the last applies to those without a family history of hemophilia.

Determining Carrier Status in Women With a Family History of Hemophilia

First, considering the X-linked transmission of the disease, pedigree analysis will determine the carrier status of some women. Thus, all daughters of hemophilic fathers and all women with an affected son and another first-degree male relative (another son, brother, uncle, cousin) are obligate carriers.

The second mode of carrier detection involves laboratory testing. In a minority (≈20%–30%) of carriers, the PTT may be prolonged and plasma levels of FVIII, or FIX may be reduced. These findings, together with a family history of hemophilia, are predictive of a carrier state. The etiology of low factor levels in carrier females is multifactorial and includes a woman's blood type and VWF levels as well as the ratio of inactivation of the hemophilic and normal X chromosomes; a random process that occurs early in embryonic development. If there is markedly skewed inactivation of the normal X chromosome, the plasma level of FVIII or FIX may be correspondingly reduced, and the carrier female may have a bleeding disorder. It is important to determine the FVIII or FIX levels in all carrier females to inform the risk of bleeding with surgical procedures or childbirth. However, carriers rarely have a prolonged PTT or low plasma levels of FVIII or FIX. Therefore, a normal factor level does not rule out the carrier state. With hemophilia A, a low FVIII to VWF ratio is a good predictor of the carrier state.[5]

The third and most definitive approach to carrier diagnosis is to use molecular genetics to identify the causative FVIII or FIX mutation. The results of such testing can be available within a few days if the information is needed urgently. Genetic carrier determination enhances family counseling for hemophilic kindreds and enables optimal preparation for delivery and future planning.

Determining Carrier Status in Women With no Family History of Hemophilia

Very rarely a hemophilia carrier may be identified in a family in which there is no history of hemophilia. This would likely occur if the woman had abnormal bleeding associated with a low FVIII or FIX level. Although estimates of the percentage of hemophilia carriers with excessive bleeding (most often heavy menstrual bleeding) vary, it is likely in the 20%–30% range. Therefore, most de novo carriers will never be diagnosed or may only be diagnosed if they have affected sons or grandsons with hemophilia. Without a family history of hemophilia, it is difficult to confirm a diagnosis of hemophilia carriership even in a woman with excessive bleeding and a low FVIII or FIX level. Often carriers of hemophilia A are incorrectly labeled as having type 1 VWD particularly if they have an O blood type and, as a result low VWF levels. In this setting, a FVIII level that is much lower than the VWF level may be helpful.

Ideally, carrier detection should be undertaken before the woman contemplates starting a family. In many countries, testing for carrier status of a genetic disease is prohibited before adolescence to ensure that the subject can meaningfully participate in discussions of testing options.

Prenatal diagnosis of hemophilia begins with determination of the fetal sex, which can usually be determined by ultrasound examination. As levels of fetal DNA in maternal blood increase late in pregnancy examination for the presence of Y chromosome sequences in maternal blood enables definitive sex determination. If the fetus is female, no additional studies are required. If the fetus is male, fetal DNA for molecular genetic analysis can be isolated from chorionic villus samples obtained after 10 weeks of gestation or from amniocytes obtained by amniocentesis from 12 to 34 weeks. The risk of miscarriage with either procedure is approximately 1%. If the studies are being used to inform decisions about therapeutic abortion, they should be performed as early as possible. Determination of the hemophilic status of the fetus will also help planning for delivery, although consensus about optimal obstetric management of an affected baby is lacking.

Over the past decade, international studies indicate that the number of reported persons with hemophilia has increased by approximately 2% each year. The likely reasons for this trend include increasing awareness and improved diagnosis of hemophilia, increasing longevity of persons with hemophilia due to improved treatment and decreased mortality from human immunodeficiency virus (HIV) and hepatitis C. This also leads to greater propagation of hemophilia mutations as affected males are more likely to reach adulthood and "pass their genes" to the next generation. Potentially there may be other reasons to explain the increase in hemophilia.

TABLE 134.1 **Genetic Mechanisms Causing Hemophilia in Females**

- *F8* or *F9* mutation homozygosity
- *F8* or *F9* mutation compound heterozygosity
- Extreme skewing of X inactivation process
- X/O karyotype: Turner syndrome
- X/autosome translocation

The clinical signs and symptoms and inheritance patterns for hemophilia A and B are identical, and it was not until the early 1950s that the two forms of hemophilia were differentiated. Subsequently, in the early 1980s, the two genes encoding FVIII, and FIX were cloned, and the specific variants responsible for hemophilia began to be determined.

FACTOR VIII BIOLOGY: GENETICS, STRUCTURE, FUNCTION, AND PATHOPHYSIOLOGY

Factor VIII Gene and FVIII Expression

The FVIII gene (*F8*) encoding the FVIII protein is located at Xq28, the most distal band of the long arm of the X chromosome (Fig. 134.1). It is a large and complex structure, 186 kb in length, consisting of 9 kb of exonic DNA arranged into 26 exons and 177 kb of intronic DNA in 25 introns. Most exons are small, ranging in size from 69 base pairs (exon 5; the smallest) to 3106 base pairs (exon 14; the largest–encoding the central B domain).

Within intron 22 of the *F8* gene there are two additional coding elements, *F8A* and *F8B*. Although its function is unclear, the *F8A* sequence within intron 22 is frequently involved in intrachromosomal recombination that is described later. The *F8B* transcript is expressed in the same orientation as the native *F8* mRNA, and this transcript comprises an initial intron 22 sequence that is spliced onto exons 23 to 26 of *F8*. As with F8A, the F8B transcript is also ubiquitously expressed. Although the function of the protein is unknown because it contains the phospholipid binding region of FVIII it may play a role in membrane binding.

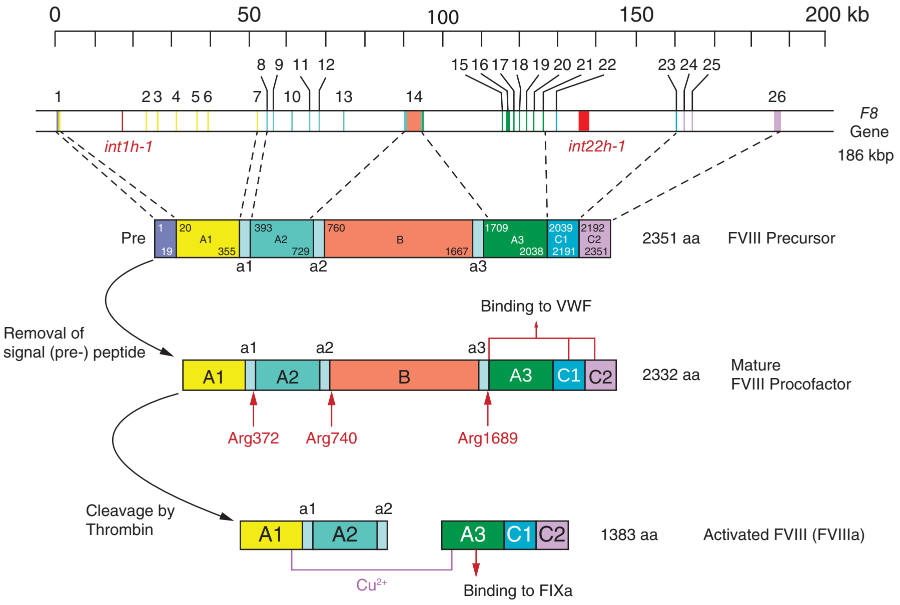

Figure 134.1 DERIVATION OF ACTIVATED FACTOR VIII FROM THE *F8* GENE. Top panel shows the *F8* gene with exons (1–26) colored according to the domains translated from them. Exon numbers are given above the gene. The primary translated product is the factor VIII (FVIII) precursor. Start and end amino acid numbers for each domain are shown. Removal of the signal peptide (Pre) generates the mature FVIII co-factor (2332 aa) that circulates in plasma. Cleavage by thrombin after the arginine residues (Arg372, 740, and 1689) shown in red activates the protein by removing the B and a3 domains.

Factor VIII Expression

Transcription of the *F8* gene is regulated by a promoter that contains binding sites for both tissue-specific and ubiquitous transcription factors. The mRNA transcribed from *F8* is 9 kb in length and contains 7053 nucleotides of coding (i.e., translated) sequence and short 5′ and long 3′ untranslated sequences. Two reports using different conditional knockout approaches in mice have shown that the vascular endothelium is the predominant site of FVIII expression in this animal model.[7,8] There is strong evidence that the liver sinusoidal endothelium is the source of FVIII production.[9] This fits with the recognition that hemophilia can be cured by orthotopic liver transplantation. Other endothelial cell vascular beds, such as those found in lymph nodes, and spleen, may also contribute to FVIII production.[10]

The transcription factors that regulate constitutive production of FVIII are not well defined but may include hepatocyte nuclear factor 1 (HNF1) and members of the CCAAT-enhancer-binding protein (C/EBP) and HNF4 families. FVIII also is an acute phase reactant, and studies have shown that FVIII expression can be induced through nuclear factor kappa-B (NFκB) and C/EBP. Working through these transcription factors, interleukin 6 can elevate FVIII expression as part of an acute systemic inflammatory response. FVIII levels are strongly influenced by circulating levels of its carrier protein, von Willebrand Factor (VWF). Both proteins are lower in blood group O individuals due to higher endogenous clearance of VWF and of the FVIII attached to it.[11] This impacts on the pharmacokinetics of FVIII administration—lasts longer in non-O blood type individuals than in O blood type individuals.

Biosynthesis of Factor VIII

FVIII biosynthesis has been extensively investigated in vitro using cell types that do not normally express this protein, such as Baby Hamster Kidney (BHK), Chinese Hamster Ovarian (CHO), and Human Embryonic Kidney (HEK 293) cells, among others. Little work has been performed on sinusoidal endothelial cells, the predominant cell type responsible for endogenous FVIII synthesis. More recently, transgene-produced FVIII in hepatocytes following gene therapy results in in-vivo expression of subnormal to normal circulating levels in this heterologous cell type.[12] The biosynthesis of transgenic FVIII has also not been well characterized.

After production of the primary polypeptide chain and cleavage of the 19 amino acid signal peptide, the protein undergoes a series of posttranslational modifications, including N- and O-linked glycosylation mainly in the B domain and sulfation of tyrosine residues (see Fig. 134.1). Furthermore, when the nascent protein transits the endoplasmic reticulum (ER), it interacts with ER chaperones, including calreticulin and immunoglobulin binding protein (BiP). Although these interactions limit the transport of misfolded or aggregated forms of the protein in heterologous cells with high levels of FVIII expression, their relevance in native FVIII-producing cells is unknown. Indeed, under conditions of high-level FVIII expression, cells can activate a classical unfolded protein response (UPR) and can succumb to apoptotic cell death. The relatively unique challenge of processing FVIII has implications for gene therapy where high expression of B-domain-deleted FVIII in a small number of heterologous hepatocytes may trigger an UPR.[13]

Efficient transit through the ER–Golgi boundary requires an interaction with glycans within the B domain of the protein. Absence of these glycans or lack of a specific cargo receptor complex that transports proteins (e.g., LMAN also known as ERGIC-53, multiple coagulation factor deficiency 2 [MCFD2]) markedly reduces levels of both secreted FVIII and FV, the latter resulting in the autosomal recessive disorder of combined deficiency of FVIII and FV (Fig. 134.2).[14]

Factor VIII Protein Structure

The DNA sequence of the *F8* gene predicts a translated single chain polypeptide with a molecular weight of 260 kDa consisting of 2351 amino acid residues, including a 19-residue signal peptide. Upon translocation to the ER, the signal peptide is cleaved. The remaining polypeptide is 2332 residues long.

The FVIII protein consists of three types of domains: the three A domains, which have a 35% to 40% amino acid sequence homology to ceruloplasmin and to FV; a central B domain with no known homologues; and two C-terminal domains that are also 35% to 40% homologous to ceruloplasmin and to FV (see Fig. 134.1). There are also three small "a" linker regions (each between 20 and 40 amino acids) consisting of predominantly acidic residues. The sequence of these domains within the protein is NH2-A1-a1-A2-a2-B-a3-A3-C1-C2-COOH. Tyrosine residues in the a2 and a3 domains, when sulfated, contribute to the cofactor function of FVIII and, with residues in the C1 domain, enable its interaction with VWF. Given the structural similarities between FVIII and FV it is not surprising that both function as cofactors for serine protease enzymes in the coagulation cascade: FVIII in the intrinsic tenase complex to generate FXa, and FV in the prothrombinase complex to generate thrombin. Of note, the FVIII B domain is not required for cofactor function; its principal role is to facilitate trafficking and secretion of the nascent polypeptide, and B-domain-deleted FVIII is fully active.

Subsequent proteolysis of the FVIII polypeptide chain in the Golgi generates a heavy chain of A1-A2-B domains with a mass of 90 kDa and a light chain consisting of the A3-C1-C2 domains with a mass of 80 kDa (see Fig. 134.1).

Circulating FVIII exists as a heterodimer of the NH_2-terminus heavy chain and the COOH-terminus light chain. The heavy and light chains are bound to one another at the A1 and A3 domains by noncovalent bonds that are divalent metal ion dependent. The involved ion is likely copper, which has been found in association with the FVIII A3 domain.

Storage, Secretion, Circulation, and Clearance of Factor VIII

After translation and ER/Golgi processing, FVIII is secreted into the circulation, where it forms a tight noncovalent complex with its multimeric partner VWF. Whereas the plasma concentration of FVIII is 100 to 200 ng/mL (≈1 nM), the concentration of VWF is approximately 10 μg/mL (50 nM); thus, the molar ratio of FVIII to VWF in the FVIII-VWF complex is about 1 to 50. The majority of VWF in plasma is synthesized and secreted by vascular endothelial cells. VWF binds strongest to the A3 and C1 regions of FVIII through sequences in the D' region (D'D3) of the mature VWF monomer.[15] The site at which FVIII and VWF first interact has been debated. However, confirmation that FVIII is expressed by endothelial cells suggest that at least some of the circulating FVIII may interact with VWF before secretion and may be co-stored with VWF in Weibel-Palade bodies.

Circulating levels of FVIII vary three-fold in the normal population (~50% to 150%), likely due to a combination of variability in synthesis and probably more importantly, variability in the clearance of FVIII mediated by VWF clearance. This in turn is related to ABO blood type as well as to other mechanisms leading to proteolysis and clearance of circulating FVIII/VWF.[16] In plasma, VWF protects FVIII from proteolysis by lipid-binding proteases including FXa. Without this interaction—for example, in cases of type 3 VWD (in which VWF is absent) or type 2N VWD (in which mutations occur in the FVIII binding region of VWF—D' region)—the plasma half-life of FVIII is markedly reduced and, consequently, plasma levels of FVIII may be very low.

VWF also protects FVIII from intracellular proteolysis by blocking binding of FVIII to cell surface lectin domain and scavenger

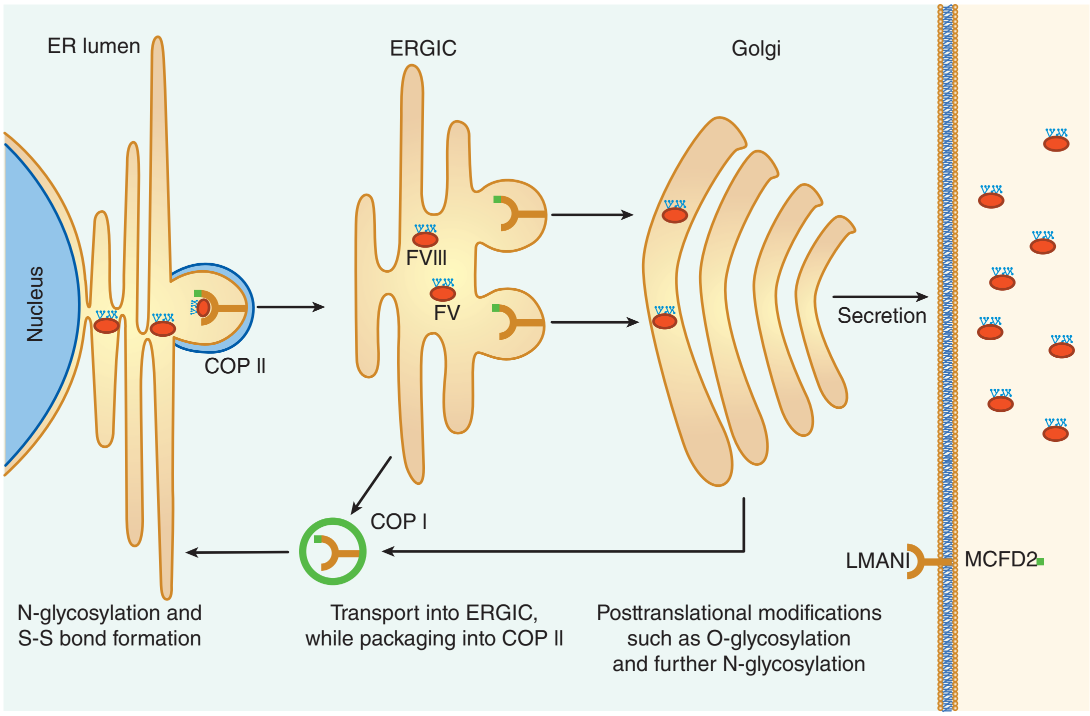

Figure 134.2 COMBINED FV AND FVIII DEFICIENCY. Factor V (FV) and factor VIII (FVIII) (which share substantial homology) are synthesized on the rough endoplasmic reticulum (ER) and translocated into the ER lumen, where both proteins undergo N-linked glycosylation, folding, and quality control. Proteins that pass the quality control are packaged into coat protein complex-II (COPII) vesicles that bud from distinct regions of the ER. After budding, COPII vesicles undergo fusion to form the ER–Golgi intermediate compartment (ERGIC). From there, specific proteins (lectin mannose binding protein type 1 [LMAN1; also called ERGIC-53] and multiple coagulation factor deficiency 2 [MCFD2]) are required for proper secretion of these factors into the blood stream. Homozygous or compound heterozygous mutations lead to the rare autosomal recessive disorder of combined FV and FVIII deficiency. COP1 recycles back to ER different transport factors.

receptors which target it for lysosomal degradation. VWF, with or without FVIII, is degraded via binding to lectin and scavenger receptors on the surfaces of Kupffer cells, hepatocytes, and endothelial cells. As the vast majority of FVIII circulates bound to VWF, FVIII much like VWF is cleared by VWF-specific catabolic pathways.[17] However, VWF-free circulating FVIII, representing 2% to 5% of the total circulating FVIII, has accelerated clearance (6- to 8-fold greater), thus representing a physiological VWF-independent clearance pathway. Thus, most of the clearance and half-life of FVIII is regulated by the clearance of VWF. This places a ceiling on the potential gain in half-life achieved by bioengineering FVIII molecules via Fc fusion or PEGylation technologies. Knowing this, one extended half-life (EHL) FVIII (efanesoctocog alpha; Sanofi) still in development has overcome this ceiling effect on FVIII half-life extension by engineering FVIII to no longer bind to endogenous VWF.[18]

VWF may also protect FVIII from recognition by the immune system in persons with hemophilia A. Endocytic uptake into antigen-presenting cells for presentation to CD4$^+$ T cells occurs largely through the C1–C2 domains, which are blocked when FVIII is bound to VWF.[19] All of this is in keeping with some clinical evidence suggesting a lower rate of neutralizing antibody development (inhibitors) with plasma-derived FVIII containing VWF than with recombinant FVIII.[20]

Activation and Coagulant Function of FVIII

FVIII plays a critical role in the propagation (amplification) phase of coagulation. The physiological activator of FVIII is thrombin, which proteolytically cleaves FVIII at three sites: Arg372 at the NH_2-terminus of the A2 domain, Arg740 at the NH_2-terminus of the B domain, and Arg1689 at the NH_2-terminus of the A3 domain (see Fig. 134.1). These cleavages release FVIII from VWF and result in the formation of a noncovalently associated A1-A2-A3/C1/C2 heterotrimeric activated FVIII (FVIIIa) molecule. FVIII can also be activated by FXa and FIXa, although the physiological contribution of activation by these proteases is less clear.

In its activated form, FVIIIa provides essential cofactor activity in the intrinsic tenase complex where FIXa is the serine protease and FX is the substrate (Fig. 134.3).[21] This reaction takes place on a procoagulant phospholipid surface, which in normal hemostasis is likely the activated platelet. Participation of FVIIIa in the complex enhances the catalytic efficiency of this reaction about 200,000-fold, and thus severe FVIII deficiency profoundly reduces the rate of FXa generation and renders this reaction biologically futile. The cofactor role of FVIIIa is assumed to be based on it serving as a “scaffold” protein that optimally aligns the enzymatic and substrate components of the complex (FIXa-FVIIIa-FX) on the phospholipid surface. The cofactor binds to the phospholipid surface through hydrophobic residues in the FVIII C1 domain. Emicizumab was developed by capitalizing on the scaffolding effect of FVIIIa. Serving as a FVIII mimetic, emicizumab is a bispecific monoclonal antibody that binds to both FIXa and FX and bridges them together thus substituting for the cofactor role of FVIIIa.

FVIIIa is inactivated via two processes (see Chapters 120 and 124). The predominant mechanism is through spontaneous dissociation of the A2 domain. The second is via activated protein C–mediated proteolysis at Arg336 and Arg562 in the FVIIIa heavy chain (see Fig. 134.1).

PATHOPHYSIOLOGY OF HEMOPHILIA A

Hemophilia A is a disorder characterized by congenital deficiency of FVIII. Almost all patients with hemophilia A have *F8* gene mutations. Because the *F8* gene is in the most distal band

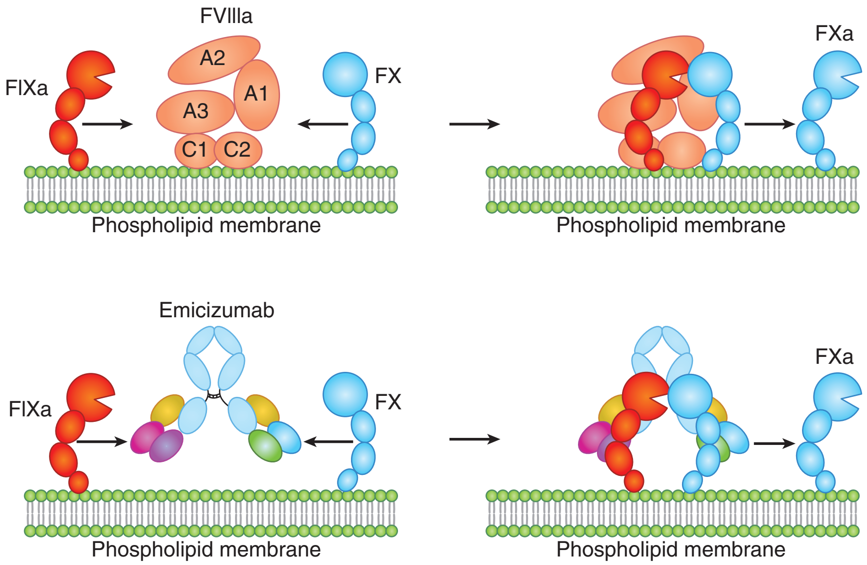

Figure 134.3 MECHANISM OF ACTION OF EMICIZUMAB. Activated factor VIII (FVIIIa) serves as an essential cofactor in the intrinsic tenase complex by binding activated factor IX (FIXa) (the enzyme) and factor X (FX) (the substrate) and promoting their interaction on the surface of activated platelets. FVIIIa binds to the phospholipid surface through residues in the FVIII C1 domain. Like FVIIIa, emicizumab binds to both FIXa and FX and promotes their interaction. Unlike FVIIIa, emicizumab does not bind to the phospholipid membrane.

(Xq28) on the X chromosome, hemophilia A follows an X-linked inheritance pattern. As a result, most affected individuals are male. Severe and moderately severe cases of hemophilia A are unusual in females but can result from the genetic mechanisms listed in Table 134.1.

Approximately 50% of cases of hemophilia A are caused by sporadic mutations and occur without a family history of the disorder. The sporadic mutation most commonly occurs in a female making her a carrier. However, because most carriers do not have excessive bleeding, the "new carrier" is unlikely to ever be diagnosed, or if diagnosed, not until later in life if she has an affected son or grandson.

The molecular genetic basis of hemophilia A has been extensively characterized over the past 35 years. A comprehensive Internet database of hemophilia A mutations is maintained and updated at https://f8-db.eahad.org/.

Approximately 45% of cases of severe hemophilia A are the result of a recurrent mutation, an inversion mutation involving sequences in intron 22 of the gene (Fig. 134.4). The mechanism responsible for this mutation involves an intrachromosomal recombination event in which there is an exchange between the F8A gene in intron 22 and one of two extragenic copies of this sequence that are located 5′ and telomeric to *F8*. The consequence of this event is inversion of the *F8* gene between exons 1 and 22 and although two distinct *F8* transcripts are expressed from separate promoters (exons 1 to 22 and exons 23 to 26), a contiguous FVIII protein sequence is not synthesized. The origin of this recurrent mutation is almost exclusively in the male germline (i.e., in sperm cells) where the single X chromosome has no partner to pair with, thereby potentially facilitating the F8A-mediated intrachromosomal recombination. The origin of this mutation in male germline explains why hemophilia often arises in daughters of older men whose sperm cells carry a greater number of mutations.[22]

A second recurrent inversion mutation involving intron 1 of the *F8* gene is responsible for approximately 2% of severe hemophilia A cases. Other mutations responsible for hemophilia A include more than 3000 DNA variants with an array of missense, nonsense, frameshift, insertion or deletion, duplication, and splicing mutations.[23] In addition, transcriptional mutations have been identified in the F8 promoter region. All regions of the gene are potential mutation targets but certain sequences, such as the CpG dinucleotide in arginine codons, are more prone to mutation because of spontaneous methylation of the 5′ cytosine and spontaneous deamination to thymine. Indeed, the recent identification of mutations deep within introns of the gene, which may alter *F8* mRNA splicing, suggests that almost all hemophilia A mutations are likely to be found within or adjacent to the *F8* gene.

Extensive genotype-phenotype studies in hemophilia A reveal a good correlation between null mutations (mutations that result in no production of factor) and severe disease and between non-null (largely missense) mutations and moderate or mild phenotypes. The phenotype of the disease remains generally consistent with specific mutations. One exception may be mutations within the B domain, which is dispensable for FVIII activity but is important for secretion of the protein after it undergoes post-translational modifications. Proteins synthesized with putative hemophilia causative B domain variants have normal activity, suggesting that many may be polymorphisms.[24]

In addition to its utility for family counseling, the *F8* genotype is also a strong predictor for the development of anti-FVIII antibodies (Table 134.2). Multidomain deletions are associated with the highest risk (≈75%) of inhibitor development, while most missense and splicing mutations are associated with the lowest risk (<10%). The largest group is those with an average risk of 20% to 30%; this includes patients with inversion, nonsense, and insertion/deletion mutations. Even within these categories there is significant variability in the risk of inhibitor development; for example, some missense mutations in the C2 and C3 domains are associated with much higher risk of inhibitor development than missense mutations in other domains.[25]

FACTOR IX BIOLOGY: GENETICS, STRUCTURE, FUNCTION, AND PATHOPHYSIOLOGY

FIX Gene and FIX Expression

The gene that encodes FIX (*F9)* was cloned and characterized by two groups in the early 1980s. The gene is located on the X chromosome at cytogenetic band Xq27 and spans 34 kb of genomic sequence (Fig. 134.5). The eight exons (previously designated as exons A to H

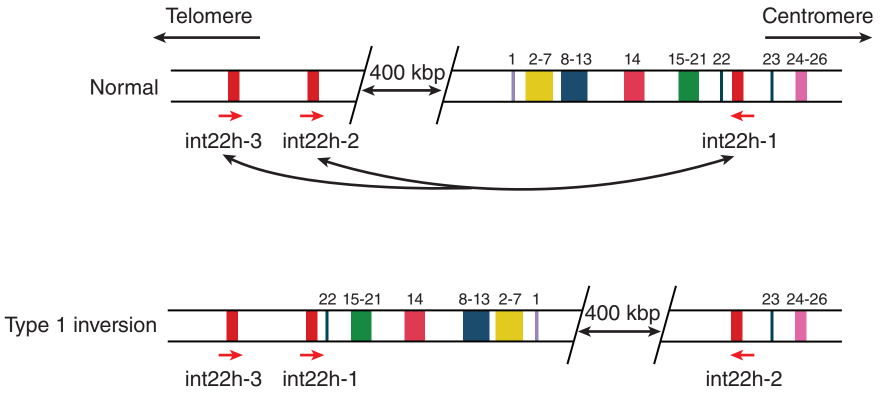

Figure 134.4 INTRON 22 INVERSION RESPONSIBLE FOR APPROXIMATELY 40% OF CASES OF SEVERE HEMOPHILIA A. The top panel shows the normal F8 gene with exons clustered and colored according to the domains they are translated into. Intron 22 contains the sequence highlighted in red, int22h-1, which has 2 homologous copies positioned 400 kbp telomeric to the gene but orientated in the opposite direction. When homologous recombination occurs during meiosis, the int22h-1 sequence can recombine with one of the homologous copies: int22h-2 or int22h-3. Because the sequences are orientated in opposite directions, there is inversion of the intervening sequence such that exons 1–22 of F8 are facing the wrong direction and are separated from exons 23–26 by 400 kbp as shown in the lower panel. This leads to disruption of the gene and abolition of transcription.

TABLE 134.2 **Factor VIII Mutant Genotype and Inhibitor Risk in Previously Untreated Patients With Hemophilia A**

Large insertion/deletions	≈75%
Light chain nonsense mutations	30%–40%
Inversion mutations (I-22 and I-1)	20%–25%
Small insertion/deletions	15%–25%
Small non-A run insertions/deletions	15%–20%
Heavy chain nonsense mutations	10%–20%
Factor VIII missense mutations	<10%
Small A run insertions/deletions	<5%
Splicing mutations	<5%

and now as exons 1 to 8) of the *F9* gene encode an mRNA transcript of 2.8 kb that is exclusively expressed in hepatocytes.

FIX Protein

FIX circulates in plasma at a concentration of approximately 5 μg/mL (90 nM). The mature circulating protein consists of 415 amino acids and has a molecular weight of 57 kDa (see Fig. 134.5). The protein is initially synthesized as a pre-pro-polypeptide with a short signal sequence, which facilitates entry into the ER, and a pro-polypeptide sequence, which interacts with γ-glutamylcarboxylase in the ER. The interaction with this microsomal enzyme catalyzes the post-translational conversion of the 12 amino-terminal glutamic acid residues of mature FIX into γ-carboxyglutamyl residues (the GLA domain). This post-translational modification enables FIX to form calcium-dependent interactions with procoagulant phospholipid membranes (see Chapter 125). A second post-translational modification at residue 64 in the first epidermal growth factor (EGF)–like domain of the mature polypeptide involves β-hydroxylation of asparagine. This modification also facilitates interactions with calcium and phospholipid membranes.

The molecular arrangement of FIX consists of an amino-terminal GLA domain followed by two EGF-like domains, an activation peptide, and the carboxyl-terminus catalytic domain, which is similar to the organization of procoagulant FVII and FX and the anticoagulant protein C (see Chapter 125). The characteristic feature of all serine proteases is the catalytic triad which in FIX is comprised of His267-Asp315-Ser411. These three residues form the active site of the enzyme which is responsible for cleavage of the Arg234-Ile235 scissile bond in FX that is required for its activation.

The FIX zymogen is activated by two processes; proteolytic cleavage mediated by FXIa and by a similar process involving the FVIIa–tissue factor complex. The activation of FIX involves sequential proteolysis of two peptide bonds at Arg191-Ala192 and Arg226-Val227 (see Fig. 134.5). These cleavages release the FIX activation peptide and result in the formation of the disulfide-linked FIXa enzyme with an NH_2-terminus light chain and a COOH-terminus heavy chain. Whereas the light chain binds to procoagulant phospholipid surfaces through a calcium-mediated process involving the GLA domain, the C-terminus catalytic domain cleaves and activates the substrate FX. This reaction involves the so-called intrinsic tenase complex in which FVIIIa participates as an essential cofactor. Absence of FVIIIa in the tenase complex reduces the catalytic efficiency of the reaction by approximately 200,000-fold.

FIXa is inhibited through an interaction with the natural anticoagulant protein antithrombin (AT). The fate of FIXa–AT complexes is incompletely understood, but specific AT–protease receptors on the surface of hepatocytes participate in this process.

PATHOPHYSIOLOGY OF HEMOPHILIA B

To date, all variants responsible for hemophilia B have involved the *F9* gene. Genetic analyses of large numbers of patients with hemophilia B have detected variants in the *F9* gene in more than 98% of cases, and it may well be that the remaining variants are located within intronic sequences that are not readily accessible using standard techniques (Fig. 134.6).[23]

In marked contrast to hemophilia A, in which approximately 50% of variants resulting in severe disease are caused by two recurrent gene inversion events, approximately 75% of variants in hemophilia B are missense substitutions. There are no common recurrent *F9* variants, although mild forms of hemophilia B may show a founder effect in some populations.

Despite the predominance of missense variants, multiple other variants can produce hemophilia B ranging from large gene deletions to a mix of nonsense, insertion or deletion, and splicing changes. The full array of *F9* variants responsible for hemophilia B can be viewed in an internet database at http://f9-db.eahad.org/.

The most biologically remarkable hemophilia B variant was discovered in Leyden and is eponymously named after that city. FIX deficiency with this variant results from disruption of a 40-bp region of the *F9* promoter around the hepatic transcription factor binding sites

Figure 134.5 DERIVATION OF ACTIVATED FIX FROM THE *F9* GENE. The top panel shows the *F9* gene with exons (1–8) colored according to the domains translated from them. Exon numbers are given above the gene. The primary translated product is the FIX precursor. Start and end amino acid numbers for each domain are shown. Removal of the signal peptide generates the FIX procofactor. The propeptide directs γ-carboxylation of glutamic acid residues in the Gla- domain. Removal of the propeptide produces the mature 415 amino acid protein. Cleavage by FXIa after Arg191 and Arg226 removes the activation peptide leaving the active protease. *EGF*, Epidermal growth factor-like domain.

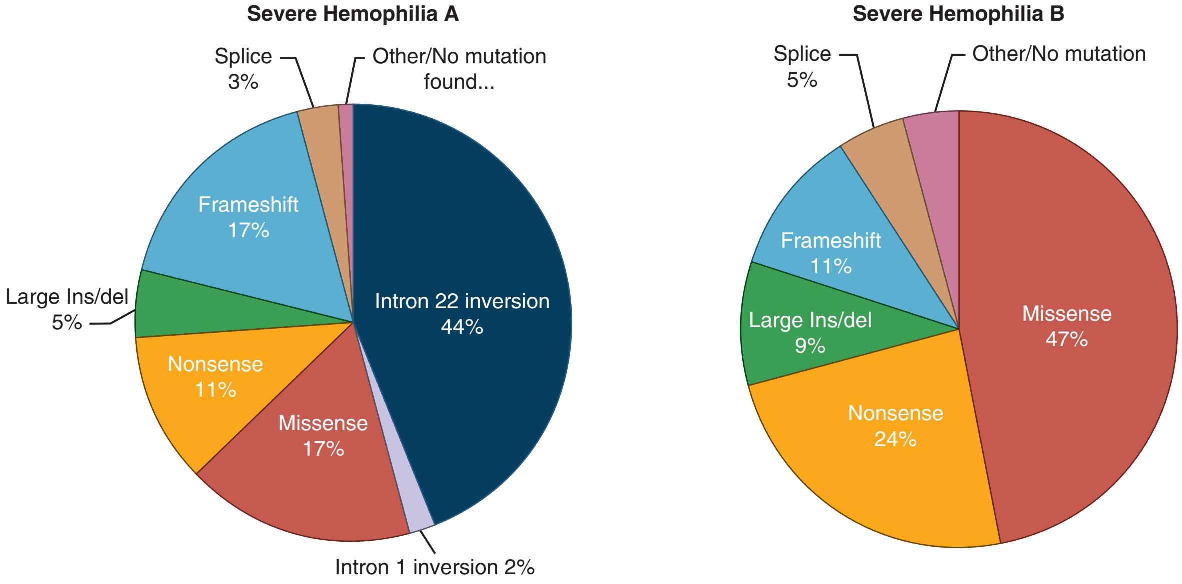

Figure 134.6 FREQUENCIES OF DIFFERENT TYPES OF F8 AND F9 VARIANTS IN SEVERE HEMOPHILIA A AND SEVERE HEMOPHILIA B. For severe hemophilia A (panel A), inversion variants (I-22 and I-1) account for 44% of all cases while missense variants account for about 17%. For severe hemophilia B (panel B), almost 50% of cases are caused by missense variants.

which are responsible for gene expression during early childhood.[26] If the variant spares an androgen responsive element in the promoter, gene expression normalizes with increasing androgen (testosterone) levels in puberty and beyond.[27] In this form of hemophilia B, FIX levels gradually increase from less than 5% at birth to greater than 30% by early adulthood. Because of the low FIX levels early in life, boys with this disorder often have bleeding episodes consistent with moderate hemophilia B. After puberty, FIX levels and bleeding phenotype improve or even resolve to the extent that the label of hemophilia is often removed from these patients.

Since the cloning of the *F9* gene in the 1980s, the association of *F9* gene deletions with FIX antibody formation has been well recognized. While most missense mutations causing hemophilia B are associated with a low risk of inhibitor development, large deletion mutations are associated with a higher risk (30% to 50% risk). In addition to neutralizing FIX enzymatic function, these antibodies can also be associated with anaphylactic or anaphylactoid reactions to FIX infusion.[28] Antibodies usually develop in young children (1 to 2 years old) after 10 to 20 exposures to FIX concentrate. In such patients, FIX concentrate use is generally no longer of benefit and attempts at inducing immunologic tolerance to FIX may be complicated by the development of nephrotic syndrome. Further discussion about inhibitors in hemophilia B is found later.

Hemophilia B is the bleeding disorder which in the past was associated with many of the royal families of Europe. Although the clinical picture in these individuals was consistent with severe hemophilia, the precise diagnosis was not reported until 2009. The "Royal" *F9* variant is a splicing abnormality occurring at the 3′ end of intron 3 that creates a new splice acceptor sequence that results in a novel out-of-frame transcript with 11 new amino acids followed by a premature stop codon.[29] This variant is predicted to result in nonsense-mediated decay of the aberrant FIX mRNA, which would inevitably result in a severe phenotype.

Missense variants elsewhere in the *F9* gene have been informative with regard to our detailed understanding of protein structure and function. Variants at both activation peptide cleavage sites have been described, and as with many genes, recurrent "hotspot" variants have been documented at arginine codons with CpG dinucleotide sequences.

HEMOPHILIA DIAGNOSIS

The initial diagnosis of hemophilia depends on the family context. In families in which hemophilia has previously been identified, family counseling can determine the risk of hemophilia transmission and usually results in a diagnosis being made in utero or early in neonatal life. In contrast, when there is no family history of the disease, the diagnosis will not be made until there are signs of bleeding, and the timing of this depends on the extent of the factor deficiency (i.e., disease severity). With severe deficiency, the diagnosis is usually made in the first 1 to 2 years of life, but with moderate disease, the diagnosis may be made later, and with mild hemophilia, the diagnosis may be delayed until well into adulthood when bleeding occurs after a surgical intervention.

Phenotypic Diagnosis of Hemophilia

The diagnosis of hemophilia involves measurement of FVIII or FIX coagulant levels in platelet-poor plasma using a functional clotting assay. Although most clinical hemostasis laboratories use a one-stage PTT (i.e., clot-based) test to quantify FVIII, some laboratories use either a two-stage or a chromogenic assay that measures the generation of FXa in a purified system (see Chapter 127). In these latter assays, the incubation time is often longer, which may influence test results. For example, some missense mutations causing mild hemophilia A result in the synthesis of an unstable FVIII with enhanced dissociation of the A2 domain from the remainder of the protein (Fig. 134.7). These unstable mutants can occasionally be missed when a one-stage FVIII assay is used but are readily apparent with two-stage or chromogenic assays that use a prolonged incubation time. Consequently, when a diagnosis of mild/moderate hemophilia A is made using a one-stage assay, it is advisable to also perform a chromogenic assay to better determine the extent of the deficiency.

The severity of hemophilia is based on the clotting factor level (severe, <1% [<0.01 IU/mL]; moderate, 1% to 5% [0.01 to 0.05 IU/mL]; and mild, >5% to 40% [>0.05 to 0.40 IU/mL]). When making a diagnosis of hemophilia B, caution must be taken in neonates because levels of FIX can be low in newborns because of their immature glutamylcarboxylase system. FIX levels double in the first few years of life and continue to rise slowly until puberty.[30] Consequently, a child initially labeled as having moderate hemophilia may be reclassified as having mild hemophilia later in life and a child initially diagnosed as having mild hemophilia B may later have normal FIX levels. In general, a FIX level greater than 20% in a neonate is considered normal as is a FIX level greater than 30% at 12 months of age.

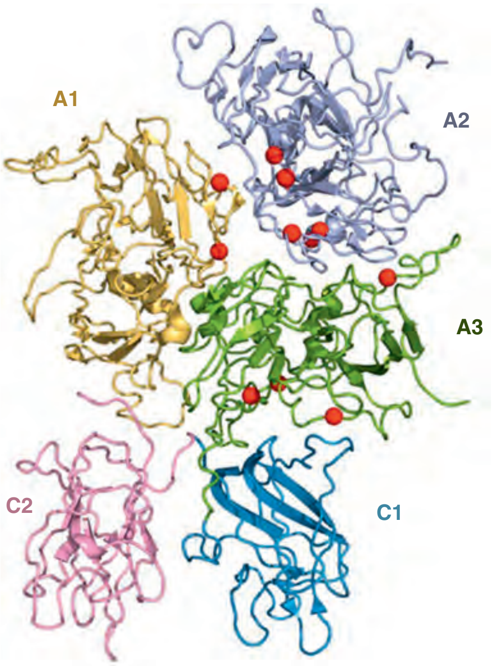

Figure 134.7 RIBBON REPRESENTATION OF THE STRUCTURE OF B-DOMAIN DELETED FACTOR VIII (FVIII). Domains are colored and labeled. Red spheres mark the positions of variants that result in hemophilia A with classical assay discrepancy (one-stage assays give a falsely higher value than chromogenic assays). These variants are clustered at the inter-domain boundaries mostly between the A2 and A1 or A3 domains. Mutations of these residues weaken the covalent bonds that tether the A2 domain to the cup created by A1/A3 resulting in more rapid dissociation and loss of activity. Because dissociation is time-dependent, the mutant proteins have higher activity in clotting assays where incubation times are short than in chromogenic assays where incubation times are longer.

Genetic Diagnosis of Hemophilia

The other diagnostic strategy that can be used for the diagnosis of hemophilia involves DNA analysis. Since the cloning of the FVIII and FIX genes in the early 1980s, molecular genetic approaches to hemophilia diagnosis have advanced dramatically. There are now greater than 3000 different *F8* mutations associated with hemophilia A and greater than 1000 *F9* mutations documented in hemophilia B.[23]

The strategy for genetic analysis depends on the type of hemophilia and the severity of the phenotype. For example, all patients with severe hemophilia A should be screened initially for the recurrent F8 intron 22 and intron 1 inversion mutations. In contrast, most patients with hemophilia B require full-sequence analysis of the entire FIX promoter, coding region, and splice sites.

If a familial mutation has already been identified in the FVIII or FIX gene, prenatal diagnosis can be accomplished with chorionic villus sampling or by amniocentesis. Outside of the prenatal context, mutation testing in hemophilia can be used for carrier detection for family planning purposes and as one component of the risk analysis for inhibitor development (see box on Hemophilia Carrier Detection and Prenatal Diagnosis). Determination of the hemophilic genotype is now regarded as standard of care.

TABLE 134.3 Differential Diagnosis of a Low Factor VIII Level

1. FVIII <10%
   - Severe or moderately severe hemophilia A
   - Severe type 1 VWD or type 3 VWD
   - Type 2N VWD
   - Acquired hemophilia A
   - Acquired VWD
2. FVIII: 10%–40%
   - Mild hemophilia A
   - VWD (any subtype)
   - Combined FVIII and FV deficiency

FV, Factor V; *FVIII*, factor VIII; *VWD*, von Willebrand disease.

Differential Diagnosis of Hemophilia

The initial clinical suspicion of hemophilia usually arises from signs and symptoms of excessive bleeding, a family history of a bleeding problem, or abnormal coagulation test results.

The initial laboratory screening test suggestive of hemophilia is a prolonged PTT. If the PTT normalizes after mixing with control plasma, factor levels are then measured to pinpoint the cause of the prolonged PTT. Although FVIII or FIX deficiency are associated with a prolonged PTT, deficiencies of FXI or FXII or combined deficiencies of various coagulation factors are other possibilities (see Chapter 135).

A low plasma FVIII level is not synonymous with a diagnosis of hemophilia A. Several disorders are associated with low FVIII levels (Table 134.3). Levels of FVIII below 10% are most often the result of inherited or acquired hemophilia A (in adults) or a severe form of inherited or acquired VWD (severe type 1 or type 3 VWD). Determination of VWF antigen and VWF activity levels is essential to differentiate these conditions. Levels of FVIII below 10% can also occur with type 2N VWD (see Chapter 133). This diagnosis can be confirmed with FVIII binding studies or by genotypic analysis of the FVIII binding codons of VWF (exons 17 to 25, which encode the D′D3 regions of the VWF protein).[31] Levels of FVIII between 10% and 50% are likely the result of either mild hemophilia A or VWD (types 1 or one of the type 2 variants: 2A, 2B, 2M, or 2N). Assessment of VWF levels (antigen and activity) must be undertaken in these cases. Rarely, mild or moderate FVIII deficiency can be co-inherited with FV deficiency. Combined inherited deficiency of FVIII and FV (levels are usually between 5% and 20%) has a prevalence of approximately 1 per million. This rare inherited trait is caused by recessive mutations in one of two genes involved in protein transport across the ER-Golgi interface: lectin mannose binding protein type 1 (LMAN1) or MCFD2.[14]

Isolated low plasma levels of FIX are almost always caused by congenital hemophilia B. In contrast to acquired hemophilia A, autoantibody development against FIX (i.e., acquired hemophilia B) is rarely encountered. Other situations in which FIX deficiency is found usually involve concomitant reductions in the other vitamin K–dependent clotting factors, such as occurs with vitamin K antagonists, vitamin K deficiency, or severe liver disease (see Chapter 126). A much less common cause of a mild deficiency of all the vitamin K–dependent proteins (FII, VII, IX, and X) is hereditary combined vitamin K-dependent clotting factors deficiency (VKCFD), an autosomal recessively inherited defect in the γ-glutamylcarboxylase (*GGCX*) gene, coding for the γ-carboxylase enzyme required for the posttranslational modification of these proteins.[32]

CLINICAL FEATURES OF HEMOPHILIA

The symptoms and signs of hemophilia A and B are identical and involve a propensity for prolonged and excessive bleeding (see Chapter 126). The bleeding tendency in hemophilia is determined in large part by the baseline activity level of the deficient or defective clotting factor. Thus, in severe hemophilia (A and B), in which the baseline clotting factor activity level is below 1% (0.01 IU/mL), pathological bleeding can occur in the neonatal period, especially intracranial bleeding from the delivery process. However, most frequently, severe disease manifests with easy bruising or soft tissue or joint bleeding beginning at around 6 to 12 months of age when children become more mobile. Excessive bleeding after circumcision can prompt diagnosis in the perinatal period. Without clotting factor prophylaxis, the annual incidence of bleeding increases in the first 5 to 6 years of life and plateaus at an average of 20 to 40 bleeds per patient per year.

TABLE 134.4 Reasons for Differences in Bleeding Phenotype

1. Differences in factor levels
2. Differences in mutations causing hemophilia: null vs. non-null mutations
3. Co-inheritance of other bleeding disorders
   - Von Willebrand disease
   - mild functional platelet disorders
4. Co-inheritance of prothrombotic disorders
   - factor V Leiden
   - prothrombin G20210A mutation
   - low levels of protein C, protein S, or antithrombin
5. Differences in the pharmacokinetic handling of factor. In the case of hemophilia A this includes the effect of ABO blood group and endogenous levels of von Willebrand factor (for patients on factor prophylaxis)
6. Differences in the pharmacokinetics and pharmacodynamics of emicizumab (for those patients on emicizumab)
7. Differences in levels of physical activity
8. Differences in the structural integrity of joints, making patients more/less susceptible to joint bleeds and joint damage

Most patients with mild hemophilia (factor levels of >5% [>0.05 IU/mL]) only experience bleeding with trauma or surgery and the disease may go undiagnosed until later in life.

The bleeding phenotype in patients with moderate hemophilia (FVIII or FIX levels between 1% and 5% [0.01 and 0.05 IU/mL]) can resemble that of patients with severe or mild hemophilia. Thus, the severity and frequency of bleeding may correlate poorly with the factor activity level and even patients with FVIII or FIX levels less than 1% or with the same mutation may have variable phenotypes for the reasons listed in Table 134.4. All these reasons for phenotypic variability may explain why some patients bleed much less than would be expected based on their factor levels while others bleed much more. These differences may also explain why some patients with joint bleeds develop arthropathy and others do not.

Hemophilia A and B are characterized by similar types of bleeds. Although not conclusively proven, several studies suggest that with similar factor levels, the bleeding phenotype in hemophilia A is less severe than that in hemophilia B as evidenced by a younger median age for the first joint bleed and for start of prophylaxis, as well as increased use of prophylaxis and greater need for joint arthroplasty in patients with severe hemophilia A than in those with severe hemophilia B.[33] Likewise, in children with moderate disease, a higher proportion with hemophilia A than with hemophilia B require prophylaxis. Although the reasons for these differences are incompletely understood, the genetics of the disorders are a likely cause; most patients with severe hemophilia A have null mutations and produce no FVIII, whereas most of those with hemophilia B have non-null mutations and synthesize small amounts of FIX. In addition, in patients with hemophilia B, the stress-induced release of FVIII with bleeds may augment the hemostatic potential of the residual FIX as FVIII is a cofactor for FIX.

Although bleeding is the hallmark of hemophilia, the types of bleeds and issues facing patients vary depending on age. This is particularly true in newborns where issues related to the birthing process can occur, which are not encountered later in life. Also, the problems in infancy, which is the highest risk period for development of inhibitors and the time when prophylaxis protocols are established, are different from those encountered later in life.

Hemophilia in Newborns

The hazards of hemophilia are greatest in the neonatal period, particularly for those with moderate or severe disease. Newborns with hemophilia can be born to mothers who are known or suspected hemophilia carriers or can be born to mothers who are not known to be carriers as there is no family history of hemophilia. The latter scenario, which is encountered in about 50% of cases,[34] is associated with the highest risk of bleeding because no precautions are taken. The optimal method for delivery of children with known or suspected severe hemophilia is uncertain. Most experts recommend atraumatic vaginal delivery to avoid the maternal risks associated with cesarean section and because delivery by cesarean section does not eliminate the risk of intracranial hemorrhage (ICH) (Fig. 134.8). Vacuum extraction or forceps delivery should be avoided because they increase the risk of extracranial bleeding (e.g., subgaleal hemorrhage and cephalohematoma) and ICH. Fetal blood sampling is not a significant risk factor for ICH.

Intracranial Hemorrhage in Newborns

The incidence of ICH in newborns with severe hemophilia is approximately 3% to 4%,[35,36] which is 40- to 80-fold higher than the risk in the non-hemophilic population. If a newborn male suspected of having hemophilia has any sign of ICH (e.g., unequal pupils, seizures, vomiting, or lethargy), the appropriate factor concentrate should be promptly administered.

If signs of ICH occur in newborn boys without a family history of hemophilia, the PTT should be determined along with central nervous system imaging. If the PTT is prolonged and imaging reveals ICH, the levels of FVIII, FIX, and VWF should be urgently quantified. While waiting for the test results, fresh plasma (10 mL/kg) can be given. Alternatively, because FVIII deficiency is more common than FIX deficiency, a FVIII concentrate can be administered, and the PTT determined 10 to 15 minutes later. If the patient has hemophilia A or type 3 VWD, the PTT will correct; with type 3 VWD, the correction will be transient because of the short half-life of FVIII in this disorder (see Chapter 133). If the PTT fails to correct, the child likely has FIX deficiency, and a FIX concentrate can then be given. If FVIII concentrate is given, fresh plasma can be administered while waiting for the PTT results to cover the possibility of hemophilia B.

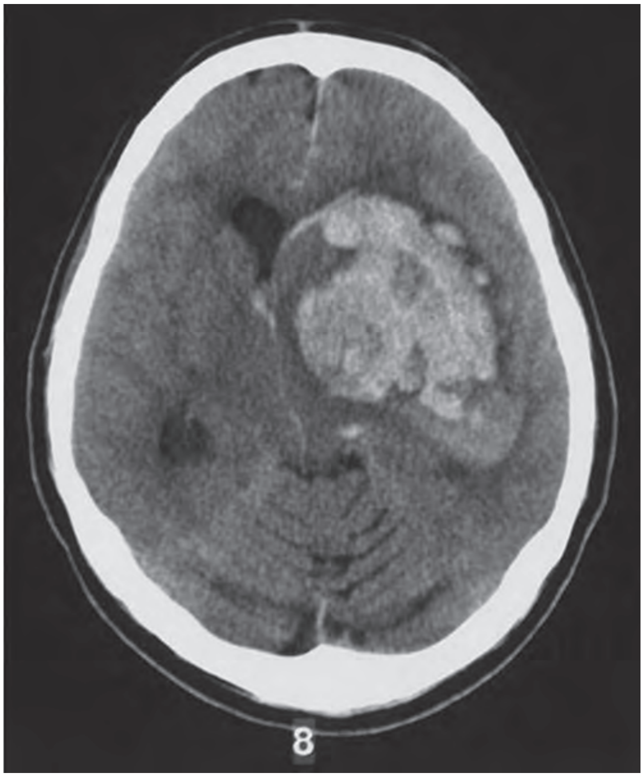

Figure 134.8 INTRACRANIAL BLEEDING IN HEMOPHILIA. A computed tomography scan shows an intracranial bleed in a person with hemophilia. This complication most often occurs after trauma with an incidence of five per 1000 per year in patients younger than 5 years of age and in 1% to 2% per year in persons 55 years of age or older.

Circumcision in Newborns

Surprisingly, excessive bleeding after circumcision only occurs in about half of boys with severe hemophilia. Consequently, the lack of excessive bleeding after circumcision does not exclude the diagnosis of hemophilia. In children suspected of having hemophilia, the diagnosis should be confirmed before circumcision. If hemophilia is confirmed and circumcision is desired, the appropriate factor concentrate should be administered before the procedure. A single dose prior to circumcision is usually sufficient although some clinicians give more after the procedure.[37]

Bleeding Manifestations With Hemophilia

The bleeding pattern in severe hemophilia is distinct and is rarely seen with other bleeding disorders. Although all types of bleeds can occur in hemophilia, musculoskeletal bleeds (hemarthrosis, muscle bleeds, and hematomas) are the most common and are responsible for most of the long-term complications. Other common sites for bleeding include the oral cavity, gastrointestinal (GI) and genitourinary tracts, and intracranial bleeding. Additionally, insufficiently treated muscle or soft tissue bleeds may result in pseudotumor formation (see box

HEMOPHILIC PSEUDOTUMOR

With no or with inadequate treatment, incomplete resorption of blood after repeated hemorrhage into muscles can result in the formation of pseudotumors—walled-off cystic structures surrounded by a fibrous membrane that can become multivacuolated and calcified over time. These cystic lesions can expand and destroy adjacent structures leading to bone fractures and deformities. Another rarer type of pseudotumor seen mostly in adults arises within the bone secondary to repeated subperiosteal bleeding. This type of pseudotumor usually occurs in the long bones of the lower extremities and in the pelvis. Distal pseudotumors in the hand are more common in children and are associated with pain from rapid growth or nerve compression.

Pseudotumors are usually diagnosed with ultrasonography or MRI and can be misdiagnosed as a neoplasm (e.g., Ewing sarcoma or osteosarcoma) or an infection (e.g., osteomyelitis or tuberculous abscess). Biopsy is contraindicated because of the potential for bleeding or infection. Small pseudotumors, particularly distal ones or pseudotumors in patients with inhibitors, can be treated conservatively with aggressive prophylactic therapy with clotting factor replacement (there are no data on long-term prophylaxis with emicizumab in this setting) along with immobilization of the affected limb.

If prophylactic therapy alone is insufficient, surgical excision is needed. This carries potential morbidity and even mortality and should only be undertaken by skilled surgeons in conjunction with appropriate hemophilia specialists. Embolization and radiation have been successful for treatment of small pseudotumors of the hand.[38]

COMPARTMENT SYNDROME

A compartment syndrome arises when a bleed (usually trauma-induced) occurs into a closed (encapsulated) space, such as the forearm or calf. The capsule restricts exit of blood, thereby raising the pressure within the compartment with resultant vascular compression, obstruction of blood flow, tissue ischemia, and the potential for nerve and muscle damage. Compartment syndrome is characterized by severe pain and swelling, limb pallor, paresthesia, and reduced limb movement. This condition requires urgent factor replacement and surgical decompression (fasciotomy) may be required. Without treatment, compartment syndrome may lead to permanent neuropathy, tissue necrosis, and even loss of the limb.

on Hemophilic Pseudotumor) or compartment syndrome (see box on Compartment Syndrome). Finally, bleeds can occur with surgery, dental procedures, or trauma.

Hemarthrosis

Joint bleeds account for about 75% of all bleeding events in hemophilia and are a hallmark of the disorder. Although bleeds can occur in any joint, the most commonly involved are the ankles, knees, and elbows, the so-called *index joints*. Less commonly involved joints are the shoulders, hips, and wrists. The least involved are the joints in the hands and feet.

The first onset of joint bleeding is highly variable. Although the median age for the first joint bleed is 1.8 years, some children experience their first bleed earlier as they begin to ambulate and others have it later in the fourth, fifth, or sixth years of life.[39] Without prophylaxis, hemarthroses, which can be spontaneous or related to trauma, become more common with age. The trauma may be imperceptible, particularly in infants who are unable to vocalize the occurrence of trauma. Even minimal trauma during sleep can trigger awakening with joint pain and swelling.

In patients with severe/moderate hemophilia, bleeding into joints continues until hemostatic therapy is given or until the extravascular pressure within the joint increases to the point where bleeding vessels are occluded. With the latter scenario, the joint pain may be excruciating. Although bleeding may stop spontaneously in patients with mild hemophilia, there still can be substantial accumulation of blood in the joint. Therefore, joint bleeds should be treated promptly with factor concentrates to reduce the risk of long-term complications. Joint aspiration to remove blood may be of benefit with bleeds into large joints such as the hips (see box on Hip Pain in Hemophilia).

With repeated episodes of joint bleeding, most older children, adolescents, and adults with hemophilia can identify early intraarticular bleeding before the classical signs appear through a feeling of warmth and tingling in the affected joint.

Joint damage occurs through at least three mechanisms: iron toxicity, inflammation, and mechanical distension of the joint. Repeated joint bleeding causes inflammation and hyperplasia of the synovial tissue (*synovitis*) which is the first step in the development of hemophilic arthropathy.[41]

Repeated bleeding into the same joint three times over a 6-month period qualifies that joint as a target joint.[42] Such joints are susceptible to further bleeding unless prophylaxis is given resulting in a vicious cycle that ultimately leads to destructive joint damage.

Early stage hemophilic arthropathy is characterized by synovial hyperplasia, extensive destruction of articular cartilage, progressive loss of joint space, cystic changes within the subchondral bone, osteoporosis, and atrophy of surrounding muscles. The final stages of hemophilic arthropathy are associated with deformed and dysfunctional joints with wasting of the muscles in the affected limb (Fig. 134.9). At this late stage, joint bleeds are less frequent because synovial hypertrophy is less prominent.

HIP PAIN IN HEMOPHILIA: HIP JOINT BLEED VERSUS ILIOPSOAS MUSCLE BLEED

Pain in the hip joint region can be caused by several conditions, for example, hip joint bleed, iliopsoas muscle bleed, bleed into surrounding muscles, retroperitoneal bleed, or appendicitis. Bleeds into the hip joint and iliopsoas muscle are serious and difficult to differentiate. Both cause pain and restricted movement of the hip joint with a tendency to maintain the leg in a partially flexed position, the position of lowest pressure. Consequently, ultrasonography or MRI is essential for accurate diagnosis; plain radiographs are insufficient.

Iliopsoas muscle bleeds can rapidly expand because there is no surrounding connective tissue to restrict their growth. This can lead to a significant decrease in the hemoglobin level and a need for blood transfusion. Furthermore, pressure on the femoral nerve can cause paresthesia, hyperesthesia, or weakness of the quadriceps muscle.

Treatment of iliopsoas muscle bleeds or bleeding into the hip joint involves prolonged administration of factor concentrates and immobilization and subsequent physical therapy, often necessitating hospitalization.[40]

The management of an acute hip joint bleed is somewhat different from management of bleeds in other joints because of the vascular anatomy of the hip joint, which renders the head of the femur vulnerable to ischemia. Persistent pain despite appropriate factor replacement may indicate ischemia in the femoral head and ultrasound-guided joint aspiration by an experienced interventional radiologist or surgeon should be considered. Graded physiotherapy should be instituted when there is symptomatic improvement. Follow-up imaging studies (MRI, bone scan, or both) should be considered for assessment of avascular necrosis.

Over the past 10 to 20 years, clinical and radiographic scoring systems have been developed to objectively evaluate the status of the joints over time (Table 134.5). Clinical scores are more readily available, do not require expensive radiological equipment, and better reflect the extent of joint disability. Plain radiographs are relatively inexpensive and widely available but are insensitive to early soft tissue changes and involve radiation exposure. Magnetic resonance imaging (MRI) is the most sensitive test for detection of early soft tissue changes and is not associated with radiation exposure but is more expensive than plain x-rays and less available. In addition, young children may require sedation to avoid movement during image acquisition. Ongoing studies are evaluating the utility of point-of-care ultrasonography for evaluation of hemophilic arthropathy.[48] Ultrasonography has the advantages of being inexpensive, not requiring sedation and being able to differentiate between synovitis and hemosiderin deposition. However, it is operator dependent, interpretation of its findings can be subjective, and it fails to identify joint structures such as cartilage. Some of these problems may be overcome with automated ultrasonography but more work is needed.

Soft Tissue Hemorrhages and Muscle Bleeds

Patients with hemophilia are prone to excessive and prolonged soft tissue and muscle bleeding. Superficial hematomas (bruises) may resolve spontaneously without the need for treatment, and as such, bruising is not an indication for treatment. However, in moderate and severe hemophilia, soft tissue hematomas often undergo progressive enlargement and may need to be treated. Furthermore, some soft tissue bleeds (e.g., retroperitoneal bleeds or hematomas of the neck) can cause extensive blood loss and be life or organ threatening because of their propensity to expand, thus causing compression of adjacent organs, blood vessels, and nerves and the airway in the case of a neck hematoma.

The muscles most often involved are, in descending order of frequency, the calf, thigh, buttocks, and forearm. Bleeds into these locations can lead to compartment syndrome, which is an emergency (see box on Compartment Syndrome).

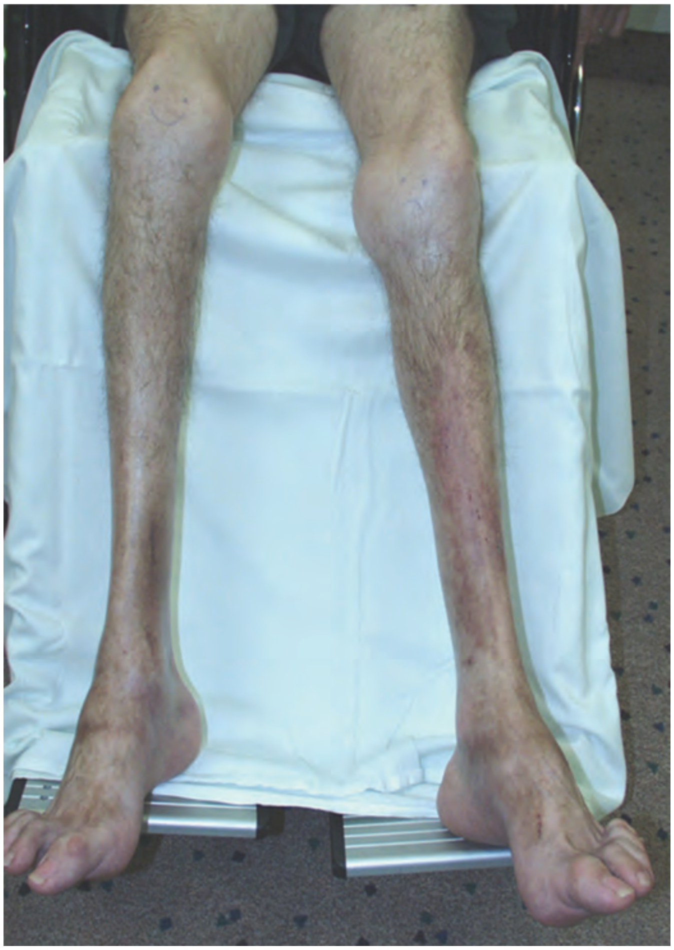

Figure 134.9 CLINICAL OUTCOME OF CHRONIC SEVERE HEMOPHILIC ARTHROPATHY. The legs of a 55-year-old patient with severe hemophilia A who is a wheelchair user. After multiple hemarthroses, the ankles and knees show deformities, and the leg muscles are atrophic because of disuse.

TABLE 134.5 Clinical and Radiological Evaluations in Hemophilia A and B

	Scores	Reference

Mucous Membrane Bleeding

While epistaxis is uncommon in hemophilia, oral bleeding frequently occurs. Bleeding from the frenulum after falling forward is often one of the first manifestations of hemophilia as is bleeding in the tongue. Such bleeds can result in significant blood loss and swelling to the point of airway obstruction. Excessive bleeding with loss of deciduous teeth and eruption of secondary dentition can occur but is uncommon. Fortunately, most oral bleeds can be managed with antifibrinolytic agents such as tranexamic acid or epsilon aminocaproic acid although factor replacement may be needed for more serious cases. For dental surgery, particularly if a nerve block is required, factor replacement or DDAVP (desmopressin) must be given to raise the factor level to at least 30% of normal.

Hematuria

Hematuria is usually spontaneous, episodic, and painless but may also occur with trauma. Rarely, hematuria can be caused by renal calculi, which are thought to be more common in males with hemophilia than in those without hemophilia. Consensus on the optimal management of hematuria in patients with hemophilia is lacking, but increased fluid intake and bed rest are recommended. If bleeding continues or is particularly severe, prophylactic therapy (e.g., daily factor replacement) should be given. The value of steroids is controversial and use of antifibrinolytic agents is contraindicated because of the risk of ureteral obstruction by clots. Fortunately, hematuria in patients with hemophilia is not associated with progressive loss of renal function, and as such, its natural history is probably benign.

Gastrointestinal Bleeding

GI bleeding can occur in adults with hemophilia, particularly in association with chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs) for arthropathy. Life-threatening upper GI bleeding can occur because of ruptured esophageal varices in patients with portal hypertension secondary to long-standing hepatitis C. Bleeds are usually treated with high doses of factor concentrate for several days together with antifibrinolytic agents.

Neurologic Bleeding

ICH, the most feared hemorrhagic event, remains a leading cause of death and morbidity (mental retardation, seizure disorders, and motor dysfunction), particularly in neonates and very young children with hemophilia.[49] The incidence of ICH is highest in neonates and is associated with the birthing process, particularly with traumatic vaginal delivery. ICH is also seen in young children with severe hemophilia, particularly those not receiving prophylaxis or in patients with high titer inhibitors not receiving emicizumab/bypassing agent prophylaxis.[50] In older adults, ICH is again more common, particularly in those with coexisting HIV or hepatitis C who have thrombocytopenia secondary to portal hypertension-induced splenomegaly or HIV-associated immune thrombocytopenia. ICH is rare in patients with mild or moderate hemophilia.

ICH may be subdural, epidural, subarachnoid, or intracerebral. Intraspinal (usually epidural) bleeding is rare, but when it occurs, can cause spinal cord compression. Most cases of ICH occur after trauma, but the trauma may be trivial, such that the ICH appears to occur spontaneously. Patients with ICH usually present with neurologic symptoms soon after trauma. Typical neurologic symptoms include drowsiness, loss of consciousness, seizures, headache, and unexplained vomiting.[51,52] Patients with any of these symptoms should immediately be given a bolus of the appropriate factor concentrate to raise the factor level to about 100% or a bypassing agent if there is a high titer inhibitor; this should be done prior to any diagnostic procedure (e.g., computed tomography or MRI). If ICH is confirmed, patients should be hospitalized for 10 to 14 days during which time they should be maintained on factor concentrate (by continuous infusion or frequent bolus infusion) to maintain factor levels over 100%. With emicizumab, the duration of treatment with aggressive factor replacement may be reduced.

Surgery and Bleeding

Except for circumcision in neonates, excessive bleeding is almost inevitable in patients with severe or moderate hemophilia who undergo surgery without adequate replacement therapy. The bleeding can be acute or delayed for several hours or days. In addition to bleeding, surgery in such patients is characterized by poor wound healing because of poor clot formation, prolonged bleeding, and wound infection. For surgical management of hemophilia see later section in this chapter.

CLINICAL MANAGEMENT OF HEMOPHILIA

The key aspects of hemophilia management are preventive therapy, treatment of bleeds when they occur, managing complications of bleeding, and dealing with the psychosocial issues of an inherited condition.

The management of hemophilia has undergone dramatic changes in the last few years. As a lifelong, expensive, and disabling illness, the management of patients with hemophilia is complex and has been and will likely continue to be best undertaken through comprehensive care at hemophilia treatment centers (HTC) with multidisciplinary teams of health professionals. These teams should include a physician (usually a hematologist) with specialist training in hemophilia, a dedicated nurse, a physical therapist, and a social worker. Additional members needed for consultation include an orthopedic surgeon, a dentist, a genetic counselor, an obstetrician/gynecologist, a psychologist, a rheumatologist, a urologist, and (increasingly, for the management of elderly persons with hemophilia) a cardiologist. Fortunately, the role of the orthopedic surgeon in the management of hemophilia has been reduced in countries where prophylactic therapy is provided.

Over the course of their lifetime, patients with hemophilia and their families will face many psychological and physical challenges. Children with hemophilia are often overprotected, which can lead to difficulties with adjustment to the school environment and to society in general as they age. Hemophilia impacts the choice of sports and recreational activities that are undertaken and some studies report poorer academic performance and behavioral and emotional problems in school-aged children with hemophilia compared with those without.[53] The causes may be multifactorial, including silent ICH. Children with hemophilia may resent their unaffected siblings and peers and they may harbor suppressed anger regarding their condition. Hemophilia can have an impact on vocational choices and opportunities for adults with arthropathy. Furthermore, those with HIV or hepatitis C have additional issues to deal with.

Hemophilia has an impact on the entire family. The child's mother may experience guilt knowing that as a carrier she passed the hemophilic mutation to her son. This can contribute to marital breakdown, although it is unclear whether marital discord is more frequent in parents of a child with versus without hemophilia. Regardless, persons with hemophilia and their families require ongoing education, counseling, and support.

Preventive Therapy

Preventing Trauma and Promoting Activity

Prior to the availability of effective prophylaxis, trauma prevention tactics were used to reduce the frequency of bleeding. One such strategy involves restriction from participation in high-risk sports (e.g., ice hockey, football, rugby, and martial arts). Even with effective prophylaxis, high-risk sports may be problematic for patients with severe hemophilia. Several other sports (e.g., soccer, basketball, baseball, and tennis) also entail a certain amount of risk, but for the child's psychological well-being, have generally been permitted if the child is on prophylaxis or receives prophylactic therapy prior to the activity. Other sports considered to be relatively safe include road cycling (with a protective helmet), running, and swimming. Ideally, persons with hemophilia should be encouraged to keep active throughout their lives because osteoporosis and obesity are growing problems in this population because of inactivity. All patients with severe and moderately severe hemophilia should be told to wear helmets for bicycle riding, rollerblading, skateboarding, and downhill skiing. There is controversy regarding the use of helmets (outside of sports) in very young children (ages 1 to 2.5 years) as they are learning to walk and are unsteady on their feet and prone to falling. It is important to advise families on the need for good dental hygiene to prevent or reduce the need for dental procedures (extractions, root canals), which entail a risk of bleeding. Unfortunately, dental care, including regular cleaning by a dentist, is often not subsidized by society and as such may be an expensive undertaking for families.

Vaccinations

Children with hemophilia have normal immune systems and should receive all routine vaccines. Vaccines should be given intramuscularly or subcutaneously using the smallest gauge needle possible (#25 or #27) and pressure should be applied at the injection site for 5 minutes. Without prophylaxis, there is a risk of hematoma formation after intramuscular injections. Subcutaneously administered vaccines appear to produce the same immune response as those given intramuscularly.[54] The enhanced safety of subcutaneous injections renders this the preferred route. Currently approved COVID-19 vaccines however require intramuscular administration.

In the past it was important that patients with hemophilia receive hepatitis B vaccinations at a young age. However, none of the current therapies (currently available plasma-derived factor concentrates, recombinant factor concentrates—both standard and EHL and nonfactor therapies) transmit hepatitis B and hence the urgency for hepatitis B vaccination has lessened. Nonetheless, vaccination should be considered because patients with hemophilia may acquire hepatitis B from blood transfusions required for surgery or trauma.

Avoidance of Aspirin and Other Medications That Increase Risk of Bleeding

The risk of bleeding in persons with hemophilia can be exacerbated by aspirin, other antiplatelet agents such as clopidogrel, and NSAIDs. Therefore, these agents should be avoided if possible. Cyclooxygenase-2 inhibitors have less of an effect on platelet function than traditional NSAIDs (see Chapter 128). If antiplatelet agents are required, coordinated care with an experienced cardiologist and a hemophilia specialist is needed.

Haemostatic Replacement Therapy

Standard Half-Life Clotting Factor Concentrates

Until the 1970s, plasma was the only source of clotting factors for replacement. Plasma contains only small amounts of FVIII and FIX. Consequently, large volumes of plasma are needed for replacement, which can lead to fluid overload. Cryoprecipitate, which contains high concentrations of FVIII, was commonly used for treatment of hemophilia A in the 1960s and 1970s. However, neither plasma nor cryoprecipitate is virally inactivated. In addition, storage issues and convenience and volume of administration have rendered these products obsolete in most countries. It should be noted that due to their low cost and wide availability in many parts of the world plasma and cryoprecipitate have continued to be used into the 21st century.

Plasma-derived clotting factor concentrates (CFCs), which are derived from thousands of units of plasma, first became available in the late 1960s. In the early 1970s and 1980s, it was evident that these concentrates were contaminated with hepatitis C and HIV.

Consequently, a generation of hemophilia patients worldwide died of HIV/AIDS or from complications of hepatitis C. This tragedy prompted development of effective viral inactivation methods for treatment of plasma-derived products such as solvent detergent, pasteurization, vapor treatment, nanofiltration, and dry heating, and the development of recombinant CFCs. Currently administered plasma-derived CFCs are not associated with any known viral transmission, although a small theoretical risk remains. These are classified as high purity (containing only the desired factor and very little else) or intermediate purity (containing the desired factor but with other factors present). In the case of FVIII, intermediate-purity products generally contain VWF (e.g., Alphanate [Grifols], Humate [CSL-Behring], and Wilate [Octapharma]). Intermediate-purity FIX products are prothrombin complex concentrates (PCC) (e.g., Beriplex [CSL Behring], Octaplex [Octapharma], and Proplex [Takeda]), which, in addition to FIX, contain other vitamin K dependent factors (FII, FVII, FX, along with protein C and S). In general, PCCs are no longer used for the management of bleeding in patients with hemophilia B because of the risk of thrombosis.

Recombinant FVIII was developed in the late 1980s. First-generation products were stabilized with human albumin in the final product. Albumin was eliminated in second-generation products, but these products were still exposed to human plasma-derived proteins during the manufacturing process. Third-generation products have no exposure to human or animal proteins and are stabilized with sucrose. Recombinant CFCs have traditionally been more expensive than their plasma-derived counterparts, but they have supplanted plasma-derived CFCs for hemophilia treatment because of enhanced safety and smaller volumes of infusion. BeneFix (Pfizer) was the first commercially available recombinant FIX, but two other standard half-life (SHL) recombinant FIX products are now available (Rixubis [Takeda], Ixinity [Emergent]).

The efficacy of factor concentrates primarily reflects their pharmacokinetic properties such as recovery and half-life. Until recently all available plasma-derived and recombinant CFCs have had similar pharmacokinetic properties; these have been referred to as SHL CFCs.

The recovery of factor concentrate refers to the increase in circulating factor activity level achieved immediately after infusion of a given amount of factor. With all FVIII concentrates, administration of 1 IU/kg of FVIII increases the FVIII level by approximately 2%. Therefore, to achieve a FVIII level of 100% in an individual with severe hemophilia, a dose of 50 IU/kg is needed. The volume of distribution for FIX is two- to threefold greater than that for FVIII. Therefore, a FIX dose of 1 IU/kg has traditionally been thought to increase the FIX level by 1%. However, with this dose, the recovery of recombinant FIX (BeneFix; Pfizer) only increases the FIX level by 0.7% to 0.8%. The recovery of EHL FIX concentrates is more variable with some behaving more like FVIII with recoveries of 1.5% per 1 U/kg administered.

The half-life determines the duration of activity after administration of the clotting factor. In general, SHL FVIII concentrates have shorter half-lives than SHL FIX concentrates (8 to 12 hours vs. 18 to 24 hours) and all the SHL concentrates have similar pharmacokinetic properties. Consequently, the choice of SHL FVIII or FIX concentrate was primarily influenced by cost and availability, and the desire to avoid the potential risks of plasma-derived products.

A major limitation of SHL CFCs is the need for frequent intravenous administration because of their short half-lives. With the requirement for every-other-day injection with some high-dose prophylaxis regimens, adherence can be problematic as evidenced by development of joint disease despite prophylaxis.[55]

Extended Half-Life FVIII and FIX Concentrates (Table 134.6)

Several EHL FVIII and FIX concentrates are now available. Although all EHL concentrates are recombinant proteins, the technology used to extend the half-life differs among products. The two main methods involve fusion technology and PEGylation. Both technologies work by interfering with the natural clearance of FVIII or FIX by the mononuclear phagocyte system and by sinusoidal endothelial cells. Attempts to prolong the half-life of FVIII by increasing its binding to VWF yielded minimal prolongation (Afstyla; CSL-Behring).

TABLE 134.6 **Extended Half-Life FVIII and FIX Concentrates**

Product	Technology	Manufacturer	$T_{1/2}$ vs. Native FVIII/FIX
Extended Half-Life FIX			
rFIXFc (Alprolix)	Fusion protein with Fc fragment of IgG1	Sanofi/Sobi	3X
rIX-FP (Idelvion)	Fusion protein with albumin	CSL-Behring	>5X
N9-GP (Rebinyn/ Refixia)	Site-specific glycoPEGylation (40 kDa PEG)	Novo-Nordisk	>5X
Extended Half-Life FVIII			
FVIII-Fc (Eloctate/ Elocta)	B domain deleted FVIII fused to a monomeric Fc fragment of IgG	Sanofi/Sobi	1.5–1.7X
BAY-94-9027 (JIVI)	Site specific PEGylation (60 kDa PEG) of a B domain deleted FVIII	Bayer	1.4–1.6X
BAX 855 (Adynovate/ Adynovi)	Controlled PEGylation (20 kDa branched chain PEG) of a full-length FVIII	Takeda	1.4–1.6X
N8-GP (Esperoct)	Single site specific glycoPEGylation (40 kDa PEG) of a B domain truncated FVIII	Novo Nordisk	1.6X

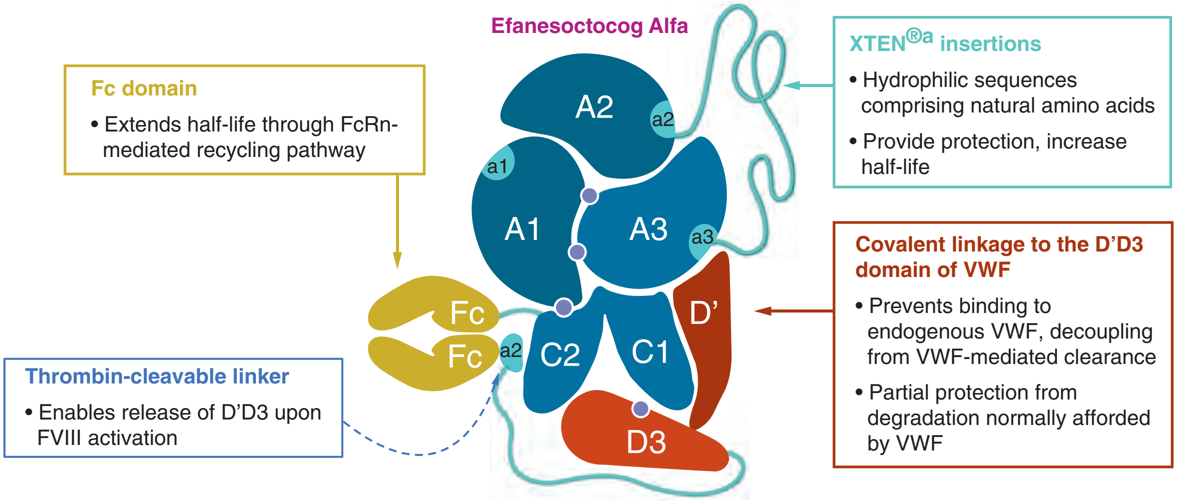
FVIII, Factor VIII; *PEG*, polyethylene glycol; $T_{1/2}$, half-life; *kDa*, kilodalton.
Adapted and updated from Carcao M. Changing paradigm of prophylaxis with longer acting factor concentrates. *Haemophilia.* 2014;20(suppl. 4):99.

Fusion technology involves molecular linking of the cDNA sequences of clotting factors to the cDNA of proteins (the Fc portion of immunoglobulin or albumin) that have long half-lives because they bind to the neonatal Fc receptor in endothelial endosomes. This protects them and whatever is attached to them from degradation within endothelial cells and recycles the proteins back into the plasma. There are currently 2 EHL fusion FIX concentrates—in one, the recombinant FIX is bound to recombinant Fc (Alprolix; Sanofi/Sobi), while in the other, it is bound to recombinant albumin (Idelvion; CSL Behring). There is also one Fc fusion FVIII (Eloctate/Elocta; Sanofi/Sobi).

For PEGylation, polyethylene glycol (PEG) molecules of different sizes are bound to either recombinant FVIII or FIX. There is one pegylated FIX product (Rebinyn/Refixia; Novo Nordisk) and 3 pegylated or glycoPEGylated FVIII products (Adynovate/Adynovi, Takeda; Esperoct, Novo Nordisk; Jivi, Bayer).

Until recently, recombinant FVIII was derived from full-length cDNA constructs. However, most of the EHL FVIII concentrates (including Eloctate/Elocta, Esperoct and Jivi) are B domain deleted; only Adynovate/Adynovi is full length.

The recovery of newer EHL FVIII products is like that of SHL FVIII. In contrast, the recovery of newer EHL FIX products is more variable with Refixia/Rebinyn and Idelvion yielding greater recovery than Alprolix, which may reflect differences in extravascular distribution. Compared with their SHL counterparts, the half-life of FIX is



Efanesoctocog Alfa

Figure 134.10 EFANESOCTOCOG ALFA (BIVV001; SANOFI); A NOVEL EXTENDED HALF-LIFE RFVIII-VWF-XTEN FUSION PROTEIN. Consisting of a D'D3 molecule fused to rFVIII, efanesoctocog does not bind to endogenous von Willebrand factor (VWF) thereby eliminating VWF mediated clearance.[18] To prolong the half-life two Fc molecules and two XTEN polypeptides (144 aa and 288 aa) composed of natural hydrophilic amino acids are fused to the protein.

extended three- to fivefold while that of FVIII is extended by about 1.5-fold likely reflecting the dominant role of VWF in FVIII clearance.[18,56,57] All EHL FVIII products have similar pharmacokinetic properties.[58,59] This is not the case for EHL FIX where the half-life of Alprolix is shorter than that of the other two EHL FIX products. New evidence suggests that extravascular FIX sequesters in the basement membrane of blood vessels, where it may contribute to hemostasis when there is a breach in the vessel wall. Consequently, higher plasma levels of FIX may be required to achieve hemostasis with EHL FIX products that are confined only to the intravascular compartment. This phenomenon may explain the breakthrough bleeding reported with Idelvion.[60]

EHL products, particularly the newer EHL FIX products, enabler fewer infusions, achievement of higher trough levels, and improved patient satisfaction.[61] EHL FIXs allow for infusions as infrequently as once every 7 to 14 days while still obtaining sufficient levels of protection to prevent bleeds. For the most part, EHL FVIII products still need to be given at least twice per week to achieve trough levels around 2% to 3%.

Ongoing research is focused on novel methods for extending the half-life of FVIII or to enable subcutaneous delivery. BIVV001 (efanesoctocog alfa; Sanofi) is a novel EHL FVIII in which the FVIII has been engineered such that it no longer binds to VWF but has been linked to rFc and has 2 XTEN polypeptides composed of natural hydrophilic amino acids. These modifications result in a half-life 4-fold longer than that of SHL FVIII and may enable once-weekly therapy for patients with hemophilia A (Fig. 134.10).[18]

Prophylaxis

If hemostatic treatment is given only on demand (also referred to as episodic therapy), meaning only after a bleed occurs, recurrent bleeds will, over time, lead to disabling joint disease. Recognizing that on-demand "therapy" does not prevent joint disease, prophylaxis is the current standard of care. Until recently, prophylaxis referred to the regular replacement of CFC to prevent or reduce the risk of bleeding. With the availability of emicizumab, the definition of prophylaxis has changed. In many parts of the world, however, no prophylaxis is available, or if prophylaxis is available, it is restricted to SHL CFC.

The longest experience with the use of prophylaxis comes from European centers in Sweden, the Netherlands, and Germany. This experience began over 50 years ago. However, the first randomized study comparing prophylaxis with on-demand therapy was performed less than 20 years ago when Manco–Johnson and colleagues demonstrated 90% fewer bleeds in very young children started on prophylaxis prior to 2.5 years of age (i.e., primary prophylaxis) vs those treated on demand. Furthermore, they showed that after only a few years, children given prophylaxis exhibited less joint damage than those treated on demand.[62] Cohort studies and a few randomized studies confirm the benefits of prophylaxis and demonstrate reduced bleeding, prevention, or reduction of joint damage, reduced hospitalization rates, reduced need for orthopedic surgery, improved work and school attendance, and enhanced quality of life.[37,53,63–65] All prophylaxis regimens (from high to low dose) have demonstrated superiority over on-demand therapy.[37,66,67] One other potential (but not conclusively proven) benefit of prophylaxis is that early initiation of prophylaxis may reduce the risk of inhibitor development, at least in the subgroup of patients with severe hemophilia with "good risk" *F8* mutations.[68,69]

Consequently, prophylaxis is now considered the standard of care for all persons with severe hemophilia and for those with moderate hemophilia with a severe phenotype.[37]

Individualization of Prophylaxis

The concept of individualization of prophylaxis has evolved over time with the recognition that patients differ in their needs for prophylaxis with some patients requiring more intense prophylaxis than others.[70,71]

Until the advent of EHL factor concentrates, full-dose prophylaxis involved the administration of 25 to 40 IU/kg of conventional (i.e., SHL) FVIII every other day (minimum, 3 days/week) for hemophilia A and the same amount of FIX 2 days/week for hemophilia B. Less intense "intermediate-dose" prophylaxis regimens involved the administration of 15 to 25 U/kg 2 to 3 times a week, and low-dose prophylaxis regimens called for the administration of 10 to 15 IU/kg one or two times a week. For the most part, the full-dose regimen maintained trough levels over 1% while trough levels below 1% occurred with the lower-dose regimens at least some of the time.

Although EHL concentrates, particularly EHL-FIX, enable the achievement of higher trough levels, full-, intermediate-, and low-dose prophylaxis regimens with these agents have yet to be defined.

Contributing to interpatient differences in prophylaxis needs is the variability in the pharmacokinetics of factor concentrates from person to person. In general, children exhibit lower recoveries of clotting factors. There are large inter-individual variations in CFC half-life. In the case of FVIII, it is most affected by the patient's endogenous VWF level, which in turn depends on the ABO blood group. The half-lives of both FVIII and FIX increase with age for reasons that are poorly understood.

Prophylaxis with CFC (particularly SHL CFC) prophylaxis is burdensome for patients, especially young children, because of the need for frequent injections and costly for healthcare systems. Patients, particularly young children, receiving full-dose prophylaxis with CFCs often require a central venous access device (CVAD) or an arterial-venous fistulas (AVF) for access. The need for an access device may lead to delays in initiating prophylaxis or its administration at a suboptimal frequency to avoid the need for frequent venipuncture.[72,73]

When to Start Prophylaxis? Primary, Secondary, or Tertiary Prophylaxis

There is abundant evidence that starting prophylaxis early in life is optimal for prevention of joint disease.[37] This is referred to as primary prophylaxis; prophylaxis started at a very young age (usually 2 years of age or earlier) before joint disease has developed (generally, before or immediately after the first joint bleed). In contrast, secondary and tertiary prophylaxis refer to prophylaxis started at a later age (after the age of 2 years) or after several joint bleeds have occurred, and prophylaxis started after there is established joint disease, respectively. The term prophylaxis also encompasses short-term prophylaxis regimens given after surgery or ICH.

In the past, starting young children on prophylaxis was onerous because it involved training families/care givers and then the patient to administer factor in the home (referred to as home care—see box on Home Care).

Because of the need for venous access, many patients were started on less intensive prophylaxis regimens (e.g., once per week) and gradually escalated to full-dose regimens to obviate the need for a CVAD. EHL concentrates, particularly EHL FIX, enable administration of prophylaxis once per week or even once every two weeks without needing to escalate. Now, many young children with hemophilia A are started on emicizumab (discussed in more detail later), which is delivered subcutaneously. Emicizumab may enable earlier initiation of prophylaxis because infrequent subcutaneous injections are well tolerated even by very young children.

Because of the benefits of commencing prophylaxis early (i.e., primary prophylaxis) in children with severe hemophilia, the World Health Organization, World Federation of Hemophilia (WFH), and many other national hemophilia organizations have endorsed primary prophylaxis as the standard of care for such children.[37,62] This endorsement has extended to include patients with moderate hemophilia, especially those with a baseline factor level of 1% to 3%.[74]

HOME CARE

Hemophilia treatment (both prophylactic therapy and therapy to treat bleeds) is best administered in the patient's home. Having a patient or other caregiver able to administer therapy enables prompt treatment of bleeds and facilitates compliance with CFC prophylaxis. In the past, when intravenous clotting factor replacement was the only option for prophylaxis, hemophilia centers focused on teaching patients and families how to administer them. Such teaching is labor intensive and time consuming and usually requires collaboration between patients, their families, and dedicated hemophilia clinic nurses. If delivery via a peripheral vein was impossible a CVAD was inserted or an AVF was created. This approach enabled most boys with hemophilia older than 3 years of age to be treated at home by their parents (via peripheral veins or CVAD/AVFs) or in some cases by a visiting nurse. Once they reached the age of 8–12, most boys could be taught how to self-administer factor via a peripheral vein. Emicizumab has replaced factor infusion for prophylaxis in many infants and children. Because it is given subcutaneously, the need for venous access devices has been eliminated. Although families or patients are taught how to inject emicizumab subcutaneously, they will be inevitably less likely to learn how to administer intravenous therapies for management of breakthrough bleeds.

Although most children in Europe and North America are receiving prophylaxis, it is less routinely used in less affluent countries.[71] However, the uptake of prophylaxis has increased world-wide with the recognition that even intermediate- or low-dose regimens provide better results than on-demand therapy, and with the availability of EHL CFCs, which enable less frequent intravenous infusions, and with emicizumab which does away with the need for intravenous infusions altogether.

The perception that prophylaxis is less essential in adults than in children or adolescents has fortunately been changing and an increasing number of adults, at least in more affluent countries, are now on prophylaxis. In a 2013 survey of prophylaxis use in high-income countries (North America, Europe, Australia, and New Zealand) it was shown that 59% of adults with severe hemophilia A and 49% of those with severe hemophilia B were on regular prophylaxis.[75] Those proportions are likely much higher now with the introduction of EHL CFCs and emicizumab. It is now accepted that the gains of prophylaxis in childhood are rapidly lost if prophylaxis is stopped in adulthood.[37]

EHL CFCs and emicizumab have transformed prophylaxis, but there are many remaining questions. For example, how early in life should prophylaxis start, and should it start with emicizumab or with CFCs? Will EHL CFCs and emicizumab eliminate the need for CVADs? If emicizumab is used for prophylaxis, will patients be able to treat bleeds at home with CFCs, and if not will delays in obtaining treatment adversely affect joint health or quality of life?

Emicizumab

Emicizumab is a humanized bispecific murine monoclonal antibody that mimics the function of FVIII by binding FIXa and FX and bridging them together.[76] By bypassing FVIII, emicizumab can be used in patients with hemophilia A with or without inhibitors (see Fig. 134.3). Although emicizumab mimics the function of FVIIIa, there are differences that impact the outcome of FVIII administration on top of emicizumab (Table 134.7).[77]

In clinical trials (HAVEN 1, 2, 3, and 4), emicizumab provided effective prophylaxis against bleeding in patients with or without inhibitors and eliminated the development of target joints (Table 134.8). These trials have also shown reduced bleeding rates compared to patients on prophylaxis (both bypassing agent prophylaxis in patients with inhibitors and FVIII prophylaxis in those without inhibitors).[76,78,79,81] In addition to preventing bleeds, emicizumab may enable patients to safely undergo minor procedures such as CVAD removal or circumcision without additional hemostatic coverage. Nonetheless, because some bleeds have been reported in such patients, many clinicians choose to administer FVIII or a bypassing agent in these settings.

In addition to its efficacy, emicizumab has advantages over FVIII. These include its capacity to be administered subcutaneously and its half-life of about 29 days,[82] which enables dosing every 1 to 4 weeks.[76,78,80] Consequently, emicizumab is less burdensome than prophylaxis with FVIII prophylaxis in patients without inhibitors or bypassing agents in those with inhibitors.[79]

Emicizumab provides a steady-state level of hemostatic protection which may convert severe hemophilia to a mild state. The thrombin generation provided by emicizumab was in one small study found to be equivalent to that of FVIII levels of 10% to 40%.[83] Between patient variability in FVIII equivalency was also reported in the pivotal HAVEN-1 trial where steady state emicizumab levels in 112 subjects varied (median 50 ug/mL; range: 25 to 80 ug/mL), which correlated with a mean FVIII-like activity of 20.3% (95% CI, 12.3% to 28.4%).[84]

The protection provided by emicizumab is sufficient to protect most patients from bleeding most of the time but may not be adequate for those engaging in high-impact activities. If breakthrough bleeding occurs, intravenously administered hemostatic therapy is needed as emicizumab cannot be used to treat bleeds. FVIII is safe to administer to patients taking emicizumab prophylaxis. Emicizumab binds less

TABLE 134.7 Main Differences Between FVIII and Emicizumab

	FVIIIa	Emicizumab
Sites of interaction	Multiple sites	Single site
Affinity for FIXa) and FX	High affinity	Low affinity
Specificity of binding	Specific for FIXa and FX	No distinction between zymogen and enzyme (binds FIX and FIXa and FX and FXa)
Cofactor activity	Full cofactor activity • Promotes phospholipid binding • Stabilizes FIXa active site • Bridges FIXa to FX	Partial cofactor activity • Bridges FIXa to FX
Rate limiting step	Concentration of FVIIIa (Enzyme and substrate in excess)	Concentration of enzyme and substrate (Emicizumab in excess)
On/off mechanism	Yes	No
Level of self-regulation	High	Low

avidly to the FIXa-FX complex than FVIIIa. Thus, if FVIII is given, it will preferentially bind to FIXa and FX displacing emicizumab.

FVIII levels in patients taking emicizumab cannot be monitored with routine one-stage clot-based or chromogenic assays. Such assays yield spurious FVIII levels of 500% or more. Although alternative assays have been developed, they are not widely available.[85]

Minor limitations of emicizumab include injection site reactions (pain and swelling particularly with larger volumes) and a low risk (<1%) of formation of neutralizing anti-drug antibodies.

Emicizumab is an option for patients with hemophilia A without inhibitors (in very young children it is likely the preferred option to avoid the need for intravenous therapy) and is the preferred prophylactic therapy for any hemophilia A patient who develops a high titer inhibitor. In older children without inhibitors, it is unclear whether emicizumab will remain the preferred option over intravenously CFCs, if very long half-life products such as BIVV001 (efanesoctocog alfa) are available.

Other FVIII mimetics (Mim8; Novo Nordisk and a second-generation emicizumab; Roche) are undergoing clinical investigation.[86] These appear to be more potent than emicizumab and potentially may convert severe hemophilia to a non-hemophilic state by providing the equivalent of FVIII levels greater than 40% at all times.

Rebalancing Therapies (Fig. 134.11)

Clinical trials exploring the efficacy and safety of therapies targeting natural anticoagulants (tissue factor pathway inhibitor [TFPI], AT, and the protein C/S pathways) are ongoing. These agents promote hemostasis by rebalancing the procoagulant to anticoagulant balance. Since that balance differs between individuals, clinical trials are assessing the dosing required to reverse the coagulation deficiency without inducing a prothrombotic state.

All these novel agents are, like emicizumab, delivered by subcutaneous injection. One major advantage of these rebalancing therapies is that, unlike emicizumab, they can be used in HB patients with inhibitors, which although rare is a condition that currently represents a very big unmet need. However, these agents are not yet approved and have had setbacks in clinical development and hence these agents may never become available.

Anti-Tissue Factor Pathway Inhibitor

Two monoclonal antibodies against TFPI are under investigation (marstacimab; Pfizer, and concizumab; Novo Nordisk). The antibodies are administered subcutaneously in regimens varying from daily to weekly. Drug-related thrombosis halted development of a third antibody against TFPI (befovacimab, Bayer)[87]; thrombosis has also been reported with concizumab.

Fitusiran (Sanofi)

Fitusiran is a small interfering RNA, which reduces the hepatic synthesis of AT, thereby enhancing thrombin generation and promoting hemostasis. Fitusiran is administered subcutaneously on a weekly or even monthly basis. In a phase 2 study in patients with hemophilia A or B, with or without inhibitors, fitusiran (50 or 80 mg once-monthly do) reduced AT levels by 80% and was associated with a median annual bleeding rate (ABR) of 1 in patients without inhibitors ($n = 19$). In the 14 patients with an inhibitor, fitusiran reduced the median ABR from 38 (pre-fitusiran) to 0.[88,89] No thrombotic episodes were observed. The phase 3 program for fitusiran was temporarily halted when a fitusiran-treated patient with hemophilia A without an inhibitor suffered a fatal cerebral vein thrombosis after being given 3 doses

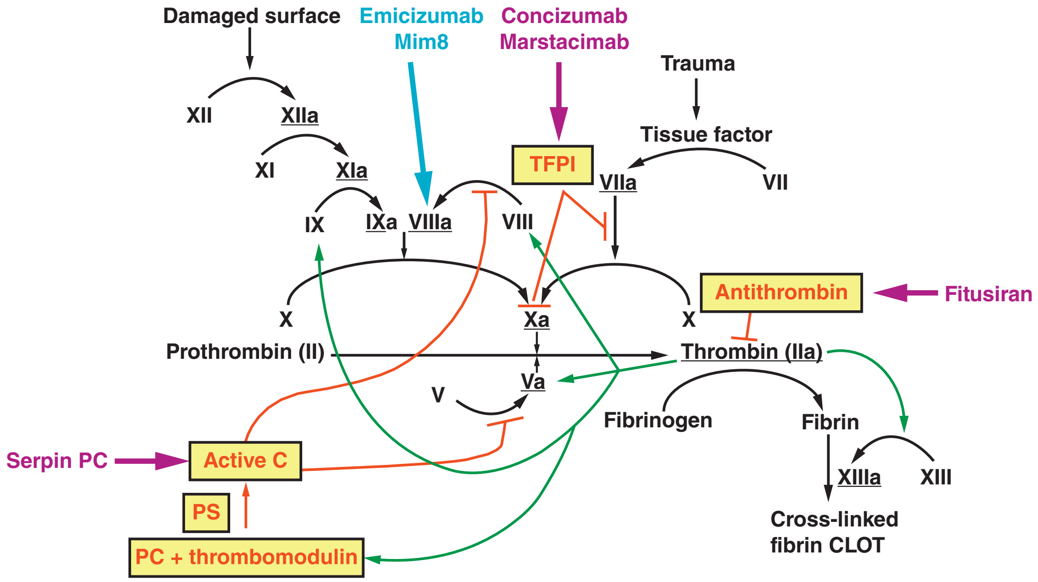

Figure 134.11 LOCATION OF ACTION OF NEW THERAPIES. Shown in *green* and *red arrows* are positive and negative feedback loops, respectively, provided by natural anticoagulants (highlighted in *yellow*: antithrombin, tissue factor pathway inhibitor (TFPI), activated protein C/protein S [PC/PS] and thrombomodulin). Activated factors are denoted by a little "a" and underlined. Factor VIII mimetics (emicizumab and Mim8; shown in *blue*) and rebalancing agents under development (shown in *purple*).

(31 to 46 U/kg) of FVIII. This event prompted a risk-mitigation strategy recommending the use of low doses of FVIII or bypassing agents in the event of bleeds. After another thrombotic event, the fitusiran dose was reduced to target an AT level of 15% to 35% and the trials are ongoing.

Other Rebalancing Agents

Additional rebalancing agents in development target other natural anticoagulants such as activated protein C or protein S.

Treatment of Bleeds

When a bleed occurs in a patient with hemophilia, immediate treatment is required to halt further bleeding. Rapid treatment prevents expansion of the bleed, accelerates healing, and reduces the risk of permanent disability. The longer the delay in providing treatment, the more bleeding that will ensue and, consequently, the longer it will take to completely resorb the blood. Blood within a joint is damaging to the synovium as well as to cartilage. Rapid treatment of joint bleeds will minimize damage to the joint and prompt treatment of muscle bleeds will limit expansion and reduce the risk of pseudotumor formation or compartment syndrome. Rapid treatment of ICH may be lifesaving and will minimize morbidity.

Even with the availability of emicizumab, treatment of bleeds still involves intravenous infusion of the missing factor. The capacity to administer rapid treatment is enhanced if the patient/family can administer factor at home (see box on Home Care).

Treatment of Bleeds With Factor Concentrates

The dose and duration of substitution therapy for treating or preventing bleeds depend on the severity of the bleed or the extent of the surgery.[37] Table 134.9 shows the desired factor levels for various types of bleeds and surgeries. After the initial bolus of factor, repeat doses of SHL concentrates have traditionally been needed. However, one dose of an EHL factor concentrate is often sufficient. For major bleeds, such as an ICH, or for major surgeries, such as joint replacement, 10 to 14 days of full factor coverage may be required, but for less severe bleeds, such as an uncomplicated hemarthrosis, 1 to 3 treatments (depending on the pharmacokinetics of the factor) are usually sufficient. For minor bleeds or minor surgeries (e.g., dental extraction) one treatment may be sufficient. For patients who require additional doses to treat a bleed or to ensure peri-surgical hemostasis, the frequency of treatment depends on the pharmacokinetics of the individual factor. Because of variable pharmacokinetics, monitoring trough factor levels every few days is useful to avoid high factor levels, which can be associated with thrombosis, or low levels, which can be associated with bleeding, and to detect inhibitor development.

An alternative method for maintaining hemostasis is to administer clotting factors by continuous intravenous infusion. The benefits of this approach include reduced overall factor consumption and elimination of the peaks and troughs associated with repeated bolus administration. In general, a FVIII infusion rate of 2 to 3 U/kg/h (with SHL FVIII or 2 U/kg with EHL FVIII) is sufficient once a FVIII level of 100% has been achieved with a bolus of 50 U/kg. Given the longer half-lives of EHL FVIII and particularly EHL FIX, continuous infusion of these products is not often necessary. Although concern has been raised about the possibility of inhibitor development with continuous infusion therapy, particularly in patients with mild or moderate hemophilia A, definitive evidence that continuous infusion poses a risk for inhibitor development is lacking.[90]

Treatment of Bleeds With Desmopressin

In the 1970s, Mannucci and colleagues showed that DDAVP (1-deamino-8 D-arginine vasopressin, desmopressin, Ferring Pharmaceuticals, Langley, United Kingdom), a synthetic analogue of the natural antidiuretic hormone vasopressin, raises circulating levels of VWF and FVIII:C.[91] DDAVP induces the release of endogenous VWF and FVIII from storage in Weibel-Palade bodies in endothelial cells. It also increases platelet adhesiveness and thus shortens the bleeding time independent of its effect on raising FVIII:C and VWF levels. Because DDAVP is not blood-derived or a factor concentrate, there is no risk of infectious complications or inhibitor development. DDAVP is less costly than factor concentrates and has few, generally mild and transient adverse events such as flushing, headache, mild tachycardia, and hypotension. DDAVP has antidiuretic activity and thus carries a risk of hyponatremia and seizures, particularly if given to very young children or to those

TABLE 134.9 **Target Factor Level for Different Types of Bleeds and Duration of Treatment**

Site of Bleed		Peak Level Desired (%)	Treatment Duration (Days)
Oral mucosa		>30	1 (plus tranexamic acid)
Epistaxis		>30	1 (plus tranexamic acid)
Joint or muscle		>50	1–3
Iliopsoas	Initial	80–100	1–2
	Maintenance	30–60	3–5
GU (hematuria)		40–50	3–5
GI	Initial	80–100	1–3 (plus tranexamic acid)
	Maintenance	30–50	4–7 (plus tranexamic acid)
CNS	Initial	80–100	1–7
	Maintenance	30–50	8–14
Surgery (minor)	Pre-op	50–80	
	Post-op	30–80	1–5 (plus tranexamic acid)
Surgery (major)	Pre-op	80–100	
	Post-op	60–80	1–3 (plus tranexamic acid)
		40–60	4–6 (plus tranexamic acid)
		30–50	7–14 (plus tranexamic acid)

Note that there is no significant difference in desired factor levels needed between hemophilia A and B. Of course, doses and frequency of dosing will differ between hemophilia A and hemophilia B and between different factor concentrates (standard half-life and extended half-life). Also note that for patients on emicizumab or rebalancing therapies guidelines need to be adapted according to more recent studies and recommendations.

with excessive fluid intake. Consequently, many clinicians avoid DDAVP in children below the age of 3, administer it only once per day, and monitor serum sodium levels and fluid intake when it is administered in hospital. The effectiveness of DDAVP decreases with repeated administration (tachyphylaxis) because of exhaustion of VWF/FVIII stores. Therefore, DDAVP should not be given for more than 3 consecutive days.

Most patients with mild hemophilia respond to DDAVP with a doubling or tripling of their FVIII:C levels to 30% or greater. In patients with moderate hemophilia, DDAVP rarely increases FVIII:C levels into a hemostatically effective range. All individuals with mild hemophilia A should be assessed for DDAVP responsiveness. This involves determining FVIII and VWF levels before and 1 hour after DDAVP administration; unlike in cases of type 1 VWD it is not necessary to measure levels 4 hours after dosing.

DDAVP can be administered intravenously, subcutaneously, or intranasally. The usual dose for intravenous administration is 0.3 μg/kg given in 50 mL of normal saline over 30 minutes. The same dose can be given subcutaneously, which enables home administration. For intranasal administration, the usual dose is 150 μg (1 nasal puff) for patients less than 50 kg and 300 μg (1 nasal puff into each nostril) for patients ≥ 50 kg. The maximum effect of DDAVP is achieved within 30 minutes when given intravenously or subcutaneously and within 60 minutes when given intranasally. In general, the safest approach to avoid hyponatremia is to restrict fluids in patients receiving DDAVP and to administer only isotonic solutions such as normal saline.

Because DDAVP increases platelet adhesiveness, its use in patients with risk factors for coronary or cerebral artery thrombosis may result in angina, myocardial infarction, or even stroke. Hence, DDAVP should be used with caution in elderly men with hemophilia. DDAVP can transiently exacerbate bleeding because it also induces the release of tissue plasminogen activator. Consequently, DDAVP is often administered in conjunction with an antifibrinolytic agent.[92]

Antifibrinolytic Agents

Antifibrinolytic agents, such as tranexamic acid or epsilon aminocaproic acid, are useful in the management of mucosal bleeding (e.g., oropharynx, nose, GI tract, and uterine-vaginal lining) and are generally used in the context of oral bleeding or dental surgery. Oral tranexamic acid (25 mg/kg every 6 to 8 hours) should be started 24 hours before the scheduled procedure whereas intravenous tranexamic acid (10 mg/kg every 8 hours) can be given immediately before the procedure. Tranexamic acid tablets each containing 500 mg can be crushed and dissolved in liquids for administration to young children. The usual dosage of epsilon aminocaproic acid is 75 mg/kg every 6 hours. In general, antifibrinolytic agents should be administered for 3 to 7 days after a bleeding episode or an invasive procedure. Longer durations of therapy are required for tonsillectomy–adenoidectomy because bleeding often occurs about 7 to 10 days post-procedure when the eschar detaches. The major contraindication to the use of antifibrinolytic agents is hematuria.

Fibrin Sealants

Fibrin sealants, which enhance local hemostasis and may promote wound healing, are particularly useful for dental procedures, circumcision, and after excision of hemophilic pseudotumors.

Adjunctive Management Strategies for Joint Bleeds

In the management of joint bleeds, appropriate hemostatic support is critical, but other important measures include appropriate joint rest, analgesia, and graduated physiotherapy. The application of rest, ice (for 20 minutes every 3 to 4 hours), compression, and elevation (RICE protocol) for the first 24 hours after a joint bleed is beneficial. The role of joint aspiration is controversial but may be useful for management of persistent pain in large-volume hemarthrosis or for exclusion of septic arthritis. Orthotics and physical therapy are important components of long-term management. Ankle guards and arch supports are useful for patients with ankle arthropathy to improve gait and weight bearing capacity; shoe lifts equalize lower extremity length if there is a discrepancy, and muscle strength training enhances the mechanics of joint movement and helps to protect and stabilize the joint.

Surgery in Hemophilia

With appropriate management (factor replacement/desmopressin with or without other adjunctive hemostatic agents), intra- and post-operative hemorrhages can be prevented in patients with hemophilia thus allowing surgery to be performed safely. Ideally, a multidisciplinary team is required to undertake surgery in a safe manner; physicians with expertise in the management of hemophilia patients should always be involved. Some surgeries might need to be adapted for patients with hemophilia (e.g., bioprosthetic heart valves are preferable to mechanical valves to avoid the need for anticoagulant therapy).

Patients with hemophilia may need to undergo surgeries that individuals without hemophilia typically undergo including dental extraction, circumcision, tonsillectomy, and appendectomy as well as surgeries related to the disease such as CVAD insertion or removal and pseudotumor excision. Surgery can be done safely if patients receive therapy (generally factor concentrate in those without inhibitors and bypassing agents in those with inhibitors). For most surgeries, the goal of therapy is to "normalize" hemostasis during and after the procedure.

The most common surgical procedures in hemophilia are related to long term complications of joint bleeds. These include surgical or arthroscopic synovectomy, nonsurgical (chemical or radionucleotide) synovectomy, arthrodesis procedures, and joint replacement. Such procedures are now uncommon in children who started prophylaxis early in life.

An open surgical or arthroscopic synovectomy removes inflamed and thickened synovial tissue that is a source of joint bleeding. Although synovectomy may reduce the frequency of bleeding, it does not improve joint mobility and may even worsen it.

Radionucleotide synovectomy involves injection of a radioisotope (e.g., yttrium^{90}, chromic phosphate P^{32}) into the joint space to obliterate synovial tissue. Compared with surgical synovectomy, radionucleotide synovectomy is less invasive, is associated with a shorter hospital stay and reduced clotting factor coverage, and is less costly than surgical synovectomy. Radionucleotide synovectomy is particularly useful for patients with inhibitors because there is a lower risk of bleeding. However, the long-term safety of radionucleotide synovectomy in hemophilia is uncertain. Chemical synovectomy (e.g., using rifampicin) requires repeated injections to achieve results like radionucleotide synovectomy. Although radionucleotide synovectomy has replaced chemical synovectomy in many countries, this is not true world-wide.[93]

Arthrodesis (surgical joint fixation) is particularly useful for painful joints with greatly compromised mobility in which joint replacement is problematic (e.g., ankles).

Joint replacement (particularly of the knee, hip, and more recently, ankle) is still commonly performed in adults with hemophilia. The elbow, which is not amenable to arthrodesis or replacement, is often the most difficult joint to manage in patients with hemophilia. The need for joint surgery has lessened with earlier and more universal uptake of prophylaxis in higher-income countries.

Complications of Treatment

Until the mid-1970s, the major impediment to optimal management of patients with hemophilia was the lack of readily administered therapies to prevent or treat bleeds. By the 1980s, such treatments were available, and prophylaxis programs were initiated in many countries. Unfortunately, the 1980s was the era of HIV and hepatitis C, and most patients with hemophilia treated before 1985 became infected with both, with smaller numbers also becoming infected with hepatitis A and B. Many of these patients have died. This tragedy prompted widespread implementation of blood donor screening programs and viral inactivation processes and accelerated the development of recombinant CFCs.

The management of HIV and hepatitis C has advanced since the 1980s. HCV can now be eradicated, and HIV can be fully suppressed in most individuals.

Other Comorbidities in Patients With Hemophilia

With progressive improvements in hemophilia care, persons with hemophilia are living longer, and morbidities associated with aging, such as hypertension and coronary artery disease, are now complicating management. This phenomenon has prompted the development of guidelines for use of antiplatelet regimens for secondary prevention in such patients.[37]

Limitations to Treatment for Hemophilia

Currently, the major impediments in the management of patients with hemophilia are cost, risk of inhibitor development, and to a lesser degree than in the past, the need for repeated IV access.

1. **Cost:** Worldwide, cost is a major issue. Currently available treatments for hemophilia (factor concentrates and emicizumab) are expensive, and prophylaxis regimens with these products pose a considerable cost. However, the cost of factor concentrates has decreased with the introduction of EHL concentrates and emicizumab and in some countries through tendering systems. With other newer products (efanesoctocog and other FVIII mimetics such as Mim8 in development) the cost of currently available products may decrease. Lower pricing would enable less-affluent countries to provide prophylaxis.
2. **Inhibitor development:** The development of an immune response against the replacement therapy (FVIII or FIX concentrates) remains a problem.
3. **Need for frequent intravenous access leading to the need for CVADs:** One of the most difficult aspects of providing hemophilia care has been the need for frequent intravenous administration of factor concentrates leading to in many cases the insertion of CVADs. These have traditionally been very useful for the management of young children with severe hemophilia and in particular those children who develop high titer inhibitors and thus require immune tolerance induction (ITI) therapy (see section on Inhibitors). CVADs are not without their complications, including infections, thrombosis, and malfunction. Several studies have shown that radiographically proven CVAD-associated thrombosis develops in up to 50% of patients with hemophilia with these devices. Such thrombi may impair CVAD function, thereby necessitating their removal. Additionally, to insert CVADs necessitates a surgical procedure and eventually such CVADs will need to be removed necessitating more surgery. Now with EHL factors (especially EHL FIX and in the years to come other even more EHL FVIIIs like efanesoctocog) and with emicizumab there is less need to insert CVADs in young children, and so CVADs will certainly now have a diminished role in hemophilia management.

INHIBITORS IN HEMOPHILIA

The formation of neutralizing antibodies, or inhibitors against FVIII or FIX, has for some time been the most important complication of therapy in hemophilia now that available replacement products are free from the risk of transmission of infectious agents such as HCV or HIV. Inhibitors render factor concentrate replacement therapy ineffective. As a result, patients who develop inhibitors have until recently suffered from increased risk of bleeding, decreased quality of life, and increased risk of mortality. The advent of emicizumab, and potentially in the future other non-factor therapies, is fortunately changing this.

Autoantibodies to FVIII or to FIX can be detected in non-hemophilic persons, presumably reflecting incomplete immunologic tolerance to antigens in these proteins.[94] Pathologic *autoantibodies* can occur in autoimmune disorders such as acquired hemophilia. Persons with hemophilia A or B, on the other hand, can generate *alloantibodies* to epitopes present on infused factor molecules. Because these people have *F8* or *F9* mutations that result in the synthesis of altered FVIII or FIX or in the total absence of these proteins, these alloantibodies can be considered the products of physiologic immune responses to exogenous antigens. In both hemophilia A and B, inhibitors are IgG molecules, with IgG4 subclass being the predominant isotype.

Epidemiology and Clinical Manifestations of Inhibitors

Inhibitors arise more frequently in patients with severe hemophilia A than in those with severe hemophilia B (about 30% vs. up to 10%)

treated with replacement therapy. Inhibitors are less frequent in patients with non-severe hemophilia, particularly in hemophilia B, although some specific F8 genotypes can be associated with an increased risk of inhibitors even with moderate or mild hemophilia A.[95]

Most inhibitors arise within the first 10 to 20 exposures to either FVIII or FIX and consequently, most inhibitors are detected in very young children—these are referred to as previously untreated patients (PUPs).[96] If PUPs get to 50 exposures to factor (and hence are relabeled as being PTPs, previously treated patients) without developing an inhibitor, they are at a low (but not zero) risk of developing an inhibitor later in life.

In severe forms of hemophilia, inhibitor development usually occurs early in life because prophylactic therapy with FVIII or FIX is started at a young age and patients will quickly receive 10 to 20 exposures. This may change with the introduction of emicizumab, which may delay inhibitor development by years or even decades.[80,97] Even now, some patients with severe hemophilia from less-affluent countries with limited access to factor replacement therapy develop inhibitors at later ages because of reduced exposure to replacement products.

Inhibitor surveillance practices are evolving now that many PUPs are receiving emicizumab prophylaxis and have only limited exposure to factor concentrates in the context of managing bleeds or surgery. There is concern (not proven) that such patients being only exposed to factor in "danger" settings such as bleeds or surgery may be at a higher risk of inhibitor development. Research regarding inhibitor reduction strategies in this population (for example, with regular low-dose exposure of FVIII to elicit tolerization) is ongoing (NCT04030052).

Inhibitors inactivate the infused factor, which decreases or abolishes its effectiveness for prophylaxis or for treatment of bleeds. Inhibitors in patients with mild or moderate hemophilia may transform such patients to a more severe phenotype because they neutralize the individual's endogenous factor.

Diagnosis of Inhibitors

Clinical

The presence of an inhibitor may be suspected if the recovery of FVIII or FIX is less than expected after infusion (see Chapter 127) or if there is an anaphylactic reaction to FIX concentrate; anaphylactic reactions to FVIII concentrate are rare. Alternatively, they may be suspected by finding reduced factor levels immediately after infusion of factor.

Laboratory

Inhibitors are diagnosed, quantified, and classified with the Bethesda assay (see Chapter 126). This is a standard laboratory test that measures the amount of inhibitory activity against FVIII or FIX. Patient plasma is incubated with normal plasma for 2 hours at 37°C, and residual factor activity is then calculated. As a control, normal plasma is diluted with buffer, and factor activity is determined and compared with the result in patient plasma (Fig. 134.12). The Nijmegen modification of the Bethesda titer differs from the "classical" Bethesda assay in two respects: the normal plasma used is buffered to pH 7.4 with imidazole, and the control mixture is made by diluting normal plasma with FVIII deficient plasma, rather than with buffer.[98] The Nijmegen modification is more specific for detection of low-titer inhibitors than the classical Bethesda assay (i.e., it results in fewer false-positive results) and, if available, is the preferred method.

The Bethesda titer is measured in Bethesda units (BU), where 1 BU is the amount of inhibitory activity required to reduce the coagulant activity of the target factor in plasma by 50%. Consequently, an inhibitor titer of 1 BU will reduce factor activity by 50% while a titer of 2 BU will reduce activity by 75%, etc. Consequently, inhibitor titers of 5 BU or more will reduce factor activity by at least 97%, thereby rendering infusion of the factor therapeutically useless. Using the Bethesda assay, inhibitors are classified as high titer (≥5 BU) and low titer (<5 BU). This separation is important because low-titer inhibitors may be transient and bleeds in patients with low-titer inhibitors may respond to high doses of FVIII or FIX. In contrast, high titer inhibitors are usually persistent and bleeds in patients with such inhibitors usually require treatment with bypassing agents. Additionally, the higher the inhibitor titer, the less likely the success of inhibitor eradication strategies.

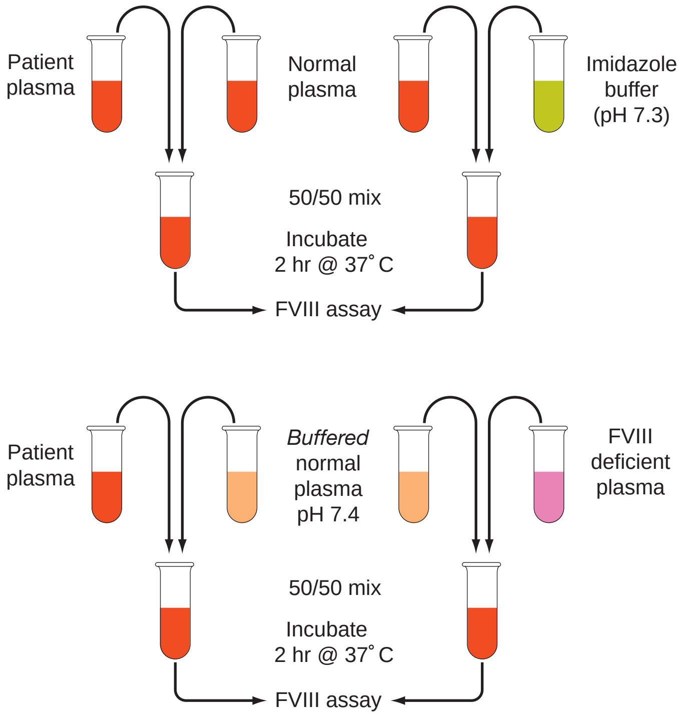

Figure 134.12 THE BETHESDA AND NIJMEGEN-MODIFIED BETHESDA ASSAYS. In the classic Bethesda assay *(top)*, patient plasma is incubated with normal plasma for 2 hours at 37°C, and residual factor activity is then quantified. As a control, normal plasma is diluted with buffer, and factor activity is determined and compared with that measured in the patient sample. The Nijmegen modification of the Bethesda assay *(bottom)* differs in two respects: first, normal plasma is buffered to pH 7.4 with imidazole, and second, the control mixture is made by diluting normal plasma with factor VIII (FVIII) deficient plasma, rather than buffer. A heat inactivation step can be used to inactivate residual FVIII in the patient plasma.

INHIBITORS IN HEMOPHILIA A

Pathophysiology of Inhibitor Development in Hemophilia A

FVIII is a peculiar protein, in that immunologic tolerance to FVIII in people without hemophilia A is not always complete. Rarely, because of autoimmune disease, immunologic tolerance to FVIII fails, and autoantibodies develop; this is known as acquired hemophilia A. Antibodies to FVIII, detectable by ELISA, can be found in the plasma of some individuals without congenital FVIII deficiency. T cells that are reactive to FVIII can also be found in normal individuals, although this reactivity is transient and less intense than that in hemophilia A patients.[99,100]

Only about one-third of patients with hemophilia A exposed to FVIII develop inhibitors. Reasons for inhibitor development are incompletely understood although some of the known risk factors for inhibitor development suggest possible explanations. For example, patients with large *F8* gene deletions and other mutations (referred to as null mutations) that cause an absence of any synthesized FVIII peptide (also referred to as cross-reactive material [CRM] negative) are at increased risk, suggesting that patients with some synthesized protein (CRM positive) may be tolerant to the epitopes that are produced. It has also been hypothesized that exposure to maternal FVIII *in utero* via maternal-fetal hemorrhage or early in life induces immunologic tolerance in the fetus.[101] However, the risk of inhibitor development is unaffected by intrauterine procedures such as amniocentesis[102] or breastfeeding.[103]

The development of FVIII inhibitors reflects a classical T-cell dependent immune response that starts with antigen presenting cells (APCs), mostly dendritic cells (DCs), which endocytose the encountered FVIII. How FVIII enters the DCs is unclear but the macrophage mannose receptor (MMR) on DCs appears to be involved.[104] After endocytosis, FVIII is processed into peptides and together with MHC class II molecules is presented on the surface of the APC to naive CD4$^+$ T cells in secondary lymphoid organs (spleen and lymph nodes).[105] In addition to the FVIII-derived peptide/MHC complex, co-stimulatory signals (ligands and receptors on the surface of T cells and APCs and pro-inflammatory stimuli such as cytokines) are necessary to fully activate naive T cells and enable binding to FVIII epitopes. If the recognition of FVIII-derived peptide by the T-cell receptor leads to the activation of specific T cells, these will migrate and activate B cells that have internalized the FVIII protein through their B-cell receptor and can present peptides in the MHC class II complex to the activated T cells. Activated naive FVIII-specific T cells consequently differentiate into effector helper CD4$^+$ T cells, which in turn activate FVIII-specific B cells, allowing them to undergo class switching and differentiate into FVIII-specific memory B cells or into plasma cells (that can be very long-lived) that produce low affinity anti-FVIII antibodies (Fig. 134.13).[104]

This differentiation is dependent on binding of the B-cell receptor, a membrane receptor in the immunoglobulin superfamily of receptors, to the antigen for which it has specificity, and subsequent interaction with a CD4$^+$ helper T cell. Numerous lines of evidence support the important role of helper T cells in the genesis of inhibitors. Thus, T-cell proliferation in response to FVIII in hemophilia A patients is greater in those with inhibitors than in those without.[106] Furthermore, blockade of CD3, a component of the T-cell receptor complex, decreases inhibitor formation in vitro,[107] as does stimulation of cytotoxic T-lymphocyte antigen 4 (CTLA-4), an inhibitory receptor involved in the downregulation of T-cell stimulation.[108] Finally, inhibitor titers often decrease in hemophilia A patients with HIV, particularly those with very low CD4$^+$ T-cells counts[109] and effective inhibitor development requires co-stimulation of T cells by APCs via the CD40/CD40 ligand or CD28/B7 pathway.[110]

Upon subsequent exposure to FVIII, memory B cells generated during the primary immune response are rapidly restimulated to proliferate and differentiate into antibody-secreting plasma cells that secrete high-affinity neutralizing antibodies.

The need for costimulatory signals in the process of forming antibodies fits with the "danger theory" proposed by P. Matzinger. The theory proposes that exposure to exogenous antigens can result in immunologic tolerance or in an immunologic response, depending on the state of the immune system at the time of exposure. Inhibitor development is more likely to occur when the immune system is exposed to FVIII in the setting of danger, a situation characterized by tissue injury such as occurs with large bleeds, infection, or surgery.[111] These events could trigger the immune system to activate a defense response to the infused clotting factor and potentially lead to an immune response to FVIII. The same theory suggests that if patients are exposed to FVIII in the absence of these danger signals, the immune system may initiate a response that leads to tolerance through the generation of T regulatory cells (Tregs). The possible role of "danger signals" or "alarm signals" in the development of inhibitors in hemophilia patients has stimulated a large body of research.[112] Investigations in hemophilic mice, and clinical observations in hemophilia A patients challenge the danger signal hypothesis, as discussed below in the section Treatment-Related and Modifiable Risk Factors in Hemophilia A. Recent evidence highlights the role of counteractive tolerogenic responses and not "danger signals" per se in inhibitor development.[113]

Tregs that suppress the activity of helper T cells may determine whether an individual patient will be immunologically reactive or

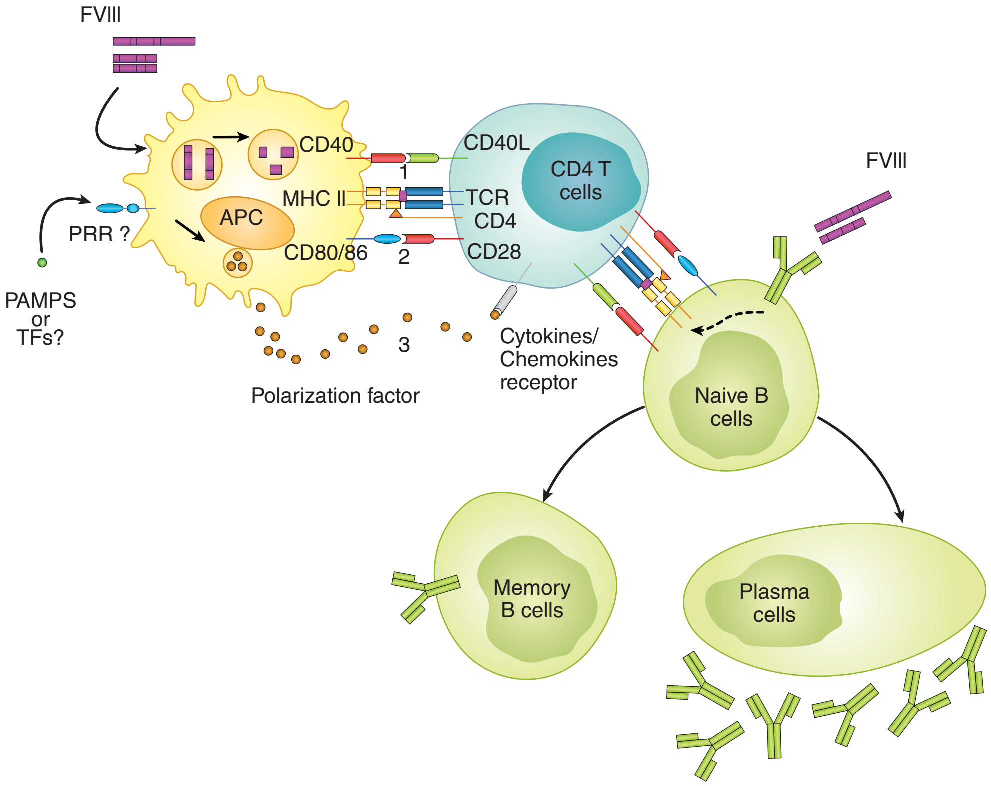

Figure 134.13 DEVELOPMENT OF FACTOR VIII (FVIII) INHIBITORS. The process starts with antigen presenting cells (APCs), which endocytose FVIII. The engulfed FVIII is processed into peptides and presented on the surface of the APC along with MHC class II molecules to CD4$^+$ T cells in the spleen and lymph nodes. Co-stimulatory signals (such as cytokines) are required for full activation of naive T cells capable of binding FVIII epitopes. T cells migrate and activate naive B cells, which undergo class switching and differentiate into FVIII-specific memory B cells or plasma cells that produce anti-FVIII antibodies.

tolerant to FVIII. T-cell proliferation in response to FVIII stimulation has been observed in Treg-depleted peripheral blood from normal (nonhemophiliac) human subjects.[99] Hemophilia A mice had lower inhibitor titers in response to FVIII when co-infused with Tregs taken from wild-type mice.[114] These observations are consistent with a role for Tregs in determining the immunologic response of hemophilia A patients to exogenous FVIII, and in tolerance to FVIII in normal individuals.[115]

FVIII inhibitors in patients with hemophilia A are predominantly of the IgG1 and IgG4 subclasses. Longitudinal analysis of the characteristics of total FVIII-binding antibody in PUPs exposed to FVIII confirms the results of previous studies and shows that high-affinity IgG1 antibodies appear first, followed by IgG3 and IgG4 anti-FVIII antibodies in patients who developed high titer inhibitors.[116]

FVIII epitopes for inhibitory antibodies have been identified in several locations in the FVIII molecule: for example, in a site in the A2 domain that is involved in the function of the tenase complex; in the FIX-binding site in the A3 domain; and in the phospholipid-binding and VWF-binding sites in the C2 domain.[116–118] The localization of these epitopes to functionally important regions of the FVIII molecule explains why these antibodies inhibit the coagulant activity of FVIII. In contrast, antibodies directed against the non-functional B domain do not appear to have inhibitory activity.

Inhibitors may be classified by the kinetics of their in vitro ability to inactivate FVIII. *Type I* inhibitors are characterized by a linear relationship between the antibody concentration and the logarithm of the residual FVIII activity; at high antibody concentrations, the inhibition of FVIII is near total. FVIII inhibitors in patients with congenital hemophilia A usually have type I kinetics. Inhibitors with *type II* kinetics do not display a linear relationship, and even high antibody concentrations do not result in complete inhibition of FVIII activity in vitro. Type II inhibitors are commonly found in acquired hemophilia A.[98] Whether an inhibitor has Type I or Type II kinetics may depend on the epitopes targeted, which could explain why antibodies with Type II kinetics are more common in acquired hemophilia A where antibodies tend to be oligoclonal and directed against epitopes less likely to result in Type I kinetics.

Other Immune Responses to FVIII

Several other immunologic reactions to FVIII are possible. These include *anaphylactic reactions*, *catalytic antibodies*, and *non-neutralizing antibodies* (NNAs). Except for anaphylactic reactions, which are of obvious importance, the clinical significance of other reactions is not clear.

Anaphylactic Reactions

Anaphylactic reactions (type 1 hypersensitivity reactions) to FVIII are rare and vary in severity. Such reactions have been reported in association with infusion of both plasma-derived and recombinant FVIII concentrates.119 Interestingly, evidence of IgE mediation is not a universal finding suggesting that some reactions may be mediated by complement activation, immune complexes, or through other mechanisms or that the trigger may be an excipient in these products, and not the FVIII.120

Because of the rarity of anaphylactic reactions to FVIII, their optimal management is unclear. Acutely, the usual supportive care for anaphylaxis should be provided. Subsequent exposures to FVIII-containing products should be attempted with caution, and with consideration of pre-medication.

The association of anaphylactic reactions to FVIII with inhibitor development is not clear. This contrasts with the situation in hemophilia B, in which anaphylaxis to FIX concentrates is often associated with inhibitor development. The reasons for these differences are unknown. It is possible that distribution of FIX to extravascular tissues is more likely to provoke such a reaction than intravascular distribution of FVIII. It is also possible that therapeutic doses of FIX, which contain more protein than therapeutic doses of FVIII, are a more potent stimulus for anaphylaxis.

Non-neutralizing Antibodies

Some antibodies to FVIII do not affect coagulant activity because they are directed against non-functional epitopes. These NNAs are detectable with ELISA but not with the Bethesda assay. NNAs to FVIII have been reported in approximately 15% to 30% of patients and can occur with any disease severity.[121] NNAs against FVIII may also be detected in healthy individuals. It has been proposed that NNAs in persons with hemophilia, particularly those of high titer, accelerate clearance, thereby shortening the half-life of infused factor, but this has not been a consistent finding.[122]

There are many unanswered but important questions about NNAs, not least of which is the issue of their proposed ability to alter the kinetics of infused factor and the clinical importance of this phenomenon. It is also unknown whether NNAs are a predictor or precursor of neutralizing antibodies (i.e., inhibitors) in some patients. In patients who have undergone immune tolerance induction (ITI; discussed later), it is not known whether persistent NNAs should be considered a form of failure of ITI, or whether persistence predicts a risk of inhibitor recurrence.[116]

Epidemiology

The reported incidence and prevalence of FVIII inhibitors in hemophilia A patients vary widely depending on the patient population studied, frequency of testing, and sensitivity of inhibitor assay.

A systematic review[123] that included several studies of PUPs estimated that the cumulative incidence of inhibitors varied from 0% to 39%. In PUPs with severe hemophilia A, the average inhibitor incidence was 23.1%, which is consistent with more recent estimates from large studies.[20,68,124] Patients with severe hemophilia A who develop FVIII inhibitors are most likely to do so early in the course of their treatment: inhibitor detection has been reported after a median of 9 to 36 EDs, and the incidence of inhibitor development plateaus at 50 EDs.[68,123]

In the same systematic review, the incidence of inhibitor development in persons with moderate hemophilia A was 7.9%. More recent data on mild/moderate hemophilia A patients with at least 100 EDs found an incidence of 13%, suggesting that inhibitors occur later in patients with non-severe hemophilia A, in one report at a median age of approximately 50 years and after a median of 30 EDs with a substantial proportion occurring between 50 and 100 EDs.[95]

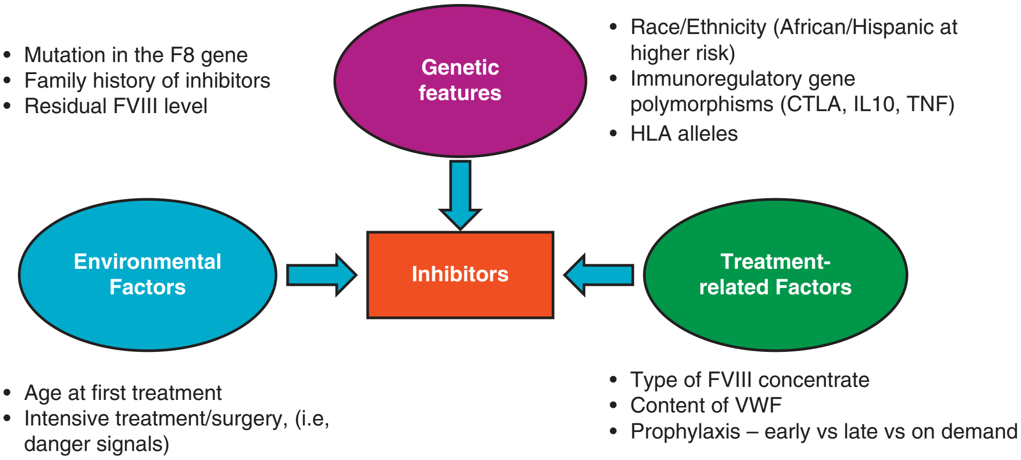
Genetic (Non-Modifiable) Risk Factors for Inhibitor Development in Hemophilia A (Fig. 134.14)

F8 genotype, which correlates with hemophilia severity, is the most important risk factor for FVIII inhibitors, with large deletions, nonsense mutations, and inversions of introns 1 and 22 associated with a higher risk than missense mutations. Even in mild/moderate hemophilia A, certain mutations in the A3 and C2 domains in the FVIII light chain confer an increased risk of inhibitor development, consistent with the observation that inhibitors are frequently directed against epitopes in these domains.[25]

Several other genetic loci also influence inhibitor risk, including polymorphisms in *TNF, CTLA4, IL10*, and *FCGR2A*. Some MHC II alleles may be involved as well. Ethnicity (African American or Hispanic) and a family history of inhibitors are also associated with increased inhibitor risk, supporting the concept of genetic determinants of risk.

Treatment-Related and Modifiable Risk Factors

How patients are treated may also influence inhibitor risk. Younger age at first FVIII exposure had been thought to be associated with increasing risk but this was likely due to the confounding effect of intense treatment at first exposure, which is itself a risk factor.[68,69]



Mutation in the F8 gene
Family history of inhibitors
Residual FVIII level
Genetic features
Race/Ethnicity (African/Hispanic at higher risk)
Immunoregulatory gene polymorphisms (CTLA, IL10, TNF)
HLA alleles
Environmental Factors
Inhibitors
Treatment-related Factors
Age at first treatment
Intensive treatment/surgery, (i.e, danger signals)
Type of FVIII concentrate
Content of VWF
Prophylaxis – early vs late vs on demand

Figure 134.14 RISK FACTORS FOR THE DEVELOPMENT OF INHIBITORS IN HEMOPHILIA A. *FVIII*, Factor VIII; *VWF*, von Willebrand factor.

There is some evidence that administering FVIII in a non-inflammatory state, that is, in a prophylactic setting, may reduce inhibitor development in contrast to administering it in the setting of a bleed.[68] This effect may be most pronounced in patients with low-risk *F8* mutations while it may have little or no impact in those with high-risk F8 mutations.[69] The role of prophylaxis in reducing inhibitor development may be related to its associated reduction in the need for intense exposure to FVIII for treatment of bleeds, intense exposure being defined as exposure to FVIII on 3 or more consecutive days.[69]

Avoidance of exposure to FVIII with other antigens, particularly antigens in adjuvant containing childhood vaccines, has been proposed to decrease risk.[125,126] More recent data suggests that this is not the case. In a hemophilia A mouse model, concurrent exposure to FVIII and influenza vaccine antigens results in competition for the immune system's "attention" between the antigens and results in no increase in inhibitor development.[127] Likewise, the PedNet group reported no increase in the risk of inhibitor development when routine childhood vaccines were given in close temporal proximity to FVIII.[128]

A prospective cohort study designed to test the hypothesis that starting low-frequency FVIII prophylaxis early would reduce the risk of inhibitor development by minimizing danger signals was stopped early because 42.1% of patients developed inhibitors.[129]

Surgery has been associated with inhibitor development, both in general[130] and when it represents the first exposure to FVIII.[68] In a meta-analysis of observational studies, the increased risk of inhibitor development associated with surgery was independent of the risk associated with the intensity of FVIII treatment.[130] Minor surgery, such as CVAD placement, may confer less risk than major surgery.[68]

Continuous infusion of FVIII independent of intensity of exposure to FVIII has also been suggested as a risk factor in the setting of mild/moderate hemophilia.[90]

Although these observations provide some support for the "danger signal" hypothesis of immunogenicity, epidemiological data suggest a more complex pathogenesis. Chronic inflammation associated with recurrent bleeding as well as acute hemarthrosis after knee injury in FVIII-deficient mice failed to increase the immune response to exogenous FVIII.[131] Overall, recent data suggest that the FVIII-specific immune response reflects the immune system's inability to develop a suppressive antigen-specific tolerogenic response, rather than excessive activation of the immune system in response to FVIII administration.[113,132]

The rate of inhibitor development has generally been assumed to be similar among the various plasma-derived and recombinant products. The results of some studies challenge this concept. The Study on Inhibitors in Plasma-Product Exposed Toddlers (SIPPET) study, a randomized comparison of inhibitor incidence across several brands of rFVIII and several VWF containing pdFVIII concentrates in PUPs, found a 1.87-fold increase in the incidence of inhibitors in patients treated with rFVIII.[20] This effect was particularly pronounced in patients with *F8* mutations predicted to result in a low risk of inhibitors, in whom the use of pdFVIII virtually eliminated the occurrence of inhibitors. Other studies however, including the PedNet study, found no significant difference in inhibitor development between plasma-derived and recombinant FVIII concentrates. However, the PedNet group and several others reported a higher rate of inhibitor development with a second-generation recombinant FVIII than with a third-generation recombinant FVIII.[20,124] The mechanistic underpinnings of these observations are not understood. Although the findings of these observational studies have been questioned, the results resulted in greater use of plasma-derived FVIII and reduced use of the second-generation recombinant FVIII product. With the current switch to EHL FVIIIs and emicizumab, the potential ramifications of these earlier studies have lessened.

While most rFVIII products have been manufactured using non-human mammalian cells (BHK or CHO cells), two rFVIII products (a SHL product—Nuwiq and an EHL product—FVIII-Fc [Eloctate/Elocta]) are manufactured in a human cell line (HEK293) and therefore bear "human-like" post-translational modifications, which could reduce the risk of inhibitor development. Although the pivotal PUP studies with these products reported a slightly lower rate of high titer inhibitors than that observed with rFVIII expressed in non-human cells, the differences were not statistically significant.[133] (See box on Choosing A Factor Concentrate for PUPs with Severe Hemophilia A to Minimize Inhibitor Risk.)

MANAGEMENT OF INHIBITORS IN HEMOPHILIA A

There are several management considerations in patients with FVIII inhibitors. These include the management of bleeds or surgery, the delivery of effective prophylaxis, and the initiation of an inhibitor elimination strategy. In the past few years with the introduction of emicizumab much has changed about the management of patients with inhibitors to FVIII.

Treatment of Bleeds

Patients with low titer inhibitors (<5 BU) can often be treated with FVIII using conventional doses, or more commonly, higher doses. Those with high titer inhibitors (≥5 BU) will not respond to typical factor replacement and require a "bypassing agent"—activated prothrombin complex concentrate (aPCC) or recombinant activated factor VII (rFVIIa).

aPCC is a plasma-derived product that contains factors II, VII, IX, and X, as well as the activated forms of these factors. The efficacy of aPCC for treatment of bleeds and for provision of effective hemostasis during surgical procedures has been established in patients with FVIII inhibitors.[134,135] Typical dosing is 85 IU/kg, given in a schedule

CHOOSING A FACTOR CONCENTRATE FOR PREVIOUSLY UNTREATED PATIENTS WITH SEVERE HEMOPHILIA A TO MINIMIZE INHIBITOR RISK

The choice of FVIII concentrate for a patient with severe hemophilia A is one of the most important medical decisions made for patients. There are several factors that can go into this decision, including the FVIII products that are available, the knowledge and comfort that the prescribing clinician has with those products, the pharmacokinetic properties of the FVIII (SHL vs. EHL), and patient/family preference.

It is uncertain whether the choice of FVIII affects the risk of inhibitor development. There are studies that support and studies that refute the premise that plasma-derived VWF-containing FVIII concentrates are associated with less inhibitor development. There are however no studies suggesting a higher rate of inhibitor development with plasma-derived FVIII. Even if plasma-derived FVIII concentrates were conclusively shown to have a lower incidence of inhibitor development some patients, particularly those in families impacted by HIV and hepatitis C infection, may not be comfortable with pdFVIII concentrates; many clinicians likely share this discomfort.

There is hope that EHL rFVIII being “shielded” by linkage to Fc or PEG may be associated with a lower risk of inhibitor development than “older” rFVIII products. This possibility requires confirmation in a comparative study. As a randomized comparison is unlikely to occur, the community will need to wait for large population-level data from adverse events surveillance programs to determine this.

With availability of emicizumab, PUPs are likely to start on it at an early age so that their exposure to FVIII will be limited to treatment of bleeds or surgery. Having a FVIII that results in less inhibitor development would be of crucial importance in such patients.

dependent on the clinical situation: in general, no more than every 6 to 8 hours. aPCC contains trace amounts of FVIII that can be sufficient to trigger an anamnestic response in patients with FVIII inhibitors; for this reason, clinicians avoid aPCC until the inhibitor titer has decreased (see below).

rFVIIa activates FX through the extrinsic pathway without the need for FVIII. For treatment of acute bleeds in patients with FVIII inhibitors, rFVIIa has been shown to be effective at a dose of 90 μg/kg; repeated doses may be required because the half-life of rFVIIa is only about 2 hours.[136] A single higher dose of 270 μg/kg is equally effective and safe and requires less frequent intravenous access, so this may be considered for bleeds that are anticipated to require more aggressive management, such as bleeding into target joints.[137] rFVIIa provides effective hemostasis during surgery.[138] Although rFVIIa has been administered by continuous infusion, bolus doses are preferred to generate bursts of thrombin (see Chapter 125).

Patients with high titer inhibitors not on emicizumab can be treated with either aPCC or rFVIIa. A randomized crossover comparison of rFVIIa and aPCC demonstrated similar overall efficacy in controlling acute joint bleeds with the two products, but their effectiveness was rated differently by approximately 30% of patients.[134] Currently, no laboratory test has been shown to predict clinical response to these agents. The choice of product for a particular patient, then, is a matter of clinical judgment, patient preference, trial-and-error, and their safety when given to patients on emicizumab.

For patients with severe or refractory bleeding, simultaneous or sequential use of rFVIIa and aPCC can be considered. However, there is a risk of serious thrombotic complications with this approach, even in younger patients. This risk may reflect the accumulation of aPCC components with long half-lives (such as FX or prothrombin) or potentiation of the effects of rFVIIa by aPCC components.[139] Combination therapy should be reserved, therefore, for severe or life-threatening bleeds for which single-agent therapy is insufficient.

Antifibrinolytics (epsilon-aminocaproic acid or tranexamic acid) may be useful adjuncts to bypassing agents, for management of bleeds or in the context of surgery.[140] Anti-fibrinolytics are thought to be safe in combination with rFVIIa, but their safety in combination with aPCC is less certain.[141]

Plasma-derived porcine FVIII, which can evade FVIII inhibitors because it lacks key epitopes against which antibodies are directed, was used in the past. A recombinant porcine FVIII concentrate (Obizur, Takeda) is now available. Although originally developed for use in acquired hemophilia A, there are reports of its successful use in patients with congenital hemophilia A with inhibitors. The plasma-derived porcine FVIII concentrate is no longer available because of adverse reactions such as thrombocytopenia and allergy, and concerns about potential infectious contaminants.

Prophylaxis in Patients With Inhibitors to FVIII

For patients with severe hemophilia without inhibitors, prophylactic therapy is the standard of care.[37] However, for patients with inhibitors, particularly high-titer inhibitors, prophylaxis with conventional doses of FVIII or FIX concentrates is ineffective. Until recently, prophylaxis for such patients relied on bypassing agents (rFVIIa or aPCC). Although effective for prophylaxis in this setting, they are less effective than prophylaxis with clotting factor replacement in patients without inhibitors.[142,143] Consequently, rFVIIa and aPCC have been supplanted by emicizumab.

Emicizumab provides effective prophylaxis against bleeding in patients with inhibitors and is superior to bypassing agents (HAVEN 1, 2). The effectiveness of emicizumab for prophylaxis in young children with inhibitors (HAVEN 2) was dramatic; 77% of children treated with emicizumab experienced no bleeding, and there was a 99% reduction in the annualized bleeding rate in 15 children who had previously been receiving bypassing agent prophylaxis.[79]

The superior prophylaxis provided by emicizumab and its convenience of administration have rendered it the preferred therapy for patients with high titer inhibitors.

Patients with inhibitors taking emicizumab can have breakthrough bleeds. Such bleeds need to be treated with bypassing agents. Although rFVIIa appears to be safe in this setting, venous thromboembolism and thrombotic microangiopathy (TMA) have been reported with aPCC, particularly if the daily dose of aPCC exceeds100 U/kg or if it is given for more than one day. This prompted an FDA black box warning against the use of aPCC in patients taking emicizumab except for those with life-threatening conditions where close clinical monitoring and low doses of aPCC are recommended.

Eradication of Inhibitors in Hemophilia A (ITI)

When a patient develops a FVIII inhibitor, he, his family, and their clinician must decide whether to attempt eradication with ITI therapy. In the past, the decision to undertake ITI was relatively straightforward because without it, patients would remain inhibitor positive resulting in increased morbidity and mortality and a significantly increased cost of care. The decision is less straightforward now that emicizumab is available.

ITI, which consists of regular and frequent administration of high doses of replacement factor concentrate, is the basic therapeutic strategy for eliminating inhibitory antibodies. In addition to factor concentrates, ITI regimens may include immunosuppressive agents or procedures such as plasmapheresis to deplete existing antibodies. ITI regimens (Bonn, Malmo, Dutch, high dose, low dose) vary with respect to the intensity and frequency of FVIII exposure and in the use and choice of concomitant immune suppression (in particular, rituximab).[144,145]

For patients (especially young children), the burden of frequent (usually daily) intravenous infusion of factor for a year or longer is considerable and for healthcare systems, the cost of ITI is enormous. CVADs are essential for undertaking ITI in young children. Despite the drawbacks of ITI, it is recommended over the alternative of allowing a child to remain with an inhibitor life-long.

The need for ITI is less clear now that emicizumab is available. Patients unlikely to respond to ITI such as those with very high inhibitor titers, those who failed to respond to previous attempts at ITI, or those unable to tolerate frequent doses of replacement therapy, may elect to take emicizumab instead of undergoing ITI. However, even with emicizumab, there may be benefits of ITI because, if successful, it allows the use of FVIII to treat breakthrough bleeds instead of rFVIIa, and it enhances access to trials of gene therapy. Finally, it is hypothesized that regular FVIII exposure may improve bone health.[146] Even if ITI is chosen, most patients are likely to be given concomitant emicizumab because it enables less intensive ITI regimens (i.e., non-daily) which reduces the need for CVADs. The use of ITI in conjunction with emicizumab is still being investigated for safety and efficacy.[147,148]

Low titer inhibitors (i.e., <5 BU) may resolve spontaneously, with or without continued exposure to FVIII. Patients with low titer inhibitors may be observed, and treatment to eliminate the inhibitor initiated only if the inhibitor titer increases. Patients with low titer inhibitors should still have a planned strategy for treating breakthrough bleeding and consideration should be given to prophylaxis.

The mechanisms through which ITI eradicates FVIII inhibitors are largely unknown. The relative proportions of different IgG subclasses may change with ITI, and the disappearance of anti-FVIII IgG4 is associated with success.[149] In a mouse model of hemophilia A, exposure to high concentrations of FVIII prevents FVIII-specific memory B cells from differentiating into antibody-secreting plasma cells in a T-cell-independent manner. Inhibition of B-cell differentiation involves caspase activation, suggesting that FVIII induces memory B cells to undergo apoptosis.[150] If these findings are correct, ITI is likely to be most successful if started soon after inhibitor development. However, even after successful ITI, some patients have residual anti-FVIII antibodies detectable by ELISA and FVIII-reactive T cells. Anti-idiotypic antibodies that neutralize anti-FVIII antibodies may account for the reduced FVIII inhibition[151,152] and emergence of T and B regulatory cells may restore tolerance to FVIII.[153]

Typically, ITI is considered successful if the patient has no detectable inhibitor by Bethesda assay (≤0.6 BU) and if infused FVIII displays normal pharmacokinetics (recovery and half-life).[144] The overall success rate of ITI ranges from 60% to 80%.[154] Several patient-related and treatment-related factors predict the success of ITI. The most important patient-related factor is the peak Bethesda inhibitor titer (prior to ITI); the lower the peak titer, the greater the chance of success with ITI. A low peak Bethesda titer during ITI may also predict success. Although a low Bethesda titer (<10 BU) at the start of ITI has been found to be a good predictor of ITI success this does not necessarily imply that clinicians should wait to start ITI until the inhibitor titer drops to less than 10 BU in those patients who develop peak titers of greater than 10 BU pre-ITI. A short interval between the detection of an inhibitor and initiation of ITI also increases the likelihood of success; consequently, some clinicians start ITI early, even if the inhibitor titer is greater than 10 BU.

The nature of the *F8* mutation may be an important predictor of ITI success. Missense mutations and small deletions and insertions confer a greater chance of success than large deletions, inversions, splice site mutations, or nonsense mutations.[155] Patient ethnicity may play a role; African ancestry is associated not only with a higher risk of inhibitor development but also with reduced rates of successful ITI.[156]

The influence of FVIII dose on ITI success is controversial. In the International ITI trial which randomized patients with “good risk” features to a high-dose regimen (200 IU/kg daily) or a lower-dose regimen (50 IU/kg given three times per week), the overall success rate was similar between the two regimens but the response was more rapid with the high-dose regimen.[144] This trial was stopped early because there were more bleeds with the low-dose regimen. Therefore, high-dose ITI regimens have been preferred both in patients with and without good risk features for ITI success.

Given the expense of FVIII concentrates, there is interest in low-dose ITI regimens that are not only more affordable but may be sufficient to prevent breakthrough bleeds in patients taking concomitant emicizumab.[157]

Some experts speculate that plasma-derived concentrates that contain VWF or EHL FVIII concentrates may be more effective for ITI, particularly for patients who have failed to respond to ITI with other products or who have poor risk features for successful ITI. This speculation is based on the concept that FVIII in these products is shielded by binding to VWF or by linkage to Fc or by PEGylation.[158,159] In addition, the Fc component of rFVIII-Fc may have antigen-specific effects on T cells and B cells.[160–162] Despite such speculation, there is no conclusive evidence that some products are better than others for ITI.

Rituximab (monoclonal anti-CD20, a B cell-depleting antibody) has been used successfully in conjunction with FVIII in patients with inhibitors refractory to conventional ITI.[145] Other immunosuppressive agents can also be considered, but their utility is uncertain.[147]

ITI fails in 20% to 40% of patients at first attempt, and even if successful, up to 30% of patients will show a recurrence of their inhibitor.[163] Although repeated course of ITI, addition of immunosuppressive agents, or changes in the FVIII product were used in such patients, these are rarely needed now that effective prophylaxis for patients with inhibitors is enabled with emicizumab.

The preceding discussion primarily applies to patients with severe hemophilia A. The situation is quite different for patients with moderate or mild disease who develop inhibitors. Many such patients will experience a spontaneous remission of their inhibitor without specific therapy. Other patients may require treatment to eliminate the inhibitor, but there is no clear advantage of ITI over a variety of immunosuppressive therapies. Eradication of inhibitors in patients with mild or moderate disease may be beneficial if the inhibitor is of sufficient titer to increase the risk of bleeding. However, as with severe hemophilia A the likelihood of undertaking ITI in mild/moderate hemophilia is lessened with emicizumab.

Prophylaxis of Patients During Immune Tolerance Induction

Patients who are receiving FVIII for ITI are in essence receiving a form of prophylactic therapy. This was seen in the International ITI study where patients receiving high-dose ITI (larger and more frequent doses of FVIII) experienced fewer bleeds than those placed on the low-dose regimen. This is suggestive of some short-lived protective activity of FVIII.[144] Although high titer inhibitors should theoretically inactivate even high doses of FVIII, there may be a short period of time before complete neutralization by antibodies which may be helpful to shut down bleeding that may have commenced.

However, many patients on ITI, particularly when their inhibitor titer remains high, continue to bleed. In the past, such patients were often put on bypassing agent prophylaxis. Given the cost, inconvenience, and limited effectiveness of prophylaxis with bypassing agents, emicizumab has taken over and it can be argued that all patients with inhibitors should now receive emicizumab whether they are on ITI or not.[164,165] If emicizumab and ITI are used together, a low-dose ITI regimen may suffice.[164] In patients who are tolerized after ITI, the duration of or the need for ongoing exposure to FVIII to prevent recurrent inhibitor formation is uncertain.[166]

INHIBITORS IN HEMOPHILIA B

Pathophysiology

Severe hemophilia B is less common than severe hemophilia A and a lower percentage of hemophilia B patients develop inhibitors. Therefore, less is known about FIX inhibitors than FVIII inhibitors.

Epitopes for FIX inhibitors have been identified in the γ-carboxyglutamic acid domain, the serine protease domain, and in the activation peptide region, where FIX is activated by FXIa (see Fig. 134.5). As is the case with inhibitory FVIII antibodies, the specificity of these antibodies for epitopes in functionally important regions of the FIX molecule explains their ability to inhibit FIX coagulant activity.

Because FIX inhibitors are antibodies of the IgG subclass (mainly IgG4), they are products of interaction between FIX-specific B cells and helper T cells. The contributions of co-stimulatory molecules, immunoregulatory genes, and Tregs to the pathogenesis of FIX inhibitors is unknown.

Epidemiology and Risk Factors for Inhibitor Development in Hemophilia B

The overall incidence of inhibitors in hemophilia B is between 3% and 5%. However, in a cohort of 154 severe hemophilia B patients, the PedNet network recently reported a cumulative inhibitor incidence at 75 EDs of 9.3% for all inhibitors and 5% for high-titer inhibitors.[167] Although the incidence in this cohort is higher than previously reported, the incidence of inhibitors in hemophilia B is still approximately one-quarter of that in hemophilia A.

Most patients (50% to 70%) who develop inhibitors develop high titer inhibitors and 50% or more of these exhibit allergic reactions to FIX products.[168] Because anaphylaxis may be the first manifestation of an inhibitor in patients with hemophilia B, it is recommended that the first 10 to 20 doses of FIX replacement be given in a medical facility where the patient can be observed. This is particularly important for patients with severe hemophilia B associated with FIX null mutations (large deletions or nonsense mutations) because they are at highest risk of inhibitor development (risk of 25% to 40%). In contrast, very few patients with severe hemophilia caused by missense mutations and virtually no patients with mild or moderate hemophilia develop inhibitors.[167,169]

The high proportion of missense mutations in patients with hemophilia B, which result in measurable amounts of FIX antigen, likely explains the lower risk of inhibitor formation compared with hemophilia A.[170] In addition, the sequence homology between FIX and other vitamin K dependent clotting factors may contribute to the diminished risk.

A family history of inhibitor development is a risk factor in hemophilia B; this is likely related to the underlying high-risk mutations in such families but could be associated with co-inheritance of other immunological determinants relevant to the immune response such as HLA alleles.

No significant associations between inhibitor development and treatment-related factors, such as type of FIX product, intensity of FIX exposure, or surgery, has been demonstrated to date.

Clinical Manifestations

The presence of an inhibitor should be suspected if the response to replacement therapy is less than expected. The morbidity with inhibitors in hemophilia B includes anaphylaxis, uncontrollable bleeding, and nephrotic syndrome, which can occur in combination. Allergic reactions can occur in up to 50% of patients with inhibitors.[28] Nephrotic syndrome, which occurs most frequently during ITI in patients with a history of allergic reactions to FIX, may not respond to corticosteroids, thereby necessitating the interruption of ITI.[171]

MANAGEMENT OF INHIBITORS IN HEMOPHILIA B

The goals of treatment of patients with hemophilia B and inhibitors are to prevent and treat bleeds and eradicate the inhibitor.

For treatment of bleeds, FIX concentrates can be used in patients with low-titer inhibitors without an allergic phenotype. It is unknown whether EHL FIX concentrates are more effective than SHL concentrates in this setting. Patients with high titer inhibitors require treatment with bypassing agents (aPCC or rFVIIa) for prevention and treatment of bleeds. Although aPCC and rFVIIa are equally effective and associated with a low risk of adverse events, the use of rFVIIa is preferred because the presence of FIX in aPCC may trigger allergic reactions or increase the titer of the inhibitor through induction of an anamnestic response.

Eradication of Inhibitors in Hemophilia B

Patients with hemophilia B and inhibitors are at higher risk for the development of life-threatening bleeding and severe arthropathy mainly because such patients do not benefit from conventional prophylaxis with FIX replacement therapy and prophylaxis with bypassing agents is less effective and less convenient. Furthermore, emicizumab (a FVIII mimetic) is not an option for such patients. Until rebalancing therapies are available, ITI remains an important part of management of high-titer inhibitors.

The experience with ITI in hemophilia B is limited to case series and case reports. ITI without immunosuppressive therapy is less effective in hemophilia B than it is in hemophilia A. In the North American Immune Tolerance Registry, the success rate of ITI in patients with hemophilia B was only 31%, and adverse reactions to therapy (including allergic reactions and nephrotic syndrome) were 10 times more frequent in hemophilia B than in hemophilia A.[172] Consequently, when ITI is considered in hemophilia B, concomitant immunosuppressive therapy is usually given with rituximab, cyclosporine A, or mycophenolate mofetil or some combinations of these.[173,174]

Because of the poor success rate with ITI and the potential complications, the decision to undertake it must be made with caution. If it is undertaken, the dose of FIX needs to be increased gradually with monitoring for allergic reactions and nephrotic syndrome. A recent report suggests that up to 50% of inhibitors to FIX can be eradicated particularly if concomitant immunosuppressive therapy is given.[174]

GENE THERAPY FOR HEMOPHILIA

Since the cloning of the *F8* and *F9* genes in the early 1980s, hemophilia has been a leading candidate for the application of gene therapy. The rationale for gene therapy in hemophilia includes the following: even small increments in FVIII or FIX levels are of clinical benefit; regulation of FVIII or FIX levels is not critical as long as they do not reach supra-physiologic levels for extended periods of time; the site of coagulation transgene expression does not need to be restricted provided that sufficient amounts of the protein enter the circulation; and animal models of hemophilia are available for preclinical evaluation of gene transfer approaches.

Modes of Transgene Delivery

The overall concept of gene therapy or gene transfer is quite simple—a normal functioning gene is delivered into host cells where the gene is then expressed, and the missing protein is produced. A key component of any gene transfer strategy is the development of a delivery system that enables efficient transfer of the therapeutic transgene into the recipient cell of choice. After 40 years of investigation, viral vectors remain the most effective means of achieving high-level gene transfer. Despite efforts to enhance the efficiency of non-viral delivery methods such as lipid encapsulation, use of physicochemical conjugates, or hydrodynamic injection, these approaches still have limitations that preclude their advancement. Development of lipid envelopes or nanoparticles has enabled successful RNA delivery to the cell cytoplasm, but methods to deliver therapeutic amounts of DNA to the nucleus remain elusive.

Hemophilia gene transfer studies have used two main types of viral vectors to deliver the gene into the host: retroviruses and adeno-associated viruses (AAV) (Table 134.10). A single hemophilia A patient treated with an adenoviral vector experienced significant hematological toxicity from a well-recognized innate immune response to adenovirus, and no further clinical studies have been undertaken with this vector type.[175]

Initial retroviral studies were performed with replication-defective γ-retroviral vectors, and one human clinical study in hemophilia A also used this vector system. The major problem with these vectors is the requirement for recipient cell replication to facilitate nuclear entry of the vector. In contrast, lentiviral vectors are equally capable of transducing both post-mitotic and replicating cells (see Table 134.10). For this reason, more recent studies have used lentiviral vector

TABLE 134.10 Comparison of Adeno-Associated Virus and Lentivirus Gene Therapies for Hemophilia

	AAV	Lentivirus
Size	~25 nm	~80–100 nm
Packaging capacity	~4.7 kb (ssDNA)	9 kb (ssRNA)
Transduction	Dividing and non-dividing cells[a]	Dividing and non-dividing cells
Integration	Primarily episomal, small % integrates, large absolute numbers[b]	Integrating near active transcription sites
Expression	Years if host immunity controlled	Lifelong
Immunogenicity	High humoral and T-cell responses	Humoral; strong innate responses
Manufacturing	Trial and commercial scale up achieved	Scale up for in vivo difficult
Clinical use	Intravenous delivery underway	Ex vivo and intravenous delivery planned
Pre-existing immunity	Widespread with most AAV serotypes (~50% in adults)	Very low
Use in children	Not likely to be durable due to liver growth and loss of episomes	Yes
Repeat dosing	No	No
Toxicities	Transaminitis, complement activation (may be serotype dependent), risk of insertional mutagenesis	Risk of insertional mutagenesis, oncogenesis

[a] Serotype-dependent.
[b] At total doses of 1E14–E16, 0.1%–1.0% integration results in millions of events per liver.
AAV, Adeno-associated virus.

protocols in which the vector construct is usually derived from elements of the HIV virus. The other major difference between lentiviral gene delivery and gene transfer with other viral vectors is that lentiviruses integrate their genome into the recipient cell genome as a natural part of their life cycle.[176] Although viral vectors do not possess the structural components that enable further rounds of viral replication, there is a risk of insertional mutagenesis, which can trigger activation of adjacent oncogenes or inactivation of tumor suppressor loci. Studies performed in the past 15 years indicate that lentiviral integrations are not random but tend to cluster in transcriptionally active sites and more often occur within introns and coding regions of genes rather than in the upstream regulatory regions where γ-retroviruses insert. Therapeutic levels of FVIII and FIX have been achieved in hemophilic dogs and in non-human primates after in vivo delivery, where lentiviral vectors localize largely in the liver.[177] Lentiviral vectors delivering the *F8* gene also have been utilized ex vivo in hematopoietic stem cells, where, depending on the specificity of the promoter, they may induce FVIII production in specific hematopoietic lineages. Autologous hematopoietic stem cells are mobilized, removed from the patient, transduced with the vector, and grown in sufficient quantities to reinfuse into the patient after at least partial bone marrow ablation to make room for the modified cells. This procedure has been pioneered for management of cancer and more recently in gene therapy for hemoglobinopathies, but carries significant morbidity risks due to partial bone marrow ablation. Both ex vivo and in vivo delivery of lentivirus delivering coagulation genes are expected to enter the clinic shortly. Lentiviral vectors are challenging to scale up and produce in sufficient quantities for in vivo delivery.[178]

Currently, the lead candidates for hemophilia gene transfer are various AAV serotypes. AAV is a small, non-pathogenic, human parvovirus with a small, single-stranded DNA genome of approximately 4.8 kb (see Table 134.10). Infection in humans, which for some serotypes of the virus is frequent, is not associated with clinical disease. Wild-type AAV requires a helper virus, usually adenoviruses or herpesviruses, to establish an infection in the host, as it borrows machinery from both the host and the replication competent viruses to replicate. For use in gene therapy, wild-type AAV genomes are exchanged for a construct of the therapeutic transgene and associated regulatory elements. The various serotypes of AAV have distinct tissue tropisms based upon specific cell surface receptor interactions, but much of the specificity is achieved by tissue or cell specific promoters and/or local administration. When administered intravenously, all serotypes localize predominantly in the liver due to the volume of blood that passes through the liver and the well-recognized fenestrated vessels that permit ready exchange between hepatocytes and the circulation. Several serotypes have been used in successful hemophilia clinical trials to produce subnormal to normal levels of circulating FVIII or FIX.

Upon receptor-mediated entry into recipient cells, AAV is trafficked through endosomes.[179] Some escape and enter the nucleus via an unidentified pathway, where the viral capsid is removed and single stranded DNA forms double-stranded DNA via second strand synthesis and annealing of positive and negative strands. Over time, the inverted terminal repeats (ITRs) flanking both ends of the transgene form circular extrachromosomal stable episomes, which in turn, form repeating episomal units, termed concatemers within the nucleus. These are stable in non-dividing cells but may be lost during cell division.

A small proportion of the virus integrates into the recipient genome at transcriptionally active sites.[180] Since $1E^{12}$-$6E^{13}$ vector genomes/kg are administered to achieve therapeutic effects in hemophilia, even a small number of insertions in the liver or other organs represents a large number, and a theoretical concern for oncogenesis. Although insertional mutagenesis may pose a risk of hepatocellular carcinoma, this has not been seen in large animal models of hemophilia or in patients but has been seen in various mouse strains. A limitation of AAV vectors is their small packaging capacity. Although this is not a problem for *F9* (cDNA ≈1.4 kb), even B domain deleted forms of *F8* exceed the 4.8 kb capacity of AAV vectors. Recent data suggest that when partial genomes of *F8* are packaged into AAV with 5′ and 3′ truncations, they anneal in the nucleus and form intact transcriptionally active transgenes.[181]

Clinical Trials of Hemophilia Gene Therapy

Over 500 patients with hemophilia have already received gene therapy in clinical trials. Despite early failures, recent AAV *F8* and *F9* trials have shown efficacy. Initial *F9* trials targeting skeletal muscle were halted because of lack of efficacy.[175] More recent trials have targeted the liver, and intravenous delivery of AAV8-FIX has resulted in a median level of FIX expression of 5% for at least 8 years with the higher dose.[182] Both a Phase 1/2 and a Phase 3 trial of AAV5-FVIII have converted severe patients into moderate, mild, or occasionally normal phenotypes, however the results are not predictable nor durable, in contrast to the FIX results.[183,184]

With the gain-of-function Padua FIX variant (Arg338Leu; R338L) now being widely used in clinical trials, even higher levels of FIX expression (7-fold higher) can be achieved.

FVIII gene therapy has historically been more challenging due to the larger size of even the B-domain deleted transgene and the well-recognized difficulty heterologous cells have in producing the recombinant protein.[185] Like the FIX clinical trials, FVIII trials have yielded results from zero (no effect) to greater than 100% factor activity. Even low levels of factor activity can have a dramatic effect on bleeding events and hence quality of life, however they do not relieve the patient of dependence on clotting factor replacement for significant trauma and surgeries. Of more concern is the loss of FVIII expression seen in patients, raising the question of the transient nature of what

TABLE 134.11 **Features of Adeno-Associated Virus-Mediated Gene Therapy**

- Wild-type AAV is a non-pathogenic virus.
- AAV integrates into the host genome at a rate of 0.1%–1%. Genotoxicity in some mouse strains, not observed in humans.
- Manageable occasional dose-dependent hypersensitivity reactions during AAV delivery.
- Innate immunity contributes to an adaptive T-cell dose dependent immune response.
- Vector re-administration cannot be achieved with different vector serotypes due to high homology between capsids and cross-reactive antibodies.
- Cytotoxic T-cell responses to capsid protein presentation on hepatocytes can kill transduced hepatocytes and limit the duration of expression.
- Transgene size is limited to ~4.8 kb but truncated genes may anneal in the nucleus to form full-length transcriptional units (i.e., factor VIII [FVIII]).
- Durability of FVIII response may be affected by ER stress response induced by FVIII translation, not observed with FIX and other transgenes.
- Responses in participants in clinical trials have shown high variability, lack of predictability for both FVIII and FIX, and for FVIII, unreliability and lack of durability.

AAV, Adeno-associated virus; *ER*, endoplasmic reticulum.

is expected to be curative. Since AAV, even other serotypes cannot be readministered due to the development of high and long-lived antibody titers, informed decision making is a necessity. Assay discrepancies in both FVIII and FIX gene therapy trials show that chromogenic assays yield a result that is 60% of one-stage assay results. Like FIX Padua, the transgene FVIII results in faster activation of the FVIII and the Tenase complex, producing a larger effect in the one-stage assay than the chromogenic assay, which is thought to be a better reflection of the true FVIII activity.[186] For FVIII, reasons for the discrepancy may include codon optimization resulting in slight variations in the folding of the newly synthesized molecule, or production in a heterologous cell type. The root cause of the discrepancy has not been identified.

Despite these clinical advances, many hurdles persist (Table 134.11).[187] The most important is an immune response against the vector capsid,[188] which necessitates exclusion of the 25% to 60% of patients with evidence of prior AAV exposure. Rates vary significantly by age and geographic population differences. Innate immunity to single stranded DNA involving toll-like receptors plays a role early in the host immune response.[188] Furthermore, even without prior AAV immunity, many patients develop a cytotoxic T-cell–mediated response that results in transient transaminitis and a reduction in transgene expression. This phenomenon is most evident with FIX gene therapy where steroid prophylaxis appears to be beneficial. Steroids appear to be less effective with FVIII gene therapy and other immunosuppressive drugs may be necessary to treat patients with very high levels of transaminases. Causes of transaminase elevations in hemophilia A trial participants may include cytotoxic T cells, but also may include the development of a UPR and concomitant hepatocyte stress.

Other concerns include durability and variability of the responses, and long-term safety (Table 134.12).[175] Full assessment of durability requires longer follow-up.[183] Rare patients exhibit a transient cytokine storm-like response to vector infusion, usually but not always manageable without stopping the infusion. More than 50% to 80% of patients in some trials are on prednisone or other immunosuppressives for an average of 8 months, with attendant side effects.[184] Although long-term data are limited, and integration into the genome occurs, AAV vectors appear to be relatively safe.

The future for hemophilia gene therapy as a curative therapy is promising but more research is required. Several Phase 3 trials of gene therapy for hemophilia A and B are ongoing or completed and represent the first step toward a cure. For hemophilia B, the results may last for many years. Better viral and nonviral delivery systems that enhance safety and durability and result in less variability are needed (see Table 134.12).[190]

TABLE 134.12 **Hurdles and Potential Solutions to Successful Adeno-Associated Virus Gene Therapy for Hemophilia**

Hurdles in AAV Gene Therapy	Problem	Potential Solutions
Pre-existing immunity	Half of patients seropositive to most primate-derived capsids	Use non-primate capsids (e.g., AAV5), deimmunized AAVs through high-throughput capsid screening, pre-treatment with agents to inhibit Ab production (i.e., rituximab), repeated plasmapheresis
Post-injection innate immunity	Some patients have acute reaction, CpGs may stimulate adaptive immunity	Manage anaphylactoid reactions with drugs, decrease CpG content
Post-injection adaptive immunity	Prevents repeat dosing due to B- and T-cell immunity	Administer immunosuppressive agents, use lower doses of vector to ameliorate
Liver transaminases	Even small elevations indicate hepatocyte stress or death due to cytotoxic T cells or cellular stress	Prednisone reactively or prophylactically, investigate root causes, use lower doses of vector
Integration	May cause oncogenesis	Identify causes of integration, use lower doses of vector
Loss of expression	Cause(s) unknown, dose-dependent	Use lower doses of vector, investigate causes
Variable response	Individuals respond to vector differently	Identify variables and drugs to boost transduction events

HEMOPHILIA IN THE WORLD—ECONOMIC CONSIDERATIONS

Although hemophilia is a worldwide disorder found in every ethnic group and race, its management highlights inequalities across countries. The inequality largely reflects the high cost of factor concentrates and non-factor therapies. The cost of plasma-derived or recombinant factor concentrates remains out of reach for many countries. This results in either no treatment or the use of cryoprecipitate or fresh frozen plasma, if available, to treat hemophilia A and B, respectively.[4] At the start of the 21st century, it was estimated that 70% to 80% of the world's hemophilia population received no therapy because of the high cost of treatment and many were undiagnosed as resources (particularly laboratory testing and clinical expertise) were not available in most countries.

With increased availability of therapy for hemophilia in affluent countries, the life span and quality of life of individuals with hemophilia have advanced, thereby widening the disparities between higher- and lower-income countries.[3] The recognition that even low-dose prophylaxis is beneficial enables care to a broader range of patients.[71] With time and the development of new products, the cost of hemophilia care has decreased. Some of this decrease reflects tender systems of purchase mainly in high-income countries. In less resourced countries cost of care remains stubbornly very expensive.

Humanitarian aid programs that provide factor concentrates and other hemophilia treatment products to countries in need have been initiated by organizations such as the WFH and industry partners.[191] The WFH program provides annually 20,000 patients in over 70 countries with access to clotting factors for prophylaxis, treatment of bleeds, or for perioperative management. Although this program has advanced access to treatment, the gaps in care remain wide in many countries.[37] Ultimately, if gene therapy can provide stable, predictable, and durable levels of FVIII and FIX cost effectively, it may solve the problem of inadequate supplies of protein replacement therapies for most of the world. Many unresolved issues must be solved before curative gene therapy is available on a widespread basis.[190]

ACKNOWLEDGMENT

We wish to thank Paul Moorehead for his initial contributions to this chapter.

CHAPTER 135

RARE COAGULATION FACTOR DEFICIENCIES

David Gailani, Benjamin F. Tillman, and Allison P. Wheeler

The term "rare coagulation factor deficiency" refers to disorders of thrombin and/or fibrin formation caused by mutations in a single gene, other than those for von Willebrand factor (see Chapter 133), factor VIII, or factor IX (see Chapter 134), that reduce plasma activity of one or more coagulation proteins.[1,2] The most common inherited deficiencies that cause defects in plasma coagulation are those for factor VIII (hemophilia A) and factor IX (hemophilia B), with frequencies of 1 in 10,000 and 1 in 30,000 male births respectively (see Chapter 134). In comparison, severe deficiency of fibrinogen, the protease zymogens prothrombin or factors VII, X, or XI, the cofactor factor V, or the transaminase factor XIII are estimated to occur in one in 500,000 to 2 million individuals (Table 135.1). These conditions are inherited primarily as autosomal recessive conditions, implying carrier frequencies ($\sim$1 in 1000 persons) that are 10-fold higher than the carrier frequencies for alleles causing X-linked hemophilia A or B. The rarity of these disorders is therefore due to their recessive nature and not low allele frequency. This is important to keep in mind because partial (heterozygous) deficiencies of these proteins are relatively common and may contribute to bleeding symptoms. As with any recessive trait, incidences are up to 10-fold higher in areas where consanguinity is common.[2]

Fig. 135.1A shows a scheme reflecting current understanding of the major enzyme reactions involved in thrombin generation and fibrin formation. Factor VIIa binds to tissue factor in the wall of a damaged blood vessel, forming a complex that activates factor X to Xa, which converts prothrombin to thrombin in the presence of factor Va. Mice lacking prothrombin, factor VII, factor X, or factor V die in utero or soon after birth, demonstrating the importance of these reactions. Thrombin converts fibrinogen to fibrin. Factor IX is also activated by factor VIIa/tissue factor and, with factor VIIIa, sustains thrombin generation by activating factor X. In some situations, factor IX activation by factor XIa is required. The older model shown in Fig. 135.1B shows the order of reactions during coagulation in the prothrombin time (PT) and activated partial thromboplastin time (aPTT) assays (see Chapter 127). Here factor XI activation requires factor XII, prekallikrein, and high molecular weight kininogen. However, deficiencies of these proteins do not result in abnormal bleeding, indicating that other mechanisms exist for factor XI activation. In Fig. 135.1A thrombin activates factor XI. Finally, factor XIII is activated by thrombin and cross-links fibrin monomers within a fibrin polymer, increasing the tensile strength of fibrin (see Fig. 135.1A).

Rare coagulation factor deficiencies represent 3% to 5% of inherited plasma coagulation factor deficiencies. This chapter contains separate sections describing inherited and acquired deficiency states for each factor. A number from the Online Mendelian Inheritance in Man (OMIM) database is given in the title for each section on an inherited deficiency. Updated lists of mutations associated with factor deficiencies can be found at several websites such as http://www.clotbase.bicnirrh.res.in and http://www.hgmd.org. The rarity and clinical heterogeneity of the inherited disorders described in this chapter, combined with limited availability of testing, present challenges for establishing evidence-based treatment guidelines.[1,2] Common symptoms include bleeding from mucosal surfaces, heavy menstrual bleeding, and hemorrhage with invasive procedures and childbirth. Bleeding involving the central nervous system or umbilical cord stump are most frequent in severe deficiencies of fibrinogen, factors X, and factor XIII, while gastrointestinal bleeding is a particular problem in factor X deficiency. Hemarthroses can occur with afibrinogenemia and severe deficiency of factors II or X. The World Federation of Hemophilia (WHF, www.wfh.org) and the International Rare Bleeding Disorder Database (RBDD, www.rbdd.org) collect information for the rare coagulation factor deficiencies (Fig. 135.2).[2,3] The European Network of Rare Bleeding Disorders (EN-RBD) has subclassified these conditions based on clinical features to facilitate development of evidence-based diagnostic and treatment strategies (Table 135.2). They noted strong associations between bleeding severity and plasma factor levels in fibrinogen, factor X, and factor XIII deficiencies, weaker associations for factor V or factor VII deficiency, and very weak association in factor XI deficiency.

Table 135.3 summarizes treatment recommendations. Several therapeutic advances could improve treatment of rare bleeding disorders soon. Single factor concentrates are now available for fibrinogen and factors VII, X, XI, and XIII, although availability for some is limited.[1,2] A new factor V concentrate awaits clinical testing. Most of these preparations are derived from human plasma; recombinant versions are currently available only for factor VIIa and the A domain of factor XIII. Strategies for enhancing thrombin generation and activity such as siRNAs to reduce plasma antithrombin, the bispecific factor IX/factor X antibody emicizumab, and the anti-tissue factor pathway inhibitor antibody concizumab have shown promise in patients with hemophilia (see Chapter 134), and may turn out to be useful in some rare coagulation factor deficiencies.

INHERITED FIBRINOGEN DEFICIENCY (OMIM 202400)

Fibrinogen was first purified from plasma in the late 19th century. Fibrinogen and *fibrin* were designated *factor I* and *Ia*, respectively, by the International Committee for Nomenclature of Blood Clotting. Inherited absence of fibrinogen (*afibrinogenemia*) was described in 1920 and has an estimated incidence of 1 in 1 million people (see Table 135.1).[4] Partial fibrinogen deficiency is called *hypofibrinogenemia*. Fibrinogen is synthesized in hepatocytes as a 340,000-Dalton protein composed of two trimers, each containing an $A\alpha$, $B\beta$, and γ chain (Fig. 135.3) that are encoded by separate genes (*FGA, FGB*, and *FGG*) within a 50-kilobase span on chromosome 4. Thrombin converts fibrinogen to fibrin by cleaving fibrinopeptides A and B from the $A\alpha$ and $B\beta$ chains respectively (see Chapters 121 and 125). Fibrinogen also binds glycoprotein IIb/IIIa, facilitating platelet aggregation. Fibrinogen in platelet α-granules is taken up from plasma by a glycoprotein IIb/IIIa-dependent mechanism. Between 8% and 15% of plasma fibrinogen contains at least one γ chain that is a product of an alternatively spliced mRNA called γ'-fibrinogen. γ'-fibrinogen modulates thrombin and factor XIII activity and influences clot architecture.

The normal plasma fibrinogen concentration is 1.5 to 4.0 g/L (150 to 400 mg/dL). Afibrinogenemic patients have levels less than 0.1 g/L as determined by clotting and immunoreactive assays, due to homozygosity or compound heterozygosity for fibrinogen gene mutations. Hypofibrinogenemia is caused by heterozygosity for such mutations. The first mutation causing fibrinogen deficiency was

TABLE 135.1 **Properties of Plasma Coagulation Factors and Characteristics of Deficiency States**

Protein	Factor Plasma Half-Life (h)	Vitamin K Dependent Modification	Factor Level in Pregnancy	Incidence of Severe Inherited Deficiency	Autosomal Inheritance Pattern of Deficiency	Other Names for Deficiency State	Bleeding Diathesis in Severe Deficiency	Screening Tests in Deficiency	
								PT	PTT

reported in 1999. Over 200 *FGA, FGB*, or *FGG* deletions, frameshifts, and point mutations have been identified in afibrinogenemic and hypofibrinogenemic patients' (https://site.geht.org/base-de-donnees-fibrinogene).[4] *FGA* is most affected. Missense mutations are more prevalent in *FGB* and *FGG*, and cluster in the polypeptide C-termini, affecting D-domain formation (see Fig. 135.3) and interfering with secretion. In afibrinogenemia, fibrinogen is not secreted due either to a lack of synthesis of a fibrinogen chain (Aα, Bβ, or γ) or a defect that prevents secretion. Fibrinogen polypeptides that are not secreted are usually degraded in hepatocytes. However, a few *FGG* mutations such as Gly284Arg (fibrinogen Brescia), Arg375Trp (fibrinogen Aguadilla), and Thr314Pro (fibrinogen Al DuPont) lead to mutant γ-chain accumulation of hepatocytes in the endoplasmic reticulum (ER) of hepatocytes and cause hepatic dysfunction and cirrhosis in a process like that associated with α_1-antitrypsin deficiency (ER storage disease).

Most hypofibrinogenemic patients are asymptomatic, but some bleed excessively with trauma or surgery, particularly with fibrinogen levels less than 0.5 g/L.[1,2,4] Spontaneous bleeding is rare with levels greater than 0.7 g/L and bleeding with surgery is unusual with levels greater than 1.0 g/L. Most (85%) afibrinogenemic patients bleed from mucosal surfaces. Heavy menstrual bleeding and bleeding from the skin, gastrointestinal tract, and genitourinary tract are common. Hemarthroses and muscle hematomas were frequent in one series (54% and 72%, respectively), but were less so (25%) in another study. Hemarthrosis-related arthropathy is less pronounced than in hemophilia A or B. Intracranial bleeding occurs in up to 10% of patients, providing justification for prophylaxis. Intracranial and umbilical cord stump bleeds are common in infancy. Afibrinogenemic patients may be prone to spontaneous splenic rupture. Pregnancy loss, usually in the first trimester, is common in afibrinogenemic women in the absence of factor replacement.[1,2,4] Fibrinogen-deficient mice also have difficulty sustaining pregnancy, confirming the importance of maternal fibrinogen to fetal viability. Pre- and postpartum bleeding are common, and intraabdominal bleeds from ruptured corpus luteal cysts have been reported.

Curiously, arterial and venous thrombosis can occur in afibrinogenemic patients. While some events are likely precipitated by known risk factors or by fibrinogen replacement, no identifiable cause is evident in many instances. By binding thrombin, fibrinogen and fibrin down regulate thrombin activity (a property previously referred to as "antithrombin I" activity), which may explain why thrombosis occurs.

The PT and aPTT assays use fibrin formation as an endpoint and will be infinitely prolonged in afibrinogenemia. In hypofibrinogenemia, the PT and aPTT may be normal because they are relatively insensitive to low fibrinogen levels. The von Clauss method is commonly used for quantifying the plasma fibrinogen concentration and is based on measuring time to clot formation after addition of a standard amount of thrombin (see Chapter 127). The assay is not reliable at low fibrinogen levels (<50 mg/dL) and may give falsely low readings with fibrinogen variants that polymerize slowly (dysfibrinogenemias), in situations where high levels of substances that interfere with fibrin polymerization are present (paraproteins, fibrin degradation products), or if the sialic acid content of fibrinogen is high (newborns, liver disease). Thus, it is important to

Figure 135.1 MODELS OF PLASMA COAGULATION. Unactivated plasma factors are indicated by Roman numerals and activated factors by Roman numerals followed by a lowercase letter a. Enzymes are indicated by black lettering and cofactors by white lettering in red ovals. Orange arrows indicate reactions involving enzyme activation. Some reactions require calcium ions (Ca^{2+}) or phospholipid (PL) to proceed optimally. The green arrow indicates feedback activation of factor XI by thrombin. Black arrows indicate fibrin formation. (A) A model of tissue factor (TF) initiated hemostasis. Please read the introduction to this chapter for a description of the events leading to the formation and stabilization of a fibrin clot that are depicted in this figure. (B) The cascade/waterfall model of hemostasis. This model serves as the basis for the prothrombin time (PT) and activated partial thromboplastin time (aPTT) assays. In the PT assay a reagent containing TF is added to plasma, and the factor VIIa/TF complex induces clot formation through activation of factor X. In the aPTT assay a reagent containing a negatively charged substance initiates clot formation through activation of factor XII (contact activation; see Fig. 134.5 for details). *HK*, High-molecular-weight kininogen; *PK*, prekallikrein; *TF*, tissue factor.

demonstrate absence of immunoreactive fibrinogen to confirm a diagnosis of afibrinogenemia. In hypofibrinogenemia, functional and antigenic fibrinogen levels are proportionately decreased. A functional level that is low relative to the antigen level indicates dysfibrinogenemia.[5] Results for the template bleeding time and standard platelet aggregometry are usually abnormal in afibrinogenemia. However, aperture closure times in the PFA-100 platelet function screen are often normal, as this test depends on von Willebrand factor and not fibrinogen to support platelet aggregation. Afibrinogenemic patients have low erythrocyte sedimentation rates and develop little induration with skin tests for delayed hypersensitivity because of the absence of fibrin deposition.

Fresh frozen plasma (FFP) contains fibrinogen, but large volumes are required to correct significant fibrinogen deficiency. Cryoprecipitate is used most often in the United States to treat low fibrinogen levels (see Table 135.3). Each unit of cryoprecipitate has ~ 300 mg of fibrinogen. The plasma volume of a patient with a normal hematocrit is ~ 40 mL/kg body mass. Administering cryoprecipitate to an afibrinogenemic patient at 1 unit/5 kg of body mass increases plasma fibrinogen to ~1 g/L. The fibrinogen concentrate RiaSTAP (CSL Behring, marketed as Haemocomplettan in some European countries) was approved by the United States Food and Drug Administration (FDA) in 2009 for treating bleeding and for prophylaxis in severe fibrinogen deficiency. In 2017 the FDA approved another fibrinogen

TABLE 135.2 Plasma Factor Levels Based on European Network of Rare Bleeding Disorders Categories

Disorder	EN-RBD Severity Category			Clinical Correlation With Factor Level
	Severe	Moderate	Mild	
Fibrinogen deficiency	Undetectable	0.1–1.0 gm/dL	>1.0 g/dL	Strong
Prothrombin deficiency	Undetectable	≤0.1 IU/mL (≤10%)	>0.1 IU/mL (>10%)	Strong
Factor V deficiency	Undetectable	<0.1 IU/mL (<10%)	≥0.1 IU/mL (≥10%)	Weak
Factor VII deficiency	<0.1 IU/mL (<10%)	0.1–0.2 IU/mL (10%–20%)	>0.2 IU/mL (>20%)	Weak
Factor X deficiency	<0.1 IU/mL (<10%)	0.1–0.4 IU/mL (10%–40%)	>0.4 IU/mL (>40%)	Strong
Factor XI deficiency	—	—	—	Very weak
Factor XIII deficiency	Undetectable	<0.3 IU/mL (≤30%)	≥0.3 IU/mL (>30%)	Strong
Combined factor V and VIII deficiency	<0.2 IU/mL (<20%)	0.2–0.4 IU/mL (20%–40%)	>0.4 IU/mL (>40%)	Weak
Vitamin K-dependent factor deficiencies	—	—	—	Weak

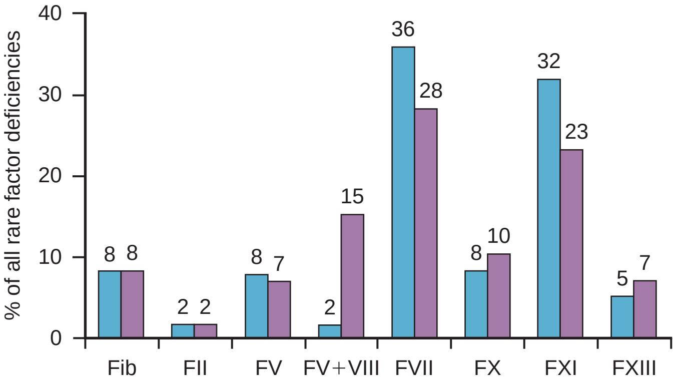

Figure 135.2 WORLDWIDE PREVALENCE OF RARE BLEEDING DISORDERS. Shown are data for each factor deficiency as a percent of total rare bleeding disorders from data collected by the World Federation of Hemophilia (WFH, *blue bars*) and the International Rare Bleeding Disorders Database (RBBD, *purple bars*). The difference in percentage for combined factor V and factor VIII deficiency between the surveys may reflect cases of factor V deficiency with mild hemophilia A being classified as combined deficiencies in the RBDD survey. (*Adapted from Peyvandi F, Menegatti M, Palla R. Rare bleeding disorders: worldwide efforts for classification, diagnosis, and management. Semin Thromb Haemost. 2013;39:579, with permission.)*

concentrate, Fibryga (Octapharma), for treating acute bleeding in adults and adolescents with inherited fibrinogen deficiency.[6] RiaSTAP and Fibryga have undergone viral inactivation. In 15 patients given RiaSTAP (70 mg/kg), the median plasma fibrinogen concentration 1-hour post-infusion was 1.3 g/L (half-life of 77.1 hours). Pharmacokinetic parameters for Fibryga are similar, but clearance appears to be slower. In patients with inherited fibrinogen deficiency, RiaSTAP was effective in 26 of 26 bleeding episodes, 10 of 11 surgical procedures, and all 90 prophylactic administrations. Subsequent studies involving trauma, cardiothoracic surgery, and obstetrical hemorrhage confirmed its ability to improve coagulation and reduce blood loss. In a randomized trial, Fibryga was non-inferior to cryoprecipitate in terms of the number of transfused blood components,[7] leading to expansion of its approval to include treatment of acquired fibrinogen deficiency in 15 European countries. Low-molecular-weight heparin may be administered with fibrinogen concentrate to reduce the risk of thrombosis. The required dose of concentrate can be determined using the following formula:

$$\text{Dose}(\text{mg/kg body weight}) = \frac{\text{Target Level }(\text{mg/dL})\quad \text{Measured Level }(\text{mg/dL})}{1.7(\text{kg body weight/dL})} \tag{5.1}$$

For significant bleeding, the United Kingdom Haemophilia Centre Doctors Organization guidelines recommend that the plasma fibrinogen concentration be maintained at 1.0 g/L until hemostasis is achieved and above 0.5 g/L until wound healing is complete. A similar strategy makes sense for managing surgical patients. A review of replacement therapy and outcomes for 50 patients with inherited fibrinogen deficiency generally agrees with these recommendations. A fibrinogen concentration of 0.5 to 1.0 g/L was adequate for the prevention or treatment of bleeding in nonsurgical or obstetrical settings, while 1.0 to 2.0 g/L was effective for the prevention of bleeding during surgery. This review reported thrombotic episodes (related or unrelated to replacement) in 30% of patients. As the half-life of transfused fibrinogen is ~3 days, dosing every 2 to days is usually adequate in the absence of consumption. Increased dosing frequency may be needed for massive hemorrhage, major surgery, or advanced pregnancy, and monitoring of fibrinogen levels is recommended to facilitate dose adjustments. The use of thromboelastometry to monitor fibrinogen concentrate dosing is popular in surgical settings.

Long-term prophylaxis may be useful for preventing initial bleeding in young patients or for preventing recurrence, particularly after central nervous system hemorrhage. Administering concentrate at 20 to 30 mg/kg every 7 to 14 days to maintain plasma levels of ~0.5 g/L is recommended. Prophylactic fibrinogen administration is required to maintain pregnancies in afibrinogenemic women and to reduce postpartum hemorrhage. Therapy should be initiated early in pregnancy because fetal loss in the first trimester is common. One study suggested that initiating therapy before conception is beneficial. Although some authors recommend maintaining fibrinogen levels above 0.5 g/L during pregnancy and the peripartum period, others suggest a higher level (1.0 g/L) based on reports of fetal loss with levels near 0.5 g/L.

The increased use of fibrinogen concentrates has prompted concerns about adverse events such as thromboembolism, hypersensitivity reactions, and viral transmission. An analysis of 27 years of pharmacovigilance data identified 21 cases of suspected viral transmission (1 per 124,300), 28 cases of thromboembolism (1 per 93,300), and 20 cases of hypersensitivity (1 per 130,600 doses). These data and recent experience from multiple centers suggest an acceptable safety profile.

Antifibrinolytic therapy with ε-amino caproic acid is an effective substitute for blood products for management of some mucosal

TABLE 135.3 Treatment Considerations for Rare Coagulation Factor Deficiencies

Protein	Blood Product Sources	Concentrate (Manufacturer)	Minimum Plasma Level Required for Hemostasis	Minimum Plasma Level Required for Surgery	Dose of Preferred Treatment for Surgery or Bleeding	Dosing Frequency for Surgery or Bleeding	Prophylaxis for Severe Deficiency	Pregnancy: Suggested Plasma Levels for Invasive Procedures and Delivery
Fibrinogen	CRYO FFP	RiaSTAP (CSL Behring)[a] FIBRYGA (Octapharma)[a]	>50 mg/dL	100 mg/dL until healing complete	20–30 mg/kg[b] 15–20 mL FFP/kg 1 bag CRYO/10 kg	Q 24–72 h depending on consumption	Keep level 50 mg/dL for recurrent bleeders	Maintain at 100 mg/dL throughout pregnancy
Prothrombin	FFP	PCC[a]	~5%	30%	20–30 factor IX units/kg	Q 48–72 h	40 factor IX units/kg Q 5–6 days	20%–30%

CRYO, Cryoprecipitate; *FFP*, fresh frozen plasma; *PCC*, prothrombin complex concentrate.

[a] Preferred treatment for inherited deficiency

[b] Assuming baseline fibrinogen is not known.

[c] FDA approved for the treatment of adults and adolescents (12 years old and older) with hemophilia A or B with inhibitors, but not currently approved for treatment of patients with inherited factor VII deficiency.

[d] Plasma concentration of factors can vary significantly, however 15 to 20 mL/kg should result in an increase of 10% to 20% factor XI activity. We recommend assessment of factor activity prior to surgical procedures and in the setting of significant bleeding if feasible.

bleeds and dental extractions (see box on Adjuncts to Factor Replacement in Inherited Factor Deficiencies). There remain concerns that such therapy increases the risk of thrombosis, particularly in patients with a history of thrombosis and also during pregnancy, surgery, or immobilization. However, the therapy is well tolerated by most patients. Fibrin sealant may be useful for tooth extraction and estrogen/progesterone therapy may be useful for controlling heavy menstrual bleeding.

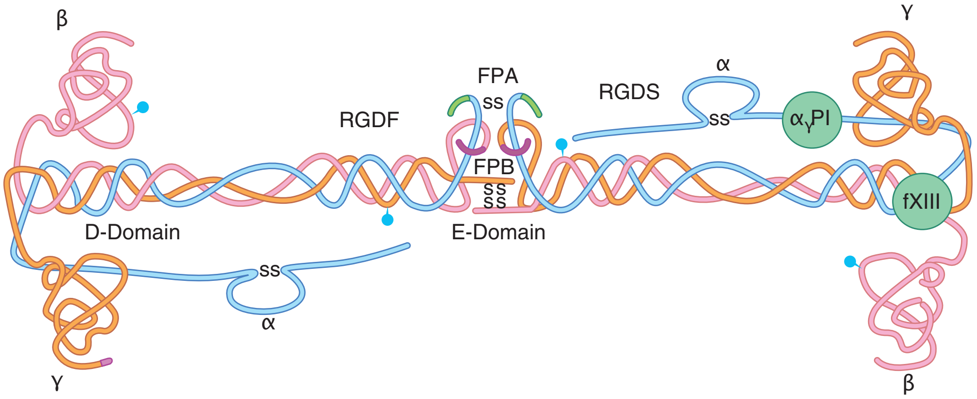

Figure 135.3 MODEL OF HUMAN FIBRINOGEN. A fibrinogen molecule consists of two trimers, each containing an Aα-chain *(blue)*, Bβ-chain *(pink)*, and γ-chain *(orange)*. The amino-termini of the six chains that compose the whole molecule are linked by disulfide bonds in the central E domain, and the C-termini of the polypeptides form two nodular D domains at opposite ends of the molecule. Fibrinopeptides A and B reside in the E domain and are removed by the proteolytic activity of thrombin during conversion of fibrinogen to fibrin monomer. *(Adapted from Mosesson MW. The roles of fibrinogen and fibrin in hemostasis and thrombosis. Semin Hematol. 1992;29:177, with permission.)*

ADJUNCTS TO FACTOR REPLACEMENT IN INHERITED FACTOR DEFICIENCIES

The antifibrinolytic agents ε-amino caproic acid and tranexamic acid can be effective adjuncts to factor replacement when treating inherited or acquired bleeding disorders and are useful alternatives to replacement therapy for mild bleeding or minor procedures. These drugs inhibit clot dissolution by interfering with plasminogen activation and plasmin activity and are particularly effective when bleeding involves tissues with high fibrinolytic activity such as the oral and nasal cavity. They are also useful for treating menorrhagia, limiting blood loss with surgery, controlling epistaxis, and reducing some types of gastrointestinal bleeding. A typical loading dose of ε-amino caproic acid is 100 mg/kg (4 g maximum) followed by 50 mg/kg (2 g maximum) every 6 h. If bleeding subsequently occurs, the dose can be increased, but should not exceed 24 g in 24 h. ε-amino caproic acid is available in oral and intravenous formulations. Identical dosing for either preparation may be used due to excellent bioavailability. Tranexamic acid may be administered at doses up to 1300 mg every 6 h.

For dental extraction in factor VIII or IX deficiency, many centers utilize a single 50%–100% dose of factor concentrate followed by 7 days of ε-amino caproic acid and it is reasonable to use this approach for patients with some rare bleeding disorders. Patients with factor XI deficiency do well with antifibrinolytic agents alone for tooth extraction (see box on Managing Factor XI Deficient Patients). Prolonged therapy with anti-fibrinolytics should be undertaken with caution in patients who are not mobile, who have a history of thrombosis, or who have significant urogenital bleeding. These drugs interfere with urokinase-mediated fibrinolysis in the genitourinary tract and can lead to thrombotic occlusion of the ureter. Antifibrinolytic agents in combination with activated prothrombin complex concentrates or recombinant factor VIIa have been used in some patients, but this should be done with caution because of the potential for increasing thrombotic risk. Patients may develop nausea or vertigo with high doses of ε-amino caproic doses and, in rare cases, rhabdomyolysis.

Recombinant factor VIIa may stop or prevent hemorrhage in rare bleeding disorders. The mechanism by which this agent contributes to hemostasis is not completely understood, particularly when used in patients with deficiencies of common pathway factors (prothrombin and factors V and X). For patients with rare bleeding disorders and an antibody inhibitor directed against the missing factor, factor VIIa may be the treatment of choice. Doses range from 15 to 120 μg/kg every 2–6 h depending upon the severity of bleeding. Because of the potential for thromboembolism with factor VIIa, we recommend frequent re-evaluation and reduction to the lowest effective dose. Doses of 90 μg/kg every 2–3 h have been used in patients with inherited factor V deficiency or combined deficiencies of factors V and VIII, with acquired factor X deficiency associated with amyloidosis, and with antibody-mediated acquired prothrombin deficiency associated with lupus anticoagulants. When compared with FFP, the volume of infused material is smaller with factor VIIa, and the risks for complications such as of fever, urticaria, transfusion-related acute lung injury (TRALI), and anaphylaxis are lower. Caution must be exercised when using factor VIIa in older patients with cardiovascular disease as arterial thrombosis can result, particularly when therapy is combined with antifibrinolytic therapy or prothrombin complex concentrate.

INHERITED DYSFIBRINOGENEMIA (OMIM 134820 Aα CHAIN, 134830 Bβ CHAIN, 134850 γ CHAIN)

In *dysfibrinogenemia*, structural variants of fibrinogen circulate in plasma.[5] Cases in which the dysfunctional protein is present at low concentration are referred to as *hypodysfibrinogenemia*. The first family with dysfibrinogenemia (15 amino acid insertion after Gln350 in the γ chain [fibrinogen Paris I]) was described in 1964. The true incidence of inherited dysfibrinogenemia is unknown, because the majority of affected individuals are asymptomatic.

Inherited dysfibrinogenemias are mostly autosomal dominant traits due to missense mutations in a fibrinogen gene (https://site.geht.org/base-de-donnees-fibrinogene/). Amino acid substitutions that affect fibrinopeptide release, fibrin polymerization or cross-linking, or fibrin degradation are described. The diagnosis is established by a measurement of fibrinogen using a rate-based clotting assay that is low relative to immunoreactive fibrinogen. The functional defects most often reported are influenced by the assays available in clinical laboratories and are unlikely to represent the full spectrum of mutations causing fibrinogen dysfunction. Variants easily detected in clinical laboratories typically have defects in fibrinopeptide release (*FGA*-Arg16His and *FGA*-Arg16Cys [fibrinogens Bicêtre and Metz]) or polymerize slowly (*FGG*-Ser434Asn [fibrinogen Caracas II], *FGG*-Arg275Cys and *FGG*-Arg275His). Indeed, ~45% of mutations in the dysfibrinogenemia database involve substitutions at *FGA*-Arg16 or *FGG*-Arg275, reflecting the ease with which such variants are detected by commonly used assays. Hypodysfibrinogenemia may be caused by single mutations that interfere with both fibrinogen assembly/secretion and function, or compound heterozygosity for reduced synthesis of one allele (usually a null mutation in *FGA* or *FGB*) and a dysfunctional second allele. As with dysfibrinogenemia, missense mutations are most common in hypodysfibrinogenemia.

Most individuals with dysfibrinogenemia are asymptomatic. In a multicenter study of 101 patients with inherited dysfibrinogenemia (with genotypes), 58% were identified incidentally because of an abnormal coagulation test. Over a mean follow-up of 8.8 years, the incidences of major bleeding and thrombosis after diagnosis were 2.5 and 18.7 per 1000 patient years, respectively, with estimated cumulative incidences of 19.2% and 30.1% at 50 years of age. There was no clear association between symptoms and fibrinogen level, fibrinogen functional abnormalities, or gene mutations, findings consistent with older observations that common substitutions such as *FGA*-Arg16His and *FGA*-Arg16Cys occur in asymptomatic individuals as well as in patients with bleeding or thrombosis.

Bleeding symptoms tend to be mild, with epistaxis, easy bruising, and heavy menstrual bleeding being common. More serious bleeding events including soft tissue hematomas, hemarthroses, postoperative hemorrhage, and bleeding during and after pregnancy occur, but are rarer. Major bleeding seems to occur primarily between the ages of 20 and 40 years, partly due to hemostatic challenges related to childbirth. Abnormal wound healing and spontaneous abortion have been reported.

Thrombosis primarily involves the venous circulation, although arterial events can occur. The mean ages for venous and arterial events in one study (34 and 49 years) were lower than for the general population. There is a high prevalence of VTE at the time of diagnosis, with an incidence during follow-up like that for carriers of the factor V Leiden polymorphism. Mutations clustering at the C-terminus of the Aα chain and near the thrombin cleavage site on the Bβ chain are associated with venous thrombosis as are abnormalities in fibrin polymerization, cross-linking, clot structure, and susceptibility to fibrinolysis. The Dusart syndrome caused by *FGA*-Arg554Cys (fibrinogen Paris V) was associated with venous thrombosis and sudden death from pulmonary embolism in adolescents and young adults in several families. Dysfibrinogenemia was reported in 5 of 33 patients with chronic thromboembolic pulmonary hypertension, with the *FGB*-Pro235Leu substitution found in three unrelated patients. Dysfibrinogenemias can alter fibrin polymer structure and its susceptibility to lysis, suggesting that the variants interfere with clot dissolution. Despite these associations, a review of 2376 patients with venous thrombosis found dysfibrinogenemia in less than 1%. Therefore, testing for abnormal fibrinogen in patients with venous thrombosis is not widely recommended (see Chapter 138).

As discussed in the section on inherited fibrinogen deficiency, maternal fibrinogen is required to maintain pregnancy. Obstetrical and postpartum complications such as spontaneous miscarriage, placental abruption, and postpartum hemorrhage occur in women with inherited dysfibrinogenemia, particularly those with a past history or family history of such complications. There are few guidelines for management of pregnant women with dysfibrinogenemia.

A group of mutations in the C-terminus of the fibrinogen Aα chain is associated with autosomal dominant hereditary amyloidosis. The amyloid deposits contain fragments of the variant fibrinogen. The kidneys are affected first, but visceral and nerve involvement may occur. Renal grafts become involved with amyloid, and liver transplantation may be a better treatment option. The allele for one responsible mutation, *FGA*-Glu526Val, is relatively common and may account for 5% of patients with apparent sporadic amyloid.

Dysfibrinogenemia is usually diagnosed because of abnormalities on routine coagulation tests such as the PT or aPTT. The thrombin time is often used to screen for dysfibrinogenemia, although its sensitivity is not established. The thrombin time involves measuring the time to clot formation after addition of a relatively small amount of thrombin to plasma (see Chapter 127). Specificity for dysfibrinogenemia is low because heparin, thrombin inhibitors (argatroban, dabigatran, hirudin), elevated levels of fibrin degradation products, paraproteins, and low fibrinogen levels all prolong the thrombin time. The reptilase time has been used as an alternative screen and is useful in combination with the thrombin time (see Chapter 127). Clot formation is induced with an enzyme from the venom of *Bothrops jararaca* or *Bothrops atrox* that cleaves fibrinopeptide A (but not fibrinopeptide B) from fibrinogen, and which is not sensitive to heparin or direct thrombin inhibitors. The plasma concentration of fibrinogen as determined by the von Clauss method (see "Inherited Fibrinogen Deficiency") may be falsely low in some forms of dysfibrinogenemia. Levels of immunoreactive fibrinogen are usually normal but are decreased in hypodysfibrinogenemia. Fibrin degradation products may appear to be elevated because variant fibrinogens may be incompletely incorporated into the clot, leading to the false impression that disseminated intravascular coagulation (DIC) is present (see Chapter 137).

Most dysfibrinogenemic patients are asymptomatic. When symptoms occur, there is little correlation with coagulation assay abnormalities, which renders it difficult to make general therapeutic recommendations. The patient's personal and family history can help to guide therapy. Active bleeding can be treated with replacement therapy as in afibrinogenemia and such treatment may be indicated in some patients before invasive procedures. In general, patients with thrombosis and dysfibrinogenemia should be treated in the same manner as other patients with thrombosis. There are no data on which to formulate recommendations as to duration of anticoagulant therapy; thus, past history, family history, coexisting conditions, and the nature (unprovoked or provoked by pregnancy or surgery) and severity of the thrombotic event are taken into consideration (see Chapters 140 and 141). As with any thrombotic event, the risk for bleeding associated with prolonged anticoagulant therapy needs to be considered. Recurrent spontaneous abortions have been associated with dysfibrinogenemia in several families and pregnancies have been carried to term using replacement therapy. While some investigators recommend fibrinogen replacement early in pregnancy, as in afibrinogenemic patients, the prothrombotic nature of the peripartum period may dictate against this approach in certain patients.

Acquired Disorders of Fibrinogen

Acquired hypofibrinogenemia occurs in DIC and primary fibrinolysis (see Chapter 137). Fibrinogen levels are usually normal or increased in liver disease, but levels less than 1 g/L may be seen in cirrhosis with hepatic failure or fulminant hepatic necrosis and indicate a poor prognosis. Patients receiving L-asparaginase for hematologic malignancies may develop severe hypofibrinogenemia (<0.2 g/L), while other coagulation factors are normal or only slightly reduced.

Acquired dysfibrinogenemia is common in liver disease, with 80% to 90% of patients with cirrhosis or liver failure showing some evidence of fibrinogen dysfunction. Increased sialic acid content like that seen with neonatal fibrinogen (see Chapter 148) decreases the rate of fibrin polymerization in the von Clauss assay, reducing the apparent fibrinogen concentration. Increased sialic acid content probably does not contribute significantly to abnormal hemostasis. Similarly, monoclonal paraproteins in patients with multiple myeloma may interfere with fibrin polymerization but usually do not cause abnormal hemostasis. Acquired dysfibrinogenemia also has been associated with malignancies and bone marrow transplantation.

Alloantibodies to fibrinogen have been described in persons with afibrinogenemia after exposure to fibrinogen containing products, including fibrin sealant and fibrinogen concentrates. While clinically significant in some persons, the frequency of this occurrence is rare, likely because many afibrinogenemic patients have trace amounts of circulating fibrinogen. Anti-fibrinogen antibodies were reported in only two afibrinogenemic patients after receiving fibrinogen concentrate and the incidence of antibody development may be lower than in patients receiving cryoprecipitate.

Autoantibodies against fibrinogen have been described in various clinical scenarios, including pregnancy, malignancy, and autoimmune disorders. Like inherited fibrinogen abnormalities, the antibodies can result in clinically silent laboratory changes or be associated with hemostatic and/or thrombotic abnormalities.

INHERITED PROTHROMBIN DEFICIENCY (OMIM 176930)

More than a century ago, Morawitz proposed that insoluble fibrin is formed from fibrinogen through the activity of fibrin ferment or *thrombin*. Thrombin was generated from a precursor, prothrombin, by thrombokinase (probably factor Xa). Prothrombin and thrombin are designated *factors II* and *IIa*. Total *prothrombin deficiency* is probably not compatible with life. Complete absence of the protein has not been observed in a human,[8] and prothrombin-deficient mice succumb to bleeding in utero or shortly after birth. Severe deficiency of plasma prothrombin activity caused by reduced plasma prothrombin antigen (*hypoprothrombinemia*) or circulating dysfunctional prothrombin (*dysprothrombinemia*) affects ~1 in 2 million people (see Table 135.1).[8] However, prothrombin deficiency is the third most common coagulation factor disorder in Puerto Rico (carrier frequency ~1 in 700), accounting for 6% of inherited bleeding disorders other than von Willebrand disease at the University of Puerto Rico Hemophilia Center. In the North American Rare Bleeding Disorder Registry, 62% of patients with prothrombin deficiency were of Latin American origin, possibly reflecting the prevalence of the Arg457Gln variant prothrombin Puerto Rico I. Globally almost 70% of patients with prothrombin deficiency have Latin or Hispanic ancestry.[8]

Prothrombin is a 72,000 Da protein that is converted to thrombin by factor Xa in complex with factor Va on phospholipid surfaces (see Fig. 135.1A). Thrombin catalyzes multiple procoagulant events including cleavage of fibrinopeptides A and B from fibrinogen (see Fig. 135.3), activation of factors V, VIII, XI, and XIII, and cleavage of protease activated receptors on a variety of cells including platelets (see Chapters 121 and 125). Thrombin binds to thrombomodulin on endothelial cells, downregulating coagulation by activating protein C and attenuating fibrinolysis by activating thrombin-activatable fibrinolysis inhibitor (TAFI).

Prothrombin deficiency is an autosomal recessive disorder that manifests as hypoprothrombinemia (reduced activity and antigen; cross-reactive material negative [CRM−] deficiency), dysprothrombinemia (activity reduced relative to antigen; CRM+ deficiency), or a combination of both.[8] Plasma prothrombin activity is typically 1% to 10% of normal in hypoprothrombinemia and 1% to 20% in dysprothrombinemia. Heterozygotes for either condition have 40% to 60% of normal activity. About 50 prothrombin gene (*F2*) mutations have been described in patients with prothrombin deficiency, three-quarters of which are missense mutations. In dysprothrombinemia, missense mutations typically cause defects in prothrombin conversion to thrombin (e.g., pArg457Gln [prothrombin Puerto Rico I] and pArg271Cys [prothrombin Madrid]), or result in functionally defective thrombin (e.g., Arg418Trp [prothrombin Tokushima]). A subset of recently identified dysprothrombinemias, caused by missense mutations in *F2* exon 14, alter thrombin regulation. Substitution of prothrombin Arg596 with leucine (prothrombin Yukuhasi), glutamine (prothrombin Belgrade), or tryptophan (prothrombin Padua 2) interferes with thrombin-antithrombin complex formation, resulting in increased circulating thrombin and a prothrombotic state that has been referred to as "antithrombin resistance."[9] In contrast to other dysprothrombinemias, these CRM+ variants do not cause excessive bleeding despite the apparent low plasma prothrombin activity. Prothrombin deficiency can be inherited in combination with deficiencies of other vitamin K–dependent proteins (see "Combined Deficiency of Vitamin K–Dependent Proteins").

Severe hypoprothrombinemia is inevitably associated with bleeding that may be life threatening. A committee of the International Society on Thrombosis and Haemostasis (ISTH) proposed classifying prothrombin deficiency as severe (<5% of normal activity), moderate (5% to 10% activity) or mild (>10% activity). This system has been adopted in the EN-RBD survey (see Table 135.2).[3] Central nervous system hemorrhage was reported in 8% to 12% of prothrombin-deficient patients, and in 20% with prothrombin levels less than 1% of normal activity.[3,8] Soft tissue hematomas, bruising (60%), and hemarthroses (42%) are common.[8] The bleeding diathesis can present at circumcision in neonates, with trauma or surgery, or as easy bruising, epistaxis, heavy menstrual bleeding, or gastrointestinal hemorrhage. Heterozygotes occasionally have excessive bleeding with surgery or tooth extraction, but most are asymptomatic.[8] Bleeding tends to be less severe in dysprothrombinemia and some variants are particularly mild. Homozygosity for the Arg67His variant causes a significant reduction in plasma prothrombin activity (<20% of normal) but relatively few symptoms.

In the PT and aPTT assays, prothrombin is converted to thrombin by factor Xa in complex with factor Va on phospholipid surfaces (see Fig. 135.1B), and severe prothrombin deficiency will prolong the clotting time in both tests (see Chapter 127). Some PT and aPTT reagents are relatively insensitive to reductions in prothrombin, and mild deficiencies may be missed. The diagnosis is usually confirmed, and the degree of deficiency established, by a modified PT assay using prothrombin-deficient plasma. A prothrombin antigen level is needed to distinguish between hypoprothrombinemia (activity and antigen are equivalent) and dysprothrombinemia (activity is less than antigen). Prothrombin deficiency must be distinguished from deficiencies of fibrinogen, factor V, or factor X, which also prolong the PT and aPTT (see Chapter 127).

Prothrombin complex concentrates (PCCs) (see Table 135.3) are the preferred treatment for prothrombin deficiency. PCCs come in four-factor forms containing prothrombin, factors VII, IX and X (e.g., Kcentra), and three-factor forms (prothrombin, and factors IX and X, e.g., Profilnine). Four-factor concentrates often include heparin, antithrombin, and/or proteins C and protein S to reduce thrombotic risk. PCCs are derived from human plasma and undergo viral inactivation. They were originally approved for use in factor IX deficiency, and their activities are still standardized in factor IX units. Prothrombin activity in PCCs is comparable to, or higher than, the factor IX activity. Hemostatic levels of prothrombin are estimated to be 20% to 40% of normal for major surgery or trauma, but 10% to 15% may be adequate for milder challenges.[8] A dose of 20 to 30 factor IX units/kg usually produces plasma prothrombin levels of 20% to 30% of normal in a severely deficient patient. The half-life of prothrombin is ~3 days and dosing every 2 to 3 days can maintain adequate levels until healing is complete. Alternatively, one fourth of the loading dose each day should keep the level therapeutic (>10%). Prophylactic infusion of PCC every 5 to 6 days prevented spontaneous bleeding in one severely deficient patient. PCC administration has been associated with thrombosis, although a meta-analysis of studies using PCCs to reverse the effect of warfarin suggests the risk is less than 2%. Similar rates of thrombosis have been reported when PCCs are used to reverse direct oral anticoagulants. It is reasonable to maintain the factor VII, IX, and X levels at less than 150% of normal to reduce risk. Dental procedures or minor bleeding may respond to antifibrinolytic therapy. Prothrombin deficiency may also be treated with FFP for bleeding episodes or surgical intervention (15 to 20 mL/kg loading dose followed by 3 mL/kg/day). Because of the long half-life, additional doses may not always be needed. Cryoprecipitate is not a source of prothrombin and plasma prothrombin levels do not increase after infusion or inhalation of desmopressin (DDAVP).

Acquired Prothrombin Deficiency

Acquired prothrombin deficiency occurs with warfarin therapy, poisoning with rodenticides such as brodifacoum, vitamin K deficiency, liver disease, and DIC. In these situations, other coagulation factors are also reduced. Cephalosporins, particularly those with N-methylthiotetrazole side chains, can also decrease prothrombin levels.

There are no reports of neutralizing antibodies forming after replacement therapy in inherited prothrombin deficiency, consistent with patients having at least trace amounts of circulating prothrombin. Phospholipid-dependent anti-prothrombin antibodies are common in patients with lupus anticoagulants and/or the antiphospholipid syndrome (see Chapter 139). They do not compromise hemostasis. More rarely, patients with a lupus anticoagulant or systemic lupus erythematosus develop antibodies that enhance prothrombin clearance, leading to true deficiency. This acquired hypoprothrombinemia occurs primarily in children under 10 years of age, usually in association with lupus anticoagulants after a viral illness. The episodes typically resolve spontaneously, but excessive bleeding can occur.[10] Intravenous immunoglobulin has been effective in reducing prothrombin clearance in this population.[10] In contrast to lupus anticoagulants, which prevent correction of prolonged clotting times when patient plasma is mixed with normal plasma, the abnormal clotting time caused by acquired hypoprothrombinemia does correct.

Treatment of antibody-mediated acquired prothrombin deficiency associated with lupus anticoagulants in patients with autoimmune diseases often requires immune suppression, because the condition does not resolve spontaneously. Steroids are effective in most patients, although relapse is common during weaning or after stopping treatment. Treatment with azathioprine or cyclophosphamide has successfully eradicated the antibody. Rituximab also is effective and is likely the preferred therapy. In a rare case of quinidine-induced lupus anticoagulant with a concomitant antiprothrombin antibody, cessation of the drug led to spontaneous resolution of acquired prothrombin deficiency, but not the lupus anticoagulant. The low prothrombin activity in these patients may protect them from thrombosis related to their lupus anticoagulant, as suggested by reports of thrombosis after successful eradication of the antiprothrombin antibody.

INHERITED FACTOR V DEFICIENCY (OMIM 227400)

In 1943, Quick reported that a labile plasma factor distinct from prothrombin was required for coagulation. At the same time, Owren noted that a patient with a lifelong bleeding diathesis lacked a plasma factor that, unlike prothrombin, did not adsorb onto aluminum hydroxide. Owren's patient was deficient in the labile factor described by Quick, which is now called *factor V*. Moderate to severe inherited *factor V deficiency* (1% to 10% of normal plasma level) occurs in 1 in 1 million persons (see Table 135.1).[11] Full-length factor V is the 330,000-Dalton precursor of the cofactor *factor Va*, which facilitates prothrombin activation by factor Xa on phospholipid surfaces (see Fig. 135.1).[11] During coagulation, the B-domain of factor V is removed by thrombin or factor Xa to produce factor Va (Fig. 135.4). An ~250,000 Da form of factor V lacking 703 amino acids from the B-domain is a minor constituent of normal plasma (see Fig. 135.4). This truncated form, referred to as factor V-short, is the product of an alternatively spliced mRNA. Eighty percent of factor V in blood is in plasma, with the remainder in platelet α-granules. In humans, platelet factor V is primarily of plasma origin. Megakaryocytes take up the protein in a process requiring low-density lipoprotein receptor-related protein-1 (LRP-1) and convert it to a partially activated form (see Chapters 123 and 124).

Severe factor V deficiency is an autosomal recessive trait with undetectable (<1% of normal) plasma factor V. In moderate deficiency the level is between 1 and 10% of normal (see Table 135.2).[11] More than 150 factor V gene (*F5*) mutations have been described in factor V deficient patients. Frameshifts and splice variants are common and are distributed throughout the gene. Nonsense mutations show a predilection for the B domain while missense mutations cluster in the A2 and C2 domains, resulting in polypeptides that are degraded within the cell and low levels of plasma factor V antigen (CRM− deficiency). Only two *F5* mutations have been reported in which plasma antigen exceeds activity (CRM+ mutations) The Ala221Val (factor V New Brunswick) and His147Arg substitutions appear to reduce factor Va activity by affecting protein stability. A few patients with abnormalities specific to platelet factor V have been described (see Chapter 123). In the Quebec platelet disorder, an autosomal dominant condition with low platelet factor V and normal plasma factor V levels, excessive proteolysis of α-granule proteins is caused by overexpression of urokinase. Platelet factor V activity is also reduced in Factor V New York, but here the platelet factor V protein appears normal and the mechanism for the disorder is unknown. Combined factor V and factor VIII deficiency is caused by mutations in proteins required for secretion of both proteins (see "Combined Factor V and Factor VIII Deficiency").

The autosomal dominant East Texas bleeding disorder is caused by an A2440G substitution in *F5* exon 13 (factor V East Texas), that increases mRNA encoding factor V-short (see Fig. 135.4), leading to increased plasma levels of this truncated form of the protein. In this disorder plasma levels of tissue factor pathway inhibitor (TFPI), an important coagulation regulator, are 10-fold higher than normal. The B-domain of full-length factor V contains basic and acid regions that likely bind to each other (see Fig. 135.4). In factor V-short, the basic region is missing, leaving the acidic region free to bind TFPI. It is thought that TFPI-mediated inhibition of factor Xa and the factor VIIa-tissue factor complex contribute to symptoms in East Texas bleeding disorder. A similar bleeding disorder was observed in a Dutch family with a C2588G substitution in *F5* exon 13, leading to loss of 632 B domain amino acids (factor V Amsterdam). These patients also have markedly elevated TFPI levels.

Symptoms in patients with severe factor V deficiency are variable and the correlation between bleeding and plasma factor V levels is relatively weak (see Table 135.2).[11] Significant, and even life-threatening bleeding occurs, but the frequency tends to be less than in patients lacking factor VIII or factor IX. Several factors may contribute to the variability. Some patients with mild bleeding have sufficient platelet factor V to support thrombin generation. This implies that their factor V is unstable in plasma but can still be taken up by platelets. Patients with the most severe bleeding may lack plasma and platelet factor V. In one such individual treated with plasma, infused factor V was taken up by megakaryocytes and was detectable in platelets 2 weeks after it was no longer detectable in plasma. Many patients with factor V deficiency have reduced plasma TFPI levels that may partly offset the need for factor V. Mucosal bleeding is the primary abnormality in inherited factor V deficiency, with 60% of patients experiencing epistaxis, heavy menstrual bleeding, or oral bleeding. Hematomas and hemarthroses occur in up to 25% of patients,[11] but debilitating arthropathy is infrequent. Severe bleeding in the central nervous system or gastrointestinal tract occurs, but is rare.[11]

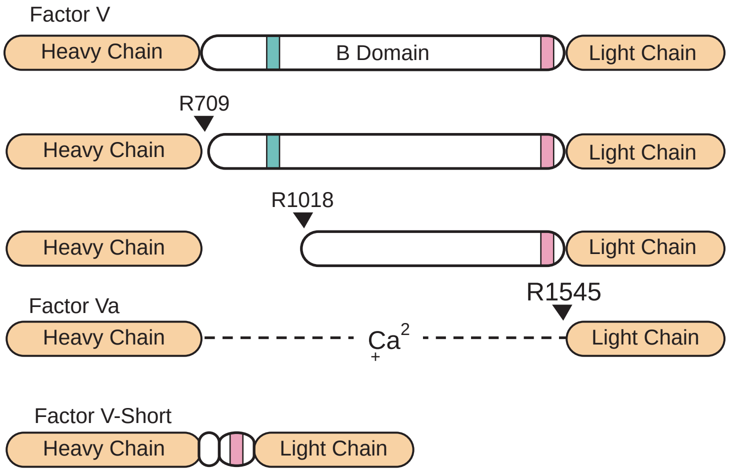

Figure 135.4 SCHEMATIC DIAGRAMS OF HUMAN FACTOR V AND FACTOR Va. In factor V, the heavy and light chains *(orange)* are separated by a central B domain (*white*, amino acids 710 to 1545) that contains a basic region (*blue*, amino acids 963 to 1008) and acidic region (*pink*, amino acids 1493 to 1537). Removal of the B domain by thrombin to generate factor Va involves sequential cleavages after Arginine 709, 1018, and 1545. Factor V-Short is the product of an alternatively spliced factor V mRNA that lacks residues 756 through 1458, which comprise most of the B domain including the basic region. In factor V-Short, the loss of the B domain basic region leaves the acidic region free to bind to tissue factor pathway inhibitor (TFPI).

Postpartum hemorrhage is common and there may be an increased incidence of miscarriage. Trauma, surgery, and dental extraction are associated with a high bleeding risk in untreated patients. Bleeding with surgery involving the urogenital tract, nose, or mouth may be particularly problematic because of high local fibrinolytic activity. Mild factor V deficiency (>10% of normal level) is not usually associated with excessive bleeding, although 10% to 15% of patients report some symptoms.

Thrombosis has been reported in factor V deficient patients. In most cases, the deficiency may not protect the patient. Indeed, except for deficiency of prothrombin or factor X, thrombosis has been reported in all severe coagulation factor deficiency states. However, the situation with factor V may be more complex. Mild to moderate factor V deficiency can occur in patients with the procoagulant polymorphism factor V Arg506Gln (factor V Leiden). If Arg506Gln and a mutation causing factor V deficiency are on opposite alleles (in-*trans*), most plasma factor V will have the Gln506 substitution. This is referred to as pseudo-homozygosity for activated protein C resistance, and it may substantially increase the risk of thrombosis beyond that typical for carriers of Arg506Gln (see Chapter 138). These patients usually do not bleed excessively, despite reduced plasma factor V antigen.

Factor V is required for normal prothrombin activation by factor Xa (see Fig. 135.1B). Therefore, factor V deficiency prolongs the PT and aPTT. The diagnosis and severity are usually established with a modified PT assay using factor V-deficient plasma (see Chapter 127). With severe deficiency, the template bleeding time may be prolonged, primarily in patients with concomitant reductions in platelet factor V. Patients with factor V deficiency should be tested for factor VIII deficiency so that the combined deficiency disorder is not missed (see "Combined Factor V and Factor VIII Deficiency"). In patients with East Texas bleeding disorder or factor V Amsterdam, the prolonged PT and aPTT are due to the inhibitory effects of TFPI and the PT and aPTT will not completely correct on mixing with normal plasma. The plasma TFPI level will be elevated, and factor V activity is usually normal.

FFP is the mainstay for treating bleeding and preparing for surgery in factor V deficient patients (see Table 135.3). The minimum factor V level required for hemostasis is 10% to 15% of normal.[11] This can be achieved in patients with less than 1% plasma factor V activity by administering 15 to 20 mL/kg FFP, followed by 5 mL/kg every 12 hours. A plasma level of 25% is recommended for major surgery. Estimates of the factor V plasma half-life vary, but 12 to 14 hours is assumed for replacement purposes. Infusing 20 mL/kg FFP over 3 to 4 hours before surgery, followed by 5 to 10 mL/kg every 12 hours is usually adequate. Infusions should be continued for 7 to 10 days to permit wound healing. Fluid overload from large volumes of FFP may be a problem in some patients. Plasma exchange has been used successfully to prepare factor V deficient patients at risk for fluid overload for surgery. Mucosal bleeding from the nose and mouth may respond to antifibrinolytic agents and superficial lacerations usually respond to local pressure. A factor V concentrate (manufactured by Kedrion) prepared from cryo-supernatant corrects clotting abnormalities in factor V deficient plasma in vitro, but it has not been extensively tested in patients. Cryoprecipitate is not a source of factor V and plasma levels do not respond to administration of DDAVP. Platelets contain factor V and may be particularly useful in patients with severe bleeding or with factor V inhibitors (see "Acquired Factor V Deficiency").[11] However, platelet transfusions are not recommended as routine first-line treatment because of the possibility of developing antiplatelet alloantibodies (see Chapter 123).

Heavy menstrual bleeding is common in factor V-deficient women. Symptoms can be managed with antifibrinolytic therapy (ε-amino caproic acid 50 to 60 mg/kg every 4 to 6 hours, or tranexamic acid 15 mg/kg every 6 to 8 hours), oral contraceptives, levonorgestrel-releasing intrauterine devices, replacement therapy, or surgical intervention (endometrial ablation or hysterectomy). Replacement should be adjusted to maintain a factor V level of 10% to 15% of normal. Factor V-deficient women may have significant bleeding with childbirth and should be treated in a similar manner.

Acquired Factor V Deficiency

Plasma factor V levels may be reduced along with other coagulation factors in patients with liver disease or DIC (see Chapter 137). Alloantibody inhibitors to factor V have been reported in a few severely deficient patients after replacement therapy and in patients treated with older topical bovine thrombin preparations that also contained bovine factor V. The latter situation occurs less frequently with newer recombinant human thrombin preparations. Acquired factor V deficiency caused by factor V autoantibodies has been reported in patients after surgery, blood transfusion, or therapy with β-lactam or aminoglycoside antibiotics, and in patients with cancer, myeloproliferative disorders, and autoimmune diseases. Rare patients with factor V deficiency in the setting of amyloidosis have been reported. Bleeding in patients with antibodies to factor V may be severe, although some patients are asymptomatic. When acquired factor V deficiency responds poorly to FFP infusion, antibodies that neutralize factor V activity may not be identifiable. Instead, it is likely that non-neutralizing antibodies that enhance the clearance of infused factor V are present.

Neutralizing factor V inhibitors cause prolongation of the PT and aPTT that does not correct when patient plasma is mixed with normal plasma. Factor V inhibitor titers are established using the Bethesda method used for inhibitors to factors VIII and IX (see Chapter 127). Unlike inhibitors to factor VIII, which typically take 1 to 2 hours to fully inactivate their target in a mixing study with normal plasma, factor V inhibitors inhibit factor V almost immediately.[12] The thrombin time should be normal, except when the inhibitor is induced by bovine thrombin, where antibodies against thrombin may also be present.

Most factor V inhibitors are transient. Steroids, immunosuppressive therapies, and exchange transfusions have been used in a few patients.[12] Platelet transfusion may be useful. Platelet factor V may either be protected from inhibition or be sufficiently different in structure from its plasma counterpart to not cross-react with antibodies directed against factor V. The effectiveness of recombinant factor VIIa (rfVIIa) and PCCs have not been clearly established. While the defect caused by factor V deficiency would hypothetically render therapy with factor VIIa ineffective, this agent has been used with apparent success in at least two patients with severe factor V deficiency requiring surgery.

INHERITED FACTOR VII DEFICIENCY (OMIM 227500)

Factor VII deficiency was first reported by Alexander and colleagues in 1951. Severe factor VII deficiency is the most common of the nonhemophilic coagulation factor deficiencies (see Table 135.1), with an estimated prevalence of 1 in 300,000 to 500,000 persons.[13] The heterozygote frequency may be ~1 in 350. *Factor VII* is the 50,000 Da precursor of the protease *factor VIIa*. Factor VII and VIIa bind to tissue factor and initiate coagulation through activation of factors X and IX (see Fig. 135.1A). Factor VII levels correlate weakly with clinical presentation (see Table 135.2). Factor VII activity levels of less than 10%, 10% to 20%, and greater than 20% have been proposed as criteria to classify deficiency as severe, moderate, or mild, respectively. However, many patients with levels less than 10% will not have significant bleeding, even with invasive procedures. Mice lacking factor VII develop normally in utero but succumb to bleeding at birth. An infant born lacking factor VII died from intracranial hemorrhage 12 days after birth, while another survived with replacement therapy. Thus, low levels of factor VII appear to be necessary to sustain life. Although factor VII deficiency is considered an autosomal recessive trait, bleeding symptoms are reported in up to 36% of patients with heterozygous deficiency. A classification system based on clinical presentation has also been proposed.

Nearly 300 factor VII gene (*F7*) mutations associated with factor VII deficiency have been described (www.factorvii.org and www.hgmd.cf.ac.uk). Most are missense mutations. Although most unique variants were identified in single families, some are widespread. In surveys of patients from Europe and Latin America, Ala244Val accounted for 84% of abnormal *F7* alleles in 88 unrelated Jewish patients, and in 14% and 7% of abnormal *F7* alleles in Germany and France, respectively. CRM+ variants are common. It is important to recognize that some factor VII variants demonstrate variable activity in PT assays, depending on the species of origin of the tissue factor used in the assay. The name "Factor VII Padua" has been applied to these variants, many of which have an Arg304Gln substitution that causes a significant defect in the interaction with rabbit tissue factor, but not with human or ox tissue factor. These variants are not associated with bleeding.

Factor VII deficiency may occur in combination with deficiencies of other vitamin K–dependent proteins (see "Combined Deficiency of Vitamin K–Dependent Proteins"). It may also present in combination with factor X deficiency from loss of both genes due to a chromosome 13q34 deletion. Factor VII deficiency has been reported in cases of trisomy 8 and in conjunction with abnormalities of bilirubin metabolism, intellectual impairment, microcephaly, epicanthus, cleft palate, and patent ductus arteriosus in the 13q deletion syndrome.

The clinical spectrum of bleeding in patients with factor VII deficiency is broad. Significant bleeding tends to be greatest with severe deficiency and patients with levels less than 1% of normal may have a syndrome similar to severe hemophilia, with spontaneous joint and soft tissue bleeding and hemarthrosis-related arthropathy.[13] The best predictor of bleeding risk seems to be the nature of bleeding (or its absence) at the time of diagnosis. Central nervous system hemorrhage is relatively common (4% to 17%). Patients with factor VII activity ≥ 10% of normal tend to have milder symptoms such as epistaxis, heavy menstrual bleeding, and bruising. Although most patients with factor VII levels ≥20% of normal have few symptoms, significant bleeding occasionally occurs. In one study, 36% of heterozygotes (factor VII activity 21% to 69%) reported bleeding problems involving skin and mucous membranes, while another study reported a greater risk for subcutaneous bleeding. One study with long-term data for heterozygotes and their family members found no statistically significant difference in bleeding between affected and unaffected family members, with affected individuals having factor activity levels between 35% and 65%. Excessive bleeding often complicates dental extraction and surgery on the oropharynx or urogenital tract in untreated patients, while abdominal surgery and hysterectomy are associated with fewer problems. This may reflect the different levels of fibrinolytic activity in these tissues. Postpartum bleeding is uncommon in factor VII-deficient women because factor VII levels rise late in pregnancy in all but the most severely deficient patients.[14] The risk of postpartum hemorrhage correlates poorly with FVII levels. This finding has led some to suggest that rfVIIa be used if there is excessive bleeding.

Factor VII deficiency has been associated with thrombosis.[15] A study of 33 reported cases of thrombosis (6 arterial, 27 venous) included 15 patients with molecular studies. Nearly all patients had other thrombotic risk factors, usually acquired, and four had inherited thrombophilia. Of the 15 patients with completed *F7* genotyping, 11 had either Arg304Gln (Factor VII Padua) or Ala294Val substitutions, both of which cause CRM+ deficiency. Those with factor VII Padua had no bleeding history, while mild bleeding was reported with pAla294Val. Treatment with vitamin K antagonists is problematic because the baseline PT is abnormal due to the mutation. Low-molecular-weight heparin or direct oral anticoagulants have been used successfully in small numbers of patients.

In factor VII deficiency, the PT is prolonged and the aPTT is normal (see Chapter 127). The diagnosis is confirmed, and the severity determined, with a modified PT assay using factor VII-deficient plasma. With sensitive thromboplastin reagents, the PT may be prolonged with factor VII levels at the lower end of the normal range. When assessing patients for factor VII deficiency, the composition of the thromboplastin reagent used to trigger clotting in the PT assay is important. Factor VII Padua-type variants interact poorly with the rabbit tissue factor-based thromboplastins widely used in North America. They function better with human tissue factor and best with ox tissue factor. The prevalence of factor VII Padua-type variants is low, but they have a worldwide distribution.

Major considerations when treating factor VII-deficient patients include the short plasma half-life of factor VII (3 to 4 hours), the relatively low recovery of infused material (possibly due to a large volume of distribution), and rapid clearance in children. A plasma factor VII level of 10% to 15% of normal is probably the minimum required for surgery, with 15% to 25% being adequate in most cases. Of 157 surgeries performed on 83 factor VII-deficient patients with a mean baseline activity of 5% who did not receive prophylaxis, 15.3% had bleeding complications. These data suggest that supplementing patients with baseline levels less than 10% should prevent bleeding. Factor replacement can be accomplished with several products (see Table 135.3). FFP is widely available, but its effectiveness is limited because of the large volumes required. Four-factor PCCs contain variable amounts of factor VII. However, these products are not favored, because they contain other vitamin K–dependent factors in higher concentrations than factor VII, which could increase the risk of thrombosis. rfVIIa is the preferred therapy for treating or preventing bleeding in factor VII deficiency. A registry of factor VII-deficient patients recorded the replacement therapy given for various bleeding events (hemarthrosis, soft-tissue hematomas, epistaxis, gum bleeding, menorrhagia, and others) and found that the majority responded adequately to a single relatively large dose of rfVIIa (60 μg/kg). Patients with heavy menstrual bleeding often required additional doses. Prophylaxis for invasive procedures may require treatment every 2 to 3 hours. In a study of 41 surgeries in 34 factor VII-deficient subjects receiving rfVIIa, bleeding occurred in only three instances, and in those the rfVIIa dose was considered low. The minimum treatment that adequately prevented bleeding was 13 μg/kg/dose, with no less than three doses given on the day of surgery. However, some patients may do well with less. In a report of patients with a mild to moderate risk of procedure-related bleeding, two doses on the day of surgery followed by once-daily dosing thereafter controlled bleeding. Continuous infusion rfVIIa has been used to cover surgery and may reduce the total amount of factor administered by 70% to 90% compared with bolus infusions. Caution should be exercised when treating patients with factor VII Padua variants with rfVIIa because replacement is often unnecessary and excessive replacement can increase the risk of thrombosis.

Patients with severe factor VII deficiency who have had life-threatening bleeding may benefit from secondary prophylaxis, particularly if bleeding involved the central nervous system (associated with 50% to 70% mortality). FFP and plasma-derived factor VII concentrates have been used, but rfVIIa is preferred. Despite its short half-life, rfVIIa can be effective at doses of 20 to 30 μg/kg given two to three times per week. The large volume of distribution for factor VII/VIIa may explain this effect. Not all bleeding episodes require factor replacement. Minor injuries may be controlled with local measures. Antifibrinolytic agents may be effective for minor bleeding, dental surgery, or procedures involving mucous membranes. Fibrin sealant may also be effective in some situations. Cryoprecipitate is not a source of factor VII and plasma levels do not respond to administration of DDAVP. An infant with severe inherited factor VII deficiency was cured with liver transplantation.

Acquired Factor VII Deficiency

Reduced levels of factor VII occur with warfarin therapy, poisoning with rodenticides such as brodifacoum, liver disease, DIC, biliary tract disease, vitamin K deficiency, and cephalosporin therapy. In most of these situations, other vitamin K–dependent factors are decreased, although the effect on factor VII is often greater because of its short half-life. Acquired factor VII deficiency has been reported as a paraneoplastic syndrome with atrial myxoma and Wilms tumor. Trisomy 8, which has been associated with inherited factor VII deficiency, has also been observed in a case of acquired factor VII deficiency in acute myeloid leukemia which resolved with chemotherapy and disappearance of the karyotypic abnormality. Other scenarios rarely associated with low factor VII include hematopoietic stem cell transplantation, aplastic anemia, and sepsis.

Alloantibody inhibitors to factor VII have been reported in deficient patients after replacement therapy. In a recent registry report, inhibitors were noted in 4 of 225 patients with activity levels less than 4% who received replacement therapy. All were high titer responders and three developed in infancy.

INHERITED FACTOR X DEFICIENCY (OMIM 227600)

Inherited *factor X deficiency* was first described by Duckert et al. in 1955 and was originally called *Stuart-Prower factor* after two patients who were missing the protein. Patient Stuart was thought to have factor VII deficiency, but mixing his plasma with factor VII-deficient plasma corrected the clotting defect. Patient Prower had multiple coagulation assay abnormalities, including a prolonged thromboplastin generation test and PT. The prevalence of severe factor X deficiency is ~1 in 1 million persons (see Table 135.1).[16] *Factor X* is a 58,000 Da protein that is the precursor of the protease *factor Xa*. Factor X may be activated by the factor VIIa/tissue factor complex or by a complex of factor IXa and factor VIIIa (see Fig. 135.1A). Factor Xa converts prothrombin to thrombin in the presence of factor Va, phospholipid, and calcium ions, and also converts factor V to factor Va.

Inherited factor X deficiency is an autosomal recessive trait. Factor X-deficient mice die in utero or shortly after birth from bleeding, indicating the protein is necessary for life. Humans with the severest form of factor X deficiency (activity <1% of normal) most likely have a trace of factor X in their plasma. More than 140 factor X gene (*F10*) mutations have been identified in factor X-deficient patients (http://www.hgmd.cf.ac.uk/ac/gene). Most are missense mutations, and many are associated with CRM+ variants.[16] A three-part classification system has been proposed. Type I deficiencies involve CRM− variants, and include patient Stuart (homozygous for Val298Met). Type II deficiencies are associated with CRM+ variants lacking activity and include patient Prower (compound heterozygote for Arg287Trp and Asp282Asn). Type III deficiencies include variants that are activated normally by Russell viper venom but not by factor VIIa/tissue factor or factor IXa/VIIIa (Factor X Friuli), variants defective only in activation by factor VIIa/tissue factor, variants defective only in activation by factor IXa/VIIIa, and variants with higher activity in chromogenic assays than in clotting assays. Factor X deficiency can be inherited with deficiencies of other vitamin K–dependent proteins (see "Combined Deficiency of Vitamin K–dependent Proteins") and in combination with factor VII deficiency when both genes are lost due to a chromosome 13 q34 deletion. In contrast to other vitamin K-dependent clotting factors (prothrombin, and factors VII and IX), there are no known factor X mutations associated with an increased risk of thrombosis.

A classification system for factor X deficiency has been proposed based on plasma activity (severe, <10%; moderate, 10% to 40%; mild, >40% of normal activity) (see Table 135.2). Bleeding in factor X deficiency is severe and occurs earlier in life in patients with the lowest plasma levels (<1%). There is an impression that factor X-deficient patients bleed more severely than patients with other rare inherited coagulopathies. In a series of 102 factor X-deficient patients, the most frequent symptom was easy bruising (55%) followed by hematoma (43%). Epistaxis and hemarthrosis were common. Intracranial hemorrhage was seen in patients homozygous for the pGly380Arg mutation. Among homozygotes, hemarthrosis was common, and all women suffered from heavy menstrual bleeding. Umbilical stump bleeding occurred in 28% of newborns. Moderate to mildly affected persons (activity >10%) may have increased bruising or bleeding with trauma. While heterozygotes tend to be asymptomatic, up to one third may have excessive bleeding from mucous membranes with invasive procedures or with childbirth.

Factor X is a component of the common pathway of coagulation (see Fig. 135.1B). Its absence prolongs the PT and aPTT, and must be distinguished from deficiencies of fibrinogen, prothrombin, or factor V. Definitive diagnosis and determination of severity are established using a modified PT or aPTT assay with factor X-deficient plasma. Some factor X variants preferentially prolong either the PT or the aPTT.

Factor X-deficient patients are treated with FFP, PCC, or newer plasma-derived factor X concentrates for most bleeding episodes (see Table 135.2).[2] The half-life of factor X is 20 to 40 hours. A trough level of 10% to 20% is usually sufficient for hemarthroses and soft tissue bleeding. FFP administered as a loading dose of 10 to 20 mL/kg followed by 3 to 6 mL/kg every 12 to 24 hours usually keeps trough levels above 10% to 20%.[16] Higher factor X levels may be required for severe bleeding or surgery, and accumulation of factor X in plasma can be achieved by increasing the transfusion frequency to every 12 hours. PCCs with a factor X:IX ratio of ~1:1 will increase plasma factor X levels by 1.5% for each factor IX unit/kg body weight. A dose of 15 to 20 factor IX units/kg every 1 to 2 days has been suggested for major surgery.[16] The factor X concentrate Coagadex is administered at a dose of 25 to 40 IU/kg twice weekly for prophylaxis. For control of bleeding, once-daily administration of 25 to 30 IU/kg is recommended. For surgery, the manufacturer suggests preoperative factor X levels of 70 to 90 IU/dL (70% to 90% of normal activity (see https://www.coagadex.com/download/coagadex-pi.pdf), which is a rather high level, based on data from a limited number of patients. While thrombosis has not been reported in patients with inherited factor X deficiency, there is a risk of thrombosis or DIC with PCC use, and it is recommended that plasma factor X levels greater than 50% of normal be avoided. Factor X levels rise modestly in pregnancy, but severely affected patients require prophylaxis with invasive procedures and at delivery to prevent hemorrhage. A factor X level of 20% to 40% is recommended. For patients with severe factor X deficiency and recurrent hemorrhage, prophylactic PCC or factor X concentrate is effective.[16] Minor bleeding can be treated with local measures and/or antifibrinolytics. Cryoprecipitate lacks factor X, and DDAVP infusion does not affect factor X levels. Severe factor X deficiency was cured by liver transplantation in a child.

Acquired Factor X Deficiency

Acquired factor X deficiency occurs with warfarin therapy, poisoning with rodenticides such as brodifacoum, vitamin K deficiency, liver disease, and DIC, all of which reduce levels of other coagulation factors. Factor X deficiency has also been reported with malignancies, infections, burns, proteinuria, and medications.

Acquired factor X deficiency may accompany systemic amyloidosis, occurring in 8.7% to 14% of patients with AL amyloidosis.[17] Factor X binds to amyloid fibrils, which reduces the plasma half-life of the protein. It can be difficult to distinguish this condition from inherited factor X deficiency in the laboratory because factor X-dependent assays correct after mixing with normal plasma in both conditions. The absence of a lifelong bleeding disorder, findings of a serum M-protein, signs of amyloidosis, and histologic confirmation of amyloid in tissues point toward AL amyloidosis. A poor response to factor X infusion in the absence of an inhibitor also distinguishes the conditions.

Patients with acquired factor X deficiency and amyloidosis have variable responses to infusions of products containing factor X rendering individual pharmacokinetic studies of factor X replacement therapy important. Treatment may include chemotherapy, splenectomy, plasma exchange, PCCs, activated factor VIIa or factor X concentrate. Optimal hemostatic management for invasive procedures has not been determined. In one series, complications occurred in only 13% of procedures and there was a poor correlation between the risk for bleeding and the factor X level.

As with prothrombin deficiency, there are no reports of acquired alloantibody inhibitors to factor X after replacement therapy in patients with inherited factor X deficiency, consistent with the notion that these patients have trace amounts of plasma factor X at baseline. There are rare reports of acquired autoantibody factor X inhibitors, most of which resolve after treatment of underlying conditions.

INHERITED FACTOR XI DEFICIENCY (OMIM 264900)

In 1953, Rosenthal and colleagues described members of a family with abnormal hemostasis, prolonged time to clot formation in glass tubes, and a normal PT. In mixing studies, patient plasma shortened the clotting times of hemophilia A and B plasmas, indicating that the missing factor was distinct from factors VIII and IX. Unlike the X-linked hemophilias, the new disorder (sometimes called hemophilia C) was transmitted as an autosomal trait. The missing factor was called *plasma thromboplastin antecedent* and subsequently *factor XI*. Early studies estimated that severe *factor XI deficiency* (<15% of normal plasma level) occurs in 1 per million persons (see Table 135.1); however, recent exome-based analyses indicate higher frequencies of 20.3 in 10^6 in East Asians, 12.9 in 10^6 in non-Finnish Europeans, 4.6 in 10^6 in persons of Latin origin, and 2 in 10^6 in Africans and South Asians.[18] The condition is most common in persons of Ashkenazi Jewish ancestry (incidence 1 in 450).[18] Factor XI is the 160,000 Da precursor of the protease *factor XIa*, which contributes to clotting by activating factor IX (see Fig. 135.1A). The protein is a homodimer,[18] a feature that has implications for inheritance of factor XI deficiency. Factor XI is activated by factor XIIa in the aPTT assay (see Fig. 135.1B); however, it is probably activated in vivo by other proteases such as thrombin (see Fig. 135.1A), because factor XII deficiency does not cause abnormal bleeding.

Factor XI deficiency in the Jewish population is an autosomal recessive condition, with two point mutations in the factor XI gene (*F11*) accounting for greater than 90% of mutant alleles. Glu117Stop is found in Jewish patients from different ethnic backgrounds and in non-Jewish patients (particularly South Asians) and is at least 2500 years old. Homozygotes lack plasma factor XI protein. Phe283Leu occurs primarily in Jews of European ancestry and is likely of more recent origin. It causes a defect in dimer formation and results in poor secretion. Homozygotes have ~10% of normal plasma factor XI activity. Compound heterozygotes for Glu117Stop and Phe283Leu have ~3% normal activity, while heterozygotes for either mutation have activities of 50% to 60%. The allele frequencies of Glu117Stop and Phe283Leu in Ashkenazi Jews (2.2% and 2.5%, respectively) indicate a carrier frequency for an abnormal factor XI allele of ~5%.

More than 250 human *F11* mutations have been identified (http://www.hgmd.cf.ac.uk/, www.factorxi.org), in addition to Glu117Stop and Phe283Leu. Several are recurrent and ethnic-specific. For example, a Phe223Leu substitution accounts for 23.5% of mutated alleles in Africans, while Gln263Stop and Leu424Cys-fs-Stop are responsible for 28.2% and 20.5% of mutations in East Asians, and Ala412Thr represents 25% of mutations in persons of Latin origin.[18] In most deficient patients, factor XI activity and antigen are comparably reduced (CRM− deficiency). CRM+ mutations are rare. A three-category scheme has been proposed for classifying CRM− factor XI deficiency. Category one contains mutations that prevent protein synthesis (e.g., Glu117Stop), while mutations in category two interfere with dimer formation (e.g., Phe283Leu). Inheritance in both categories follows a recessive pattern because mutant polypeptides do not interfere with the product of the normal *F11* allele in heterozygotes. Category three includes mutations that impair secretion but do not prevent dimer formation (e.g., Gly400Val). In heterozygotes, mutant and wild type polypeptides form non-secretable heterodimers, trapping normal protein in the cell. This phenomenon likely accounts for families in which severe to moderate factor XI deficiency appears to be a dominant trait.

Bleeding in severe factor XI deficiency is usually injury-related and occurs most frequently in tissues with robust fibrinolytic activity, such as the oral and nasal cavities and the urinary tract.[18] Injury to these areas causes excessive bleeding in two-thirds of patients, regardless of genotype. Bleeding with injury at other locations is less frequent and tends to occur in those with the lowest factor XI levels.[18] Bleeding may start at the time of injury or be delayed by hours, and oozing from tooth extraction may persist for days. Excessive bleeding with skin laceration, circumcision, appendectomy, and orthopedic surgery is infrequent. Spontaneous bleeding, except for heavy menses, is uncommon. In clinical trials evaluating factor XI inhibitors for thromboprophylaxis after knee replacement surgery, bleeding was uncommon even in those with less than 5% factor XI activity before or after surgery.

Bleeding correlates poorly with plasma factor XI activity (see Table 135.2). Patients with severe deficiency may not bleed excessively, even with surgery, and a patient may exhibit different bleeding tendencies over time. Opinions differ regarding the bleeding risk associated with mild deficiency (plasma level 20% to 50%). Some studies describe minimal bleeding with tooth extraction, tonsillectomy, nasal surgery, and urologic surgery, while others report

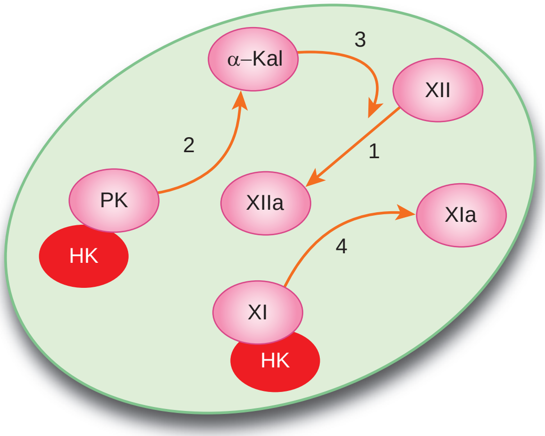

Figure 135.5 CONTACT ACTIVATION. In the aPTT assay, contact activation is initiated by conversion of factor XII (XII) to factor XIIa (XIIa) (reaction 1) when plasma is exposed to a negatively charged surface *(light green disk)*. Factor XIIa converts prekallikrein (PK) to the active protease plasma kallikrein (Kal) (reaction 2), and kallikrein reciprocally activates additional factor XII (reaction 3). Factor XIIa initiates coagulation through conversion of factor XI (XI) to factor XIa (XIa) (reaction 4). PK and factor XI require high molecular weight kininogen (HK) to bind properly to the surface. Factor XIa ultimately promotes thrombin generation and fibrin clot formation through activation of factor IX (see Fig. 135.1).

difficulty distinguishing severe and mild deficiency on clinical grounds. In a study of 45 families, the odds ratios for excessive bleeding were 13.0 and 2.6 for homozygotes and heterozygotes respectively. Thus, mild deficiency may confer a slightly increased risk for bleeding, but considerably less that in severe deficiency. One study indicated that ristocetin cofactor activity is significantly lower in symptomatic patients with heterozygous factor XI deficiency, compared with non-bleeders, suggesting that von Willebrand factor levels influence bleeding propensity. Thrombin generation and fibrinolysis assays have shown promise in predicting the bleeding propensity in factor XI deficiency, but this requires confirmation in larger studies.

In the aPTT assay, factor XI is bound to the contact surface through high molecular weight kininogen and is converted to factor XIa by factor XIIa (see Fig. 135.1B and Fig. 135.5). Factor XIa then activates factor IX. Therefore, factor XI deficiency prolongs the aPTT, but not the PT. Diagnosis and severity are established by a modified aPTT assay using factor XI-deficient plasma. The aPTT is often normal in mild (heterozygous) factor XI deficiency.

Perioperative therapy should be individualized for factor XI-deficient patients (see box on Managing Factor XI–Deficient Patients). In situations where replacement of factor XI is deemed appropriate, FFP or factor XI concentrate (Hemoleven or FXI Concentrate; see Table 135.2) have been used.[1,2,18,19] Plasma exchange has been used in some cases to avoid fluid overload. Cryoprecipitate does not contain factor XI. The half-life of factor XI is 45 to 52 hours, facilitating daily or every-other-day dosing. Hemoleven has orphan drug-status in the United States. A 3-year post-marketing analysis of the concentrate indicated it was effective for treating bleeding and as prophylaxis for surgery, invasive procedures, and pregnancy.[19] In the past, factor XI concentrate use could be associated with thrombosis and DIC, mostly in older patients with cardiovascular disease receiving doses greater than 30 units/kg.[19] More recent analyses suggest that patients receiving 20 to 30 units/kg may still have thrombotic events. This has led to a recommendation that initial doses do not exceed 10 to 15 U/kg. Concentrates should be used sparingly (or avoided) in patients with a history of thrombosis or risk factors for thrombosis,[1,2] and antifibrinolytic therapy should probably not be used concomitantly with concentrate. There has been a shift in management strategy for factor XI-deficient patients at some centers, with less reliance on factor replacement and greater use of rfVIIa and antifibrinolytic drugs (see box on Managing Factor XI–Deficient Patients). rfVIIa at relatively low doses (10 to 15 μg/kg), with or without antifibrinolytic therapy, was found to be effective in factor XI-deficient patients with alloantibody inhibitors against factor XI, and similar strategies were subsequently used successfully in deficient patients without inhibitors.[20] The bispecific antibody emicizumab, which is used in patients with hemophilia A with neutralizing inhibitors, enhances coagulation in factor XI–deficient plasma, but has not been tested in factor XI–deficient patients.

MANAGING FACTOR XI–DEFICIENT PATIENTS

Selecting treatment for patients with factor XI deficiency is challenging because of the poor correlation between symptoms and plasma factor levels. While patients of Jewish ancestry with severe deficiency have more bleeding problems than those with mild deficiency, this does not appear to hold for the general population. When preparing patients with severe factor XI deficiency (factor XI level <15 of normal) for an invasive procedure it is important to keep in mind that (1) a negative bleeding history does not indicate a low risk with subsequent procedures, (2) certain procedures are associated with lower risk of bleeding than others, and (3) patients with very low factor XI levels (<1%) frequently develop neutralizing inhibitors after replacement therapy. These observations have led to refinements in treatment recommendations that rely less on factor replacement and more on antifibrinolytic therapy and rfVIIa.

Antiplatelet drugs should be stopped 1 week before surgery. The prothrombin time and platelet count should be normal, and the possibility of co-existing hemostatic abnormalities investigated. Patients with factor XI levels greater than 40%–50% of normal generally do not experience abnormal bleeding and a history of excessive bleeding in such an individual suggests other hemostatic abnormalities are present. If the patient has been exposed to factor XI in the recent past, the possibility that a neutralizing inhibitor is present should be considered.

Traditionally, factor replacement has been used for major surgery in most factor XI–deficient patients, with treatment initiated prior to the procedure. Patients undergoing surgery on areas at high risk for bleeding such as the oropharynx, nasopharynx, or urinary tract are treated with FFP or factor XI concentrate to keep the plasma trough factor XI level greater than 40% of normal for at least 7 days. Administering FFP at 15 mL/kg every 1–2 days is the most common way to achieve this. A similar strategy has been applied for patients undergoing neurosurgery, head and neck surgery, cardiothoracic procedures, and major abdominal or pelvic surgery. For nasal surgery and oral procedures such as tonsillectomy, supplementing FFP with antifibrinolytic therapy should be considered. Antifibrinolytics must be used with caution in patients receiving factor XI concentrate because of the potential for thrombotic events. For prostatectomy and other surgery on the lower urinary tract, flushing the bladder with saline containing an antifibrinolytic agent may be beneficial. For some minor surgeries, patients may receive replacement to maintain levels of 30% for 5 days. However, a “Wait and See” strategy in which replacement is withheld unless bleeding occurs appears to be appropriate for circumcision, appendectomy, some orthopedic surgery, and with normal vaginal deliveries. In a phase II trial in which antisense oligonucleotide therapy was used to reduce plasma factor XI as prophylaxis to prevent venous thrombosis with knee arthroplasty, patients underwent surgery with factor XI levels as low as a few percent of normal without excessive bleeding. This demonstrates that factor XI probably plays a minor role in hemostasis during certain types of procedures.

Low doses of recombinant factor VIIa (rFVIIa, 15 to 30 μg/kg) administered every 2–4 h in conjunction with antifibrinolytic therapy has been used successfully instead of replacement therapy in patients without factor XI inhibitors undergoing surgery. In some centers, rFVIIa-based strategies are now preferred over replacement therapy for most indications. Benefits of this approach include the smaller volumes of infusion and the avoidance of induction of anti-factor XI alloantibodies, which frequently develop in patients with very low plasma factor XI levels (<1% of normal) after replacement therapy. In patients with factor XI alloantibodies, hemostasis remained intact after major surgery (including an aortic dissection) with administration of a single dose of rFVIIa (15 to 30 μg/kg) followed by antifibrinolytic therapy. The higher doses of rFVIIa typically used to treat patients with factor VIII inhibitors are not required in factor XI-deficient patients (with or without inhibitors) and should be avoided to keep the thrombotic risk low. In pregnancy, there are few data evaluating the safety of epidural anesthesia in the absence of some sort of coverage. While many physicians consider this situation an indication for factor replacement, coverage with a single dose of rFVIIa has been used successfully.

Alternatives to factor replacement are recommended in several situations. Tooth extraction or skin biopsies can be managed with anti-fibrinolytic drugs alone (ε-amino caproic acid 4 g loading dose and 2 g every 6 h thereafter or tranexamic acid 1300 mg every 6 h), starting 12 h before the procedure and continuing for 7 days. Dental procedures such as scaling or root canal can be performed safely using ε-amino caproic acid or tranexamic acid mouthwash prepared from the intravenous formulation three to four times daily with or without systemic antifibrinolytic therapy. Fibrin sealants can be used in place of fibrinolytic therapy for skin biopsy or resection of skin lesions.

Patients with factor XI deficiency can experience thromboembolic episodes. Aspirin or clopidogrel can be used in factor XI-deficient patients with myocardial infarction or other manifestations of atherosclerosis. Direct oral anticoagulants (DOACs) may be used for atrial fibrillation or venous thromboembolism. If these conditions are treated with warfarin, the INR should preferably not exceed 2.5.

Circumcision, orthopedic surgery, and appendectomy carry low bleeding risks in patients with severe factor XI deficiency, and replacement can often be withheld unless bleeding occurs.[18] A similar “wait and see” approach has been proposed for factor XI–deficient women during labor and delivery, which is associated with a relatively low (~ 20%) rate of excessive bleeding.[21] However, others have advocated replacement for childbirth. Mild factor XI deficiency (plasma level 20% to 70% of normal) does not appear to increase bleeding risk during childbirth. rfVIIa has been used to cover epidural block in deficient women during labor and delivery.[21] Dental procedures such as tooth extraction can be covered with antifibrinolytic therapy. The effectiveness of DDAVP in mild factor XI deficiency is not established. There are a few reports that levels increase in response to this drug.

Acquired Factor XI Deficiency

Factor XI levels are reduced in liver disease and DIC but are not affected by vitamin K deficiency or warfarin therapy. Mild to moderate factor XI deficiency occurs in ~25% of patients with Noonan syndrome and is common in carbohydrate-deficient glycoprotein syndrome, a group of inherited disorders involving defects in glycosylation of secreted glycoproteins.

Alloantibody inhibitors to factor XI are common after replacement therapy, particularly in patients with no circulating factor XI. In one study, one-third of individuals homozygous for Glu117Stop developed neutralizing antibodies, often after a single exposure to plasma. While factor XI-deficient patients with inhibitors do not usually have increased spontaneous bleeding, the antibodies interfere with replacement therapy during surgery. rfVIIa may be used in patients with factor XI antibodies as coverage for surgery. Some physicians prefer it to factor replacement, even in patients without inhibitory antibodies, to avoid inducing alloantibody formation.[20]

Factor XI autoantibodies have been reported in patients with autoimmune disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis, Crohn disease, or membranoproliferative glomerulonephritis) and malignancies (e.g., chromic myelomonocytic and lymphocytic leukemia, or gastrointestinal adenocarcinoma). Significant bleeding is rare, but if it occurs can be treated with rfVIIa and/or antifibrinolytic therapy.

DEFICIENCIES OF FACTOR XII, PREKALLIKREIN OR HIGH MOLECULAR WEIGHT KININOGEN

Factor XII, prekallikrein, and high molecular weight kininogen (HK) form the plasma kallikrein-kinin system, a mechanism for generating vasoactive kinins such as bradykinin. The KKS is required for normal factor XI activation in the "contact phase" that initiates coagulation in the aPTT assay (see Figs. 135.1B and 135.5). Patients lacking a KKS component have a prolonged aPTT, but do not have abnormal hemostasis. While no specific therapies are required to prepare patients deficient in factor XII, prekallikrein, or HK for invasive procedures, the conditions must be identified to distinguish them from deficiencies of factors VIII, IX, or XI, which also prolong the aPTT, but do cause abnormal hemostasis.

Factor XII Deficiency (OMIM 234000)

In 1955, Ratnoff and Colopy described asymptomatic individuals with a novel abnormality of surface-induced coagulation. The missing plasma component was called *Hageman factor* after the index case and later designated *factor XII*. The incidence of severe *factor XII deficiency* is not known, as many deficient persons likely go undiagnosed. *Factor XIIa*, the activated form of factor XII, is an 80,000 Da protease that activates factor XI and prekallikrein in the contact phase of the aPTT assay (see Fig. 135.5).[22] A C/T polymorphism referred to as 46 C/T (or -4C/T) in the 5′-untranslated region of the factor XII gene (*F12*) strongly influences plasma factor XII levels. The frequency of *F12* 46T is high (73%) in Japanese and Han Chinese individuals, who have lower factor XII levels than members of other ethnic groups such as Caucasians (20%).

More than 50 *F12* gene mutations have been reported in factor XII-deficient individuals (http://www.hgmd.cf.ac.uk/ac/gene). Activity and antigen are usually reduced in parallel (CRM− deficiency), and CRM+ variants are rare. Factor XII deficiency is not associated with spontaneous or excessive post-traumatic bleeding and most cases are identified by the incidental finding of a prolonged aPTT. There is conflicting literature regarding an association between factor XII deficiency and thrombosis. Two studies reported inverse relationships between plasma factor XII levels and the risk for cardiovascular events; however, most analyses indicate no increased thrombotic risk for severe or partial deficiency. A meta-analysis examining the *F12* 46 C/T polymorphism suggests that a correlation with venous thrombosis or myocardial infarction, if present, is weak. Low factor XII levels have been linked to pregnancy loss or failure of in vitro fertilization. Interestingly, factor XII deficient mice do not exhibit abnormalities in reproduction. It is possible that anti-factor XII antibodies that are often associated with antiphospholipid antibody syndrome, rather than true factor XII deficiency, are responsible for pregnancy-related complications in humans. A few *F12* mutations have been associated with detrimental phenotypes. Arginine or lysine substitutions for Thr309 introduce a novel cleavage site for several proteases resulting in a truncated factor XII protein that accelerates prekallikrein activation and bradykinin generation.[22] This leads to a form of hereditary angioedema, characterized by episodic soft tissue swelling primarily involving the face, airway, limbs, or gastrointestinal tract. A Trp268Arg substitution also leading to a truncated form of factor XII has been associated with an autoinflammatory syndrome.[22]

Factor XIIa initiates the sequence of reactions required for clot formation in the aPTT assay (see Fig. 135.3). Factor XII undergoes autocatalytic conversion to factor XIIa on contact surfaces. Factor XIIa then activates prekallikrein to α-kallikrein, which activates additional factor XII (see Fig. 135.3). Factor XIIa also activates factor XI to factor XIa. In severe factor XII deficiency, the aPTT is very long (greater than the assay upper limit). Definitive diagnosis is established using a modified aPTT with factor XII-deficient plasma. Antiphospholipid antibodies may disproportionately affect factor XII measurements in aPTT-based assays. Factor XII antibodies are present in up to half of plasmas with anti-phospholipid antibodies and may account for many cases of presumed mild factor XII deficiency.

Prekallikrein Deficiency (OMIM 229000)

In 1965, Hathaway and coworkers described asymptomatic members of a family with long plasma clotting times that corrected on prolonged incubation with glass. The missing plasma component, initially called *Fletcher factor* after the index cases, was subsequently shown to be *prekallikrein*. Prekallikrein is the 95,000 Da precursor of the protease *plasma kallikrein*, which activates factor XII and cleaves HK to release bradykinin.

Severe *prekallikrein deficiency* is an autosomal recessive trait, presenting in the homozygous or compound heterozygous forms with plasma prekallikrein levels that are usually less than 1% of normal. The condition was thought to be rare; however, recent work indicates it is relatively common in individuals of African ancestry,[23] with a causative frameshift mutation (451dupT) in the prekallikrein gene (*Klkb1*) present in 1% to 1.5% of such individuals. This implies a prevalence for severe CRM− deficiency of ~1:5000 to 7000 in this population. In comparison, the Cys548Tyr substitution in persons of European ancestry has an allele frequency of ~0.1%.[23] These findings are consistent with older observations that Black PK-deficient individuals are usually CRM−, while PK-deficient individuals of European descent or Japanese individuals are usually CRM+. Mild prekallikrein deficiency is probably missed because a low level of prekallikrein activity is sufficient to normalize clotting in most aPTT assays. Partial prekallikrein deficiency (plasma level 10% to 50% of normal) is seen with severe deficiency of HK. This is likely due to increased clearance because most prekallikrein normally circulates in a complex with HK.

Severe prekallikrein deficiency presents as a prolongation of the aPTT in a person without a history of excessive bleeding. While thrombotic events have been described in deficient patients, it is not clear that the deficiency is contributory. Indeed, studies in mice suggest that reducing prekallikrein levels attenuates thrombus formation. Recent analyses raise the possibility that the incidence of hypertension is increased in prekallikrein deficient individuals, possibly related to reduced bradykinin generation.

In the aPTT, prekallikrein is converted to kallikrein by factor XIIa. Kallikrein activates additional factor XII (see Fig. 135.5). Severe prekallikrein deficiency causes a prolonged aPTT, and the diagnosis is confirmed using a modified aPTT with prekallikrein deficient plasma. The prolonged aPTT in prekallikrein deficiency may be shortened by increasing the incubation time with the contact reagent, which allows factor XII autoactivation to compensate for the prekallikrein deficiency. This distinguishes prekallikrein deficiency from deficiencies of factors VIII, IX, XI XII, and HK, where the prolonged aPTT does not correct with prolonged incubation. aPTT reagents that use ellagic acid as the contact activator are relatively insensitive to prekallikrein and may fail to identify some severely deficient patients.

High Molecular Weight Kininogen Deficiency (OMIM 228960)

In 1974, Schiffman and Lee reported that a plasma factor distinct from prekallikrein is required for factor XI activation by factor XIIa. In 1975, asymptomatic individuals from three families were described with in vitro abnormalities of coagulation, fibrinolysis, and kinin generation who lacked the unknown factor. The condition, originally named for the affected families (*Fitzgerald trait, Williams trait, and Flaujeac trait*), was subsequently determined to be due to deficiency of *high molecular weight kininogen (HK)*. The disorder appears to be rare. HK is a 110,000 Da multi-domain glycoprotein containing the vasoactive peptide bradykinin. Prekallikrein and factor XI circulate in plasma in complex with HK. In humans, low molecular weight kininogen (LK) and HK are products of a single kininogen gene (*Kng1*). LK is not required for in vitro coagulation. HK deficiency is an autosomal recessive trait. Depending on the genetic abnormality, patients may have isolated HK deficiency or combined HK and LK deficiency. HK deficient patients are usually identified by the incidental finding of a prolonged aPTT and they do not bleed excessively.

In the aPTT assay, HK facilitates binding of prekallikrein and factor XI to the contact surface, enhancing their activation by factor XIIa (see Fig. 135.5). Severe deficiency is characterized by a very prolonged aPTT. Definitive diagnosis is established using a modified aPTT with HK-deficient plasma. Partial prekallikrein deficiency is common in severe HK deficiency, likely due to increased catabolism of prekallikrein when it is not in complex with HK.

INHERITED FACTOR XIII DEFICIENCY (OMIM 134570 [A SUBUNIT] AND 134580 [B SUBUNIT]

In 1944, Robbins demonstrated that fibrin formed from purified fibrinogen was soluble in weak acid, while fibrin formed in the presence of serum or plasma was not. He proposed that plasma contained a *fibrin-stabilizing factor*. In 1960, Duckert and colleagues described the first patient with deficiency of this factor, which was subsequently designated *factor XIII*. The incidence of severe *factor XIII deficiency* is estimated at 1 in 2 million (see Table 135.1).[24] In blood, factor XIII is distributed between plasma and platelets, with a small amount in monocytes. The plasma protein is a 330,000 Da tetramer composed of two catalytic A subunits and two carrier B subunits. Factor XIII in platelets, monocytes, and placenta has only A subunits. The A subunit of the plasma protein appears to be synthesized primarily in hematopoietic cells, while the B subunit is synthesized in the liver. Factor XIII is converted to the transglutaminase *factor XIIIa* by thrombin. Factor XIIIa catalyzes formation of γ-glutamyl-ε-lysyl bonds between fibrin monomers (see Fig. 135.1A), resulting in a fibrin mesh resistant to dissolution in mild acid or urea (see Chapters 121 and 125). Factor XIIIa also cross-links fibrin to extracellular matrix and cytoskeletal proteins, thereby enhancing clot adherence to injury sites.

Inherited factor XIII deficiency is an autosomal recessive condition.[24] The current classification scheme recognizes factor XIII-A and factor XIII-B defects. Factor XIII-A deficiency is divided into type I (quantitative) and type II (qualitative) deficiencies. In patients with apparent combined FXIII-A and -B deficiency, low levels of the A subunit are likely the result of rapid clearance because of the absence of the stabilizing B subunit. Most cases of inherited factor XIII deficiency are due to mutations in the A subunit gene, with less than 5% in the B subunit gene.[24] More than 100 different mutations have been reported in the factor XIII-A gene (*F13A1*), with about 20 mutations in the factor XIII-B gene (*F13B*).[4] The incidence of *F13A1* and *F13B* mutations affecting plasma activity may be higher than suspected, as screening tests tend to pick up only severely decreased plasma activity (<5% of normal). A few mutations show evidence of a founder effect, with the *F13A1* IVS5-1 G>A splice-site defect and Arg661Stop nonsense mutations each identified in ten apparently unrelated individuals.[4]

Delayed bleeding from the umbilical stump occurs in 80% to 90% of newborns with severe factor XIII deficiency (activity ≤5% of normal) and is considered a diagnostic feature of the disorder. Ecchymoses, soft tissue hematomas, and prolonged bleeding with trauma are common, and recurrent soft tissue bleeding may lead to formation of hemorrhagic cysts (pseudotumors).[24] Hemarthroses is less frequent than in factor VIII or IX deficiency. Bleeding that is delayed 12 to 36 hours post-injury is characteristic of factor XIII deficiency, although hemorrhage is immediate in some cases. Bleeding at the time of invasive procedures may be minimal, but delayed hemorrhage often occurs. Intracranial bleeding is more frequent in factor XIII deficiency than in other inherited coagulation disorder, with an incidence as high as 40% to 60% in the first two decades of life.[4,24] This justifies prophylactic replacement. Delayed wound healing has been observed, possibly related to a defect in angiogenesis. Spontaneous abortions occur with most pregnancies in untreated factor XIII–deficient women,[24] possibly due to abnormal formation of the cytotrophoblastic shell and poor attachment of the placenta to the uterus. The issue of excessive bleeding in patients with milder (>5% of normal) factor XIII deficiency is more controversial. In at least two reports, patients heterozygous for factor XIII deficiency reported excessive bleeding, although the studies lacked control groups. Experience with pregnant women with severe factor XIII deficiency indicates that the factor XIII level needs to be higher than 10% to reliably prevent pregnancy loss.[24,25] This suggests that clinically significant hemostatic problems may occur in patients with levels between 5% and 10% of normal.

The PT and aPTT measure time to fibrin clot formation, but do not assess clot stability. Results of these assays are normal in factor XIII-deficient patients. Clots formed in plasma lacking factor XIII are soluble in 5 M urea or 1% monochloroacetic acid, while clots from normal plasma are stable for at least 24 hours. Solubility in 5 M urea (urea clot stability assay) is often used to screen for factor XIII deficiency or inhibitors. Plasma clots lacking α_2-antiplasmin are also soluble in the urea clot stability assay and can be identified with specific assays. Solubility tests have low sensitivity for detecting factor XIII deficiency, failing to detect some samples with less than 2% of normal activity and probably almost all samples with levels ≥5% of normal. Chromogenic assays that quantitatively measure factor XIIIa activity are available and are replacing the urea clot stability assays in many institutions (see Chapter 127). These assays can also detect and quantify neutralizing factor XIII inhibitors, using a mixing method with normal plasma. The ISTH recommends starting an evaluation with a quantitative assay for factor XIII activity. If abnormal, this is followed by measurements of FXIII-A and B antigens, assessment for autoantibodies with a mixing study to assess for neutralizing antibodies and binding assays for non-neutralizing antibodies. Depending on the results, additional molecular genetics testing to identify causative mutations should be performed. Implementation of this strategy has been limited by the technical expertise required and the expense.[24]

The plasma half-life of factor XIII is 10 to 14 days,[24] facilitating prophylactic replacement therapy. While some consider a level as low as 5% adequate for hemostasis, others suggest that levels greater than 10% are required to reduce bleeding.[24,26] An assessment by the Prospective Rare Bleeding Disorders Database included a 3-year prospective assessment of 29 patients that demonstrated a linear relationship between factor XIII activity and bleeding symptoms.[26] An activity of less than 15% was associated with a significant increase in spontaneous major bleeding. The FranceCoag network assessed 33 patients and concluded that prophylaxis should be considered during pregnancy or at diagnosis if factor XIII is less than 10%, due to the increased risk of life-threatening umbilical or intracranial hemorrhage during infancy. [25] Both plasma and cryoprecipitate contain factor XIII; however, the factor XIII concentrate Corifact (formerly Fibrogammin; see Table 135.2) is preferred for replacement.[24] Corifact contains factor XIII purified from human plasma and is pasteurized. Recombinant factor XIII-A subunit (Tretten) received FDA approval in December 2013 to prevent bleeding in patients with inherited factor XIII A-subunit deficiency. Tretten is produced in yeast and contains no human blood components. In a prospective study, prophylactic replacement with recombinant factor XIII to maintain activity at greater than 0.05 to 0.2 IU/mL (5% to 20% of normal activity) prevented spontaneous bleeding without adverse effects. A subsequent study in pediatric patients (<6 years old) with inherited factor XIII A subunit deficiency also demonstrated efficacy as prophylactic treatment.[27]

Dosing regimens are the same for plasma derived and recombinant factor XIII. A dose of 40 units/kg every 4 weeks is recommended for prophylaxis. Although factor XIII concentrate is preferred for prophylaxis or treatment of acute bleeding, if it is not available plasma (10 to 20 mL/Kg every 4 to 6 weeks) or cryoprecipitate (1 unit for every 10 to 20 kg body weight every 3 to 4 weeks) can be used. A dose of 20 to 30 units/kg/day should be used with major surgery to keep the plasma activity 20% to 50% of normal. For minor surgery, 10 to 20 units/kg/day for 2 to 3 days is sufficient. Bleeding can be treated with 10 to 30 units/kg/day depending on severity. In pregnancy replacement should be started early, preferably before gestational week 5, because decidual bleeding at the site of implantation will occur without replacement. The optimal plasma factor XIII concentration in pregnancy is not established, but greater than 10% of normal is recommended.[24] This can be achieved by infusing 250 units of concentrate every 7 days through week 22 of gestation, then 500 units per week until delivery, with a 1000-unit bolus during labor.

Acquired Factor XIII Deficiency

Plasma factor XIII levels decrease in DIC and liver disease, but significant deficiency is rare in liver disease and may indicate a poor prognosis. While increased consumption or decreased production of factor XIII may result in bleeding, it can also be clinically silent because relatively small amounts of the protein are required for hemostasis. Acquired deficiency has been reported in leukemia, Crohn's disease, ulcerative colitis, and Henoch-Schönlein purpura, but levels are usually greater than 30% of normal and replacement is not required.

Alloantibodies to factor XIII induced by replacement therapy in factor XIII-deficient patients are very uncommon with fewer than five patients currently reported in the medical literature.[28] Patients with antibodies to the A subunit demonstrate bleeding symptoms that are refractory to replacement therapy. Immunosuppressive agents have been used in attempts to eliminate the antibodies. In one case an alloantibody to the B subunit was identified, resulting in increased bleeding and minimal response to factor XIII infusions.

Autoantibodies, most often IgG, to factor XIII can be directed against either the A or B subunits. Approximately 100 cases have been reported and the frequency may be increasing, perhaps because of the superiority of quantitative testing over older clot solubility tests. Antibodies to the A subunit are more common (approximately 90%). Neutralizing antibodies can block factor XIII activation (subclassified as Aa inhibitors), factor XIIIa activity (Ab inhibitors), or factor XIIIa fibrin binding capacity, while non-neutralizing antibodies may increase protein clearance from plasma. Some antibodies have both capacities. Antibodies to the B subunit are non-neutralizing and result in rapid clearance of the factor XIII tetramer.

Autoantibodies to factor XIII are most commonly seen in the elderly and have been linked to the use of certain medications (isoniazid, penicillin, phenytoin, amiodarone, procainamide), and to medical conditions such as cancer, lymphoproliferative disorders, and rheumatologic conditions such as systemic lupus erythematosus.[28] In 50% of cases there is no clear association with another process. Symptoms range from trauma-induced joint and soft tissue bleeding to catastrophic intracranial hemorrhage. Diagnosis requires a high index of suspicion as these patients frequently have normal PT/aPTT and platelet count evaluations. A thorough hemostatic evaluation is required to rule out other bleeding diatheses. The ISTH has developed recommendations for diagnostic criteria including possible, probable, and definite indicators for the disorder. Complete laboratory evaluation for factor XIII antibody inhibitors may be complex, usually requiring quantitative factor XIII functional assays, plasma mixing studies, inhibitor assays, binding assays, and clearance studies. [28]

Concentrates of plasma or recombinant factor XIII are recommended for treating acute bleeding in patients with factor XIII autoantibodies because these preparations have larger amounts of the protein than cryoprecipitate or FFP. rfVIIa, anti-fibrinolytic agents, and plasma-exchange/immunoadsorption have been used to treat bleeding. Immunosuppressive agents such as prednisone, rituximab and cyclophosphamide have been used to eradicate pathogenic antibodies.

INHERITED DEFICIENCIES INVOLVING MULTIPLE COAGULATION FACTORS

Numerous cases of inherited deficiencies of more than one coagulation factor have been described. While most represent chance coinheritance of distinct deficiencies, several are unique familial syndromes (Table 135.4). Such syndromes are likely caused by abnormalities in intracellular protein processing or alterations in posttranslational modification. Two inherited conditions, combined factor V and VIII

TABLE 135.4 **Combined Familial Deficiency States**

Type	Deficient Factors	OMIM Designation	Underlying Cause
1	V and VIII	227300	Mutations in *LMAN1* or *MCFD2* genes
2	VIII and IX	134510	Unknown
3	II, VII, IX, X, protein C, and protein S	277450 (gamma-glutamyl carboxylase) 607473 (vitamin K oxidoreductase)	Mutations in γ-glutamyl carboxylase *(GGCX)* or vitamin K oxidoreductase *(VKORC1)* genes
4	VII and VIII	134430	Unknown
5	VIII, IX, and XI	134520	Unknown
6	IX and XI	134540	Unknown
	VII and X	www.omim.org/entry/227600	Gene deletion 13q34

LABORATORY TESTING IN RARE COAGULATION FACTOR DEFICIENCIES

When deficiency of a coagulation factor is being considered, it is important to keep in mind that (1) acquired conditions causing multiple factor deficiencies are more common than inherited deficiency of a single factor, and (2) common inhibitors of coagulation, such as lupus anticoagulants, heparins, and the direct oral anticoagulants (DOACs) interfere with coagulation factor assays. Unexplained prolongation of the PT or PTT should be evaluated in a qualified laboratory. Plasma should be prepared from blood collected by venipuncture. In our experience, the common practice of collecting blood from central venous catheters/ports or peripheral intravenous catheters frequently introduces fluids or drugs that adversely affect clotting assays and contribute to misdiagnosis. We use the thrombin time assay and factor Xa-based assays to screen samples for the presence of heparins or DOACs prior to evaluation.

The evaluation of a plasma sample with a prolonged PT and/or aPTT should start by repeating the abnormal test on a mixture of patient and normal plasma to determine if the abnormality is related to a clotting factor deficiency (clotting time becomes normal after mixing) or an inhibitor that interferes with clotting (clotting time remains prolonged after mixing). The mixing study should be performed with and without incubation (2 h), as some antibody inhibitors demonstrate a time-dependent pattern of inhibition. Slight (a few seconds) prolongations of the PT or PTT can be difficult to evaluate with a mixing study. We evaluate such samples with assays for lupus anticoagulants prior to measuring specific levels of coagulation factors.

The antibodies to clotting factors that most physicians are familiar with neutralize factor activity, leading to a prolonged PT and/or aPTT that do not correct on mixing with normal plasma. However, non-neutralizing antibodies can cause severe factor deficiency. These antibodies enhance clearance of a clotting factor from the plasma *in vivo* and often are not detected in a mixing study. A failure to respond to replacement therapy in the absence of a clearly measurable inhibitor suggests a non-neutralizing antibody is present. In our practice, we have observed severe acquired deficiencies of prothrombin, factor V, factor X, factor XI, and factor XIII caused by non-neutralizing antibodies.

If the level of a vitamin K–dependent protein (prothrombin or factors VII, IX or X) is low, levels of factor V and at least one other vitamin K–dependent factor should be measured. If multiple vitamin K–dependent factors are low and factor V is normal, a process affecting vitamin K is likely. If factor V is also low, liver disease or DIC should be considered. Tests for hepatic function (albumin) or injury (transaminases) can facilitate interpretation of the coagulation factor studies. Distinguishing DIC from liver disease can be difficult, because results of standard tests such as the PT, PTT, platelet count, fibrinogen, and D-dimer may be abnormal in both conditions. Measuring factor V and factor VIII may be useful in this situation, because both are often low in DIC, while factor VIII is normal or elevated in liver disease.

It is likely that the apparent rarity of inherited factor XIII deficiency is partly due to the insensitivity of clot solubility assays still used in many institutions to screen for this disorder. Such assays detect only the most severe deficiencies. Quantitative measurements of factor XIII activity are preferable.

Patients with factor XI, factor XII, prekallikrein, or high-molecular-weight kininogen deficiency may require anticoagulation for treatment or prophylaxis for thromboembolism. Assays based on contact activation such as the aPTT or the activated clotting time (ACT) cannot be used for monitoring therapy with heparin, or the direct thrombin inhibitors argatroban or bivalirudin, in these patients because baseline aPTT and ACT clotting times are prolonged. Chromogenic heparin assays based on factor Xa inhibition are widely available for monitoring heparin and should be used in place of the aPTT in patients with these deficiencies. Alternatively, low molecular weight heparin, fondaparinux, or a DOAC, which do not generally require monitoring, can be used instead of unfractionated heparin, argatroban, or bivalirudin.

deficiency and deficiency of vitamin K–dependent factors, are best characterized and are discussed below. When considering the possibility of multiple coagulation factor deficiencies, it is important to recognize that common nonspecific inhibitors such as lupus anticoagulants can produce artifactual effects that may lead to the false impression that more than one coagulation factor is deficient (see box on Laboratory Testing in Rare Coagulation Factor Deficiencies). Similarly, potent antibody inhibitors directed at a single coagulation factor, such as factor VIII, occasionally are strong enough to interfere with assays for other coagulation factors.

Combined Factor V and Factor VIII Deficiency (OMIM 227300)

Inherited combined deficiency of factor V and factor VIII was first reported in 1954. It is an autosomal recessive trait caused by mutations in either the *LMAN1* or *MCFD2* gene. The protein products of these genes, mannose-binding lectin, and multiple combined factor deficiency protein respectively, form a cargo receptor that transports factors V and VIII from the ER to the ER-Golgi intermediate compartment. The incidence of this disorder is thought to be 1 in 1 million persons in the general population, although the allele frequency is particularly high (~1%) in Tunisian Jews originating from a community on the island of Djerba.

Deficiency of the *LMAN1* or *MCFD2* gene products reduces factor V and factor VIII secretion, lowering plasma levels of the proteins to 5% to 30% of normal. In Tunisian Jews, a T-to-C substitution at a donor splice site in *LMAN1* intron 9 is responsible. A history of consanguinity, co-segregation of factor deficiencies, and similar reductions in factor V and VIII favor the familial disorder over chance inheritance of distinct deficiencies. Affected individuals bleed primarily after trauma. Epistaxis, gingival bleeding, easy bruising, and menorrhagia are common. Hemarthrosis unrelated to trauma may occur in 20% of patients, but bleeding from the GI tract or intracranial hemorrhage is less common.[29] Postpartum hemorrhage occurs in most affected women and invasive procedures, including tooth extraction, are usually accompanied by bleeding in the absence of factor replacement.

The PT and aPTT are both prolonged in combined factor V and factor VIII deficiency. As isolated factor V deficiency also prolongs these tests, a patient with a low factor V level should also have factor VIII measured to avoid missing the combined deficiency. Patients with mucosal bleeding and menorrhagia may respond to antifibrinolytic therapy. For more significant bleeds, or in preparation for surgery or tooth extraction, combinations of FFP and factor VIII concentrate have traditionally been recommended. DDAVP can be used to raise the factor VIII level but will have little effect on factor V. Trough levels of ~50% for factor VIII and 25% for factor V have been recommended for surgery. Plasma exchange may be used to increase factor V in situations in which volume overload from large volumes of FFP is a concern. rfVIIa was used successfully to stop bleeding in one surgery patient. Counterintuitively, a recent study suggests that lower levels of factor V improve thrombin generation and may ameliorate bleeding in patients with this condition, possibly by lowering the plasma level of the coagulation inhibitor TFPI.[29] As the factor V level in plasma and platelets may be adequate in most of these patients, strategies for raising factor VIII alone with administration of DDAVP or factor VIII concentrate may be effective for many patients.

Combined Deficiency of Vitamin K-Dependent Proteins (OMIM 277450 and 607473)

In 1966, McMillan and Roberts described a newborn girl with prolonged PT and aPTT, low levels of prothrombin and factors VII, IX, and X, and no evidence of liver disease or malabsorption. She responded partially to large doses of vitamin K. Subsequently, low protein C and protein S levels were reported in association with mutations in the *GGCX* gene for the ER enzyme *γ-glutamyl carboxylase* in other patients with the syndrome. γ-glutamyl carboxylase catalyzes post-translation modifications in proteins involved in several processes including coagulation (prothrombin; factors VII, IX, and X, protein C and protein S) and bone biology (osteocalcin and matrix Gla protein).[30] Specifically, the enzyme catalyzes addition of carboxyl groups to the N-terminal Gla-domains of certain proteins in a reaction that requires reduced vitamin K as a cofactor. The reactions result in formation of vitamin K 2,3-epoxide that must be reduced by *vitamin K epoxide reductase complex subunit 1* (*VKORC1*) to replenish the vitamin K pool. Reduced activity of γ-glutamyl carboxylase or vitamin K epoxide reductase due to mutations in the *GGCX* or *VKORC1* genes can impair γ-carboxylation, resulting in reduced functional levels (10% to 50% of normal) of all vitamin K–dependent coagulation factors and a bleeding tendency that may be severe. More than 40 disease-causing mutations have been identified in the human *GGCX* gene.[30] Although it is generally thought they produce autosomal recessive conditions, severe bleeding was reported in one neonate who appeared to be heterozygous for a *GGCX* mutation.

Combined deficiencies of prothrombin and factors VII, IX, and X cause prolongation of the PT and aPTT. Protein C and protein S are also reduced. The abnormalities correct on mixing with normal plasma. Failure to correct suggests that a nonspecific inhibitor such as a lupus anticoagulant is present and is interfering with the factor assays (see box on Laboratory Testing in Rare Coagulation Factor Deficiencies). Patients with deficiencies of vitamin K–dependent proteins should be evaluated for liver disease, malabsorption, and exposure to vitamin-K antagonists such as warfarin or the rodenticide brodifacoum. Toxicology screens can identify these agents in blood long after ingestion because of their long half-lives. Some patients have adequate clinical response to vitamin K_1 (10 mg weekly), but others require unusually high doses. Nonresponders or responders with significant bleeding episodes can be treated with FFP or PCC. Interestingly, some *GGCX* mutations are associated with skeletal, skin (pseudoxanthoma elasticum-like syndrome), or cardiovascular abnormalities due to failure of properly γ-carboxylated proteins other than those involved in coagulation.[30] These abnormalities may predominate in certain patients over abnormalities in blood coagulation, depending on the causative mutation.

Vitamin K–dependent proteins are reduced in patients taking warfarin, as a result of poisoning with rodenticides such as brodifacoum, and with vitamin K deficiency. In 2013 a cluster of cases of severe vitamin K deficiency causing hemorrhagic disease in newborns were linked to failures to administer prophylactic vitamin K after birth. In 2018 an outbreak of a coagulopathy, first identified in Illinois, was connected to smoking brodifacoum-laced synthetic marijuana. Patients presented with profound coagulopathy and no history of anticoagulant use. Subsequent plasma analysis confirmed the presence of brodifacoum. The levels of vitamin K–dependent proteins are also low in liver failure, in conjunction with other proteins synthesized in the liver (such as factor V), and in malabsorption syndromes. An acquired antibody that resulted in fatal bleeding in a patient with a lymphoproliferative disorder bound to an epitope on the Gla-domains of prothrombin and factors IX and X , likely interfering with the function of all three proteins.

CHAPTER 136

TRANSFUSION THERAPY FOR COAGULATION FACTOR DEFICIENCIES

Elizabeth Roman and Catherine S. Manno

This chapter reviews products available to treat deficiencies of plasma coagulation proteins. The development of blood component therapy and subsequently protein concentrates that are enriched in particular coagulation factors and other proteins made possible the effective treatment of bleeding episodes in patients with hemophilia and other diatheses. In the 1940s, a collaborative effort funded by the US government was undertaken among protein scientists with the goal of rapidly developing a method to isolate albumin from human plasma to provide a lyophilized intravascular volume expander for use in the military. As part of this effort, Dr. Edwin Cohn developed an ethanol fractionation procedure that was amenable to large-scale manufacturing.[1] Building on the foundation of the Cohn fractionation procedure (see Chapter 115), the first coagulation factor concentrates were developed in the mid-1960s and provided a safer and more effective treatment for patients with the X-linked coagulation deficiencies, hemophilia A and B. Given the limited human plasma resource as a raw material for the production of all but a few coagulation protein concentrates, manufacturers of human plasma–based products attempted to derive the maximum yield from each pool of plasma by deriving more products from these processes.

The development of recombinant products was fueled by infectious disease transmission through derived products. Currently licensed products are produced in mammalian cell culture to optimize necessary posttranslational modifications required for biologic activity. These recombinant expression processes are complicated and expensive. Transgenic recombinant technology has been explored as a way to decrease or eliminate reliance on the human plasma resource.

Recently, recombinant technology has made substantial progress in the development of long-acting factor VIII and IX preparations, which are effective in preventing as well as treating bleeding episodes; however, the advances have been more significant in the extension of the factor IX half-life, rather than factor VIII. By multiple mechanisms the half-lives of these coagulation proteins have been extended, profoundly impacting the daily life of patients with hemophilia who use factor concentrate as prophylaxis, as prolonged half-life factors have reduced the number of infusions to maintain factor efficacy.

During the last decade, several non-factor concentrates, novel agents with preferred routes of administration and improved dosing schedules have become available for patients with hemophilia with and without inhibitors. In addition, results from gene therapy for both factor VIII and IX deficiencies are promising and may lead to a dramatic shift in the future paradigm treatment for these patients. Viral vectors enable the liver cells to make a functional copy of the missing factor, eliminating the need for routine prophylactic therapy and reducing the number of spontaneous or trauma-related bleeding episodes.

HEMOPHILIA A AND B

The hemophilias are X-linked disorders caused by deficiencies of either factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease). The genes for these coagulation factors are located in close proximity to the long arm of the X chromosome. Whereas hemophilia A affects 1:5000 males, hemophilia B affects 1:30,000. This difference in incidence is roughly correlated with the size of the genes, and more than 30% of cases arise from spontaneous mutations.

The major morbidity of the severe hemophilias A and B is arthropathy, a result of recurrent joint bleeding developing over the course of years in those with inhibitors or those who are untreated or undertreated. The major cause of hemorrhagic mortality is bleeding into critical closed spaces (e.g., intracranial).[2] Central nervous system (CNS) bleeding occurs in 3% to 14% of patients, and mortality from CNS hemorrhage ranges from 20% to 50%[3–5] with neurologic sequelae (including seizures, motor impairment, or mental retardation) observed in 40% to 50% of survivors.[3] CNS bleeding episodes occur predominantly in patients with severe disease (<1% factor level).[3] A more detailed discussion of the hemophilias and the molecular biology of factors VIII and IX can be found in Chapter 134.

TRANSFUSION THERAPY FOR HEMOPHILIA A AND B

History of Transfusion for Hemophilia

Transfusion was first proposed by Schönlein and his student Hopf in 1832 as a treatment for “bleeders” who were suffering from exsanguinating hemorrhage, and these two were likely the first to have used the term *Haemophilie* to describe the disease.[6,7] The first effective transfusion-based intervention for hemophilia is credited to Samuel Lane who, in 1840, infused 10 to 12 ounces of fresh human blood into a 12-year-old boy with postoperative hemorrhage after eye surgery for correction of a squint.[8] Subsequently, a variety of interventions, using the infusion of human and animal blood and blood derivatives, were used in the therapy of hemorrhage in patients with congenital bleeding diatheses (Table 136.1). Citrated plasma was first used in 1923 for the treatment of hemophilia by Feissly in a father-to-son transfusion.[9] Development of modern blood banking in the 1930s and expansion of transfusion during and after World War II allowed for more widespread use of whole blood and subsequently frozen plasma in the treatment of hemophilia. Because of limited availability, the use of whole blood and components of whole blood for the treatment of hemophilia and other diseases was initially confined to larger metropolitan areas. In addition, volume constraints associated with the quantity of whole blood or plasma needed to achieve therapeutic levels of coagulation limited their usefulness.[31]

The advent of modern transfusion therapy for hemophilia came with the observation that the cold-insoluble precipitate remaining after the thawing of frozen plasma at 4°C contains high concentrations of factor VIII.[32] Application of this procedure to the separation of components of the whole blood[18] allowed for the production of a reduced-volume blood product known as *cryoprecipitate*. Cryoprecipitate derived from a single whole blood collection contains approximately 125 units of factor VIII and quickly replaced frozen plasma as the therapy of choice for the treatment of bleeding episodes in hemophilia A in the 1960s. The availability of cryoprecipitate made the treatment of bleeding episodes by patients in their homes, rather than at a hospital, a reality. In addition, the development of quantitative assays for factor VIII[14] and factor IX[13] meant that the two diseases could now be distinguished and the effects of transfusion therapy on circulating levels of factors could be more accurately assessed.

TABLE 136.1 **Development of Transfusion Therapy for Hemophilia**

1832	Schönlein proposes transfusion for exsanguination[7]
1840	Lane transfuses whole blood to stop postoperative bleeding in hemophilia[8]
1905	Weil reports use of human serum to treat hemophilia[9]
1911	Addis fractionates plasma by acid method[10]
1923	Feissly uses citrated plasma in ABO blood group-mismatched father-to-son transfusion for hemophiliaia[11]
1930s–1940s	Development of modern blood banking. Availability of whole blood and frozen plasma for therapy (allows levels of approximately 5%)
1946	Cohn develops ethanol fractionation of plasmaia[1]
1949	Graham uses FFP in canine hemophilia modelia[12]
1945–1960	Fractionation of plasmas with AHF activity
1952	Biggs distinguishes hemophilia B from hemophilia Aia[14]
1953	Graham, Langdell, and Brinkhous develop quantitative assays to measure AHFia[14,15]
1958	Barium precipitation of plasma to enrich for factor IX[16,17]
1963	Wagner uses glycine precipitation to partially purify factor VIII
1964	Pool develops clinically useful cryoprecipitate for factor VIII deficiency (allows levels of >20%)[18]
1966	Johnson uses PEG to partially purify factor VIII[19]
1967	Brinkhous develops glycine and PEG method to produce large-scale high potency factor VIII product (allows levels of 100%)[20]
1965–1970	Home infusion therapy
1969	Hoag produces large-scale prothrombin complex concentrate for factor IX deficiency[21]
1970s	HBsAg assay is developed
1978–1985	HIV contaminates blood supply and factor concentrates
1979–1986	Heat treatment of factor concentrates reduces transmission of hepatitis B and HIV[22,23]
1985	Assay for HIV is licensed
1982	Immunoaffinity method of purification for factor VIII[24,25]
1986	S/D method of treating infusible protein solutions to inactivate enveloped viruses[26,27]
1992–1993	First recombinant factor VIII concentrates are licensed[28,29]
1998	Recombinant factor IX concentrate is licensed[30]
1999	Nucleic acid amplification testing of blood donor
1999	Recombinant factor VIIa approved for hemophilia A and B with inhibitor
2007	Recombinant factor VIIa approved for acquired hemophilia
2011	First plasma-derived factor XIII product approved by the FDA
2011	Successful report of AAV mediated gene therapy for factor IX deficiency

AAV, Adeno-associated virus; *AHF*, Human antihemophilic factor; *FDA*, Food and Drug Administration; *FFP*, fresh-frozen plasma; *HBsAg*, hepatitis B surface antigen; *HIV*, human immunodeficiency virus; *PEG*, polyethylene glycol; *S/D*, solvent/detergent.

Before the discovery of plasma cryoprecipitate, significant advances had been made in the fractionation of plasma using ethanol,[1] glycine,[20] polyethylene glycol,[19] a combination of glycine and polyethylene glycol,[20] and calcium or barium[16,21,33] to precipitate plasma proteins. These techniques, in conjunction with cold precipitation of frozen plasma, laid the groundwork that resulted in the production of the first factor VIII and factor IX concentrates for clinical use.[20,21] These concentrates could be lyophilized and stored at temperatures up to 4°C with extended stability. Infusion of factor concentrates resulted in high circulating levels of factor VIII and factor IX without the complication of volume overload and paved the way for intensive infusion therapy for serious and life-threatening bleeding complications such as intracranial, retroperitoneal, and retropharyngeal hemorrhages and to prevent bleeding following surgery. Because they were produced from large pools of single plasma donations (>1000), initial concentrates were nearly universally contaminated with viral pathogens such as hepatitis B and non-A, non-B hepatitis (hepatitis C). Initial attempts to attenuate viral transmission using pasteurization and dry heat, instituted by manufacturers in the late 1970s and early 1980s,[22,34,35] were found to limit the transmission of hepatitis B. Eventually, these techniques were found to inactivate the human immunodeficiency virus (HIV).[23,36,37] Before the widespread application of these techniques, however, the majority of patients with severe hemophilia treated with concentrates between 1978 and 1985 were infected with HIV and hepatitis C virus. This tragic consequence of infusion therapy helped fuel the development of modern strategies to reduce the risk of viral transmission by products derived from human plasma. These strategies include[1] careful screening of potential donors for risk factors leading to infection with transfusion-transmissible infections,[2] more vigilant surveillance of the blood donor base for the appearance of new pathogens,[3] development and implementation of testing specifically for markers of infectious agents,[4] purification strategies that reduce viral contamination in final products, and[5] physical and chemical viral inactivation methods to treat infusible products. Development and refinement in techniques of molecular biology in the 1970s and 1980s resulted in the cloning of the genes for many plasma proteins, including factor VIII and factor IX.[38–40] Within the next decade, the production and licensure of biologically active recombinant factor VIII and factor IX products had become a reality.[28,41–43] Concentrates of these recombinant products have been shown to be effective and have not been associated with the transmission of pathogens. Further development of recombinant products centered on the removal of all human and animal proteins in the production and formulation to further reduce the risk of inadvertent contamination with emerging pathogens, such as variant prions,[44,45] and newly discovered agents, such as hepatitis G virus and other transfusion-transmitted viruses.[46,47] In addition, episodic supply constraints incurred in the manufacture of recombinant proteins in mammalian cell culture systems resulting in supply shortages of recombinant factor VIII[38] have led to greater interest in transgenic production of human plasma proteins compared with mammalian cell culture. With transgenic systems, raw material from which the protein of interest is purified (milk, plant tissue) can be produced in abundance.

Infusion Regimens and Dosing for Hemophilia

Traditionally, the mainstay of therapy for hemophilia involved the treatment of bleeding episodes with infusing products capable of replacing the missing factor VIII or IX. This so-called on-demand therapy is effective in staunching hemorrhages, but not before tissue damage has occurred. Bleeding is especially destructive in the synovium, where a vicious cycle develops in which the initial bleed results in a proliferative inflammatory response and hypertrophy of synovial tissues that then become more susceptible to further trauma and bleeding. The result in the short term is repeated bleeds into the same joint, resulting in what is referred to as a "target joint," and eventually chronic joint destruction or hemophilic arthropathy. Patients with chronic arthropathy often require surgical intervention, including synovectomy, debridement, joint replacement, or even joint fusion.

With the availability of factor concentrates that allowed for the attainment of high plasma levels of factor VIII or IX, prophylactic therapy became possible. This approach was pioneered by Swedish treaters who demonstrated that the use of prophylactic regimens,[49] wherein trough factor levels maintained at greater than 1% of normal, reduces the incidence of arthropathy and CNS hemorrhage.[29] Greater availability of virally safe factor concentrates has allowed for the initiation of prophylactic regimens in early childhood. This "primary" form of prophylaxis has become the standard of care in developed countries. For prophylaxis, the National Hemophilia Foundation Medical and Scientific Advisory Council recommends infusion of factor VIII 25 to 50 U/kg 3 times a week or every other day for hemophilia A and factor IX 40 to 100 U/kg 2 or 3 times a week for hemophilia B.[50] Prophylaxis is not universally practiced, however, owing to the high cost of factor concentrates, the requirement for frequent intravenous (IV) infusion, and the need for the placement of central venous catheters in some patients, especially small children, to obtain IV access. The cost factor makes primary prophylaxis and even on-demand treatment prohibitive to more than 60% of the hemophilia patients in the world.[51]

To understand how prophylaxis was instituted in the United States, a survey of hemophilia treatment centers in March 2010 was conducted: 62 centers responded, and 32% (or 20 centers) initiated prophylaxis on a once-weekly schedule, 21% (13 centers) on a twice-weekly schedule, and 47% on a thrice-weekly schedule.[52] This survey demonstrated the diversity in practice and deviation from the recommendation from the National Hemophilia Foundation. Alternative schedules for prophylaxis have been investigated. For example, the Canadian Hemophilia Primary Prophylaxis Study, a small, prospective, multicenter study, evaluated a tailored prophylaxis regimen in 25 patients with severe hemophilia A; patients were started at 50 U/kg once a week and were escalated to 30 U/kg twice weekly and then 25 U/kg on alternate days if one of the three situations occurred: development of a target joint, four bleeds in 3 months, or five or more bleeds occurred into any one joint. This seemed to be well-tolerated, resulting in 1.2 bleeds per year while maintaining good joint function; long-term follow-up of tailored prophylaxis is needed, but it may be a cost-effective and central line-sparing option.[53]

Dosing regimens for the treatment of bleeding episodes in hemophilia have also evolved paralleling the availability of high-concentration pathogen-safe replacement products. Although no universal regimen for "on-demand" treatment has been established, certain trends prevail. In general, for non-life-threatening bleeding episodes, the goal of therapy is to achieve a plasma factor VIII or IX level of between 30% and 100%. For life-threatening bleeds or prophylaxis for surgical procedures, the goal is a level of 100% to be maintained by repeated bolus infusions or continuous infusion for a duration of 10 to 14 days or longer, depending on the severity of the bleed or surgical intervention.

The majority of prophylaxis regimens aim at achieving a trough factor level of approximately 1%. Primary prophylaxis, instituted in young children, is aimed at preventing any joint bleeding episodes that would eventually result in chronic arthropathy. Secondary prophylaxis refers to limited or prolonged periods of prophylactic therapy, instituted after a serious bleed or the development of repeated bleeding into a single joint (target joint); tertiary prophylaxis entails the initiation of prophylaxis subsequent to the onset of joint disease. The landscape of prophylaxis regimens is changing and the novel agents, with less frequent, subcutaneous administration may replace the more traditional practice; as of August 2020, the current Medical and Scientific Advisory Council of the National Hemophilia Foundation did not recommend a preferred prophylaxis regimen.[54]

To prevent the development of a target joint and chronic arthropathy, many hemophilia treatment centers have recently adopted a regimen of two, three, or more infusions after hemarthrosis (aggressive on-demand treatment). Specific dosing regimens for bleeding episodes have been developed by treaters and treatment centers. Although slight variations in indications and target plasma levels of factor VIII and factor IX among treatment centers exist, representative dosing regimens are similar and are presented in Table 136.3.[55,56]

TREATMENT OF HEMOPHILIA

Products Available for Treatment of Factor VIII Deficiency

Factor VIII Concentrates

In high-income countries, the current standard of care for the treatment and prevention of bleeding episodes in patients with severe hemophilia A and in patients with a mild or moderate disease who do not respond to 1-deamino 8-D arginine vasopressin (DDAVP) is the infusion of recombinant or plasma-derived factor VIII. Recovery of recombinant factor VIII ranges from 1.5% to 2.5%/IU/kg so that dosing assumes a rise in plasma factor VIII activity of 2% for every 1 IU/kg infused. Available concentrates are optimized to enhance viral clearance during purifications and undergo one or more viral inactivation steps during manufacture. Plasma-derived factor VIII concentrates, treated with multiple purification and viral inactivation steps, are also available and have an excellent recent record of safety.

Recombinant Factor VIII Products

Highly purified recombinant factor VIII concentrates have been licensed in North America, Europe, and Japan since the early 1990s. These are either full-length or B domain–deleted molecules (the B domain is not required for activity in coagulation) that are expressed in mammalian cell culture (Chinese hamster ovary, embryonic hamster, or human kidney cell lines) and are purified using immunoaffinity techniques. The development of these recombinant products was fueled primarily by concerns regarding the safety of the human blood donor pool and the viral epidemics that occurred within the hemophilia population with the use of early plasma-derived products. As with highly purified plasma-derived factor VIII concentrates, the first-generation recombinant products contain animal or human proteins in cell culture and final formulation for stability. "Second-generation" products (Kogenate FS, Bayer, Refacto, Pfizer) contain animal or human proteins in cell culture only. Third-generation products

(Advate, Takeda Pharmaceutical Company Limited; Xyntha, Pfizer) do not have human proteins or other additives in the cell culture or as a stabilizer.[57,58] Recombinant production methods that do not rely on the human plasma resource theoretically should provide for unlimited supply.

The first extended half-life recombinant factor VIII product, Eloctate, Biogen Idec, synthesized in a human embryonic kidney cell line, was US Food and Drugs Administration (FDA) approved in June 2014. It is a B domain–deleted factor VIII covalently linked to human immunoglobulin G1; this Fc fusion protein has extended the half-life of factor VIII: in adults, almost 20 hours, 12 to 17 years old almost 16.5 hours, 6 to 11 years old about 14.5 hours and 2 to 5 years old, 12 hours.[59] Almost all of the patients (99%) receiving Eloctate for 6 months were able to use the product every 3 days or longer to maintain a factor VIII level of 1% to 3%.[59] Eloctate, Biogen Idec, has been used on-demand, for prophylaxis and in the perioperative setting. For prophylaxis, Biogen Idec recommends 50 IU/kg every 4 days and suggests personalizing the dose based on response, 25 to 65 IU/kg at 3 to 5-day intervals.[59] The package insert also indicates that children less than 6 years old, may require more frequent or higher doses (up to 80 IU/kg).[59] For minor and moderate bleeds, Eloctate 20 to 30 IU/kg can be given every 24 to 48 hours; however, in children less than 6 years old, Eloctate should be given every 12 to 24 hours.[59] For major bleeding episodes, Eloctate 40 to 50 IU/kg should be given every 12 to 24 hours and in children less than 6 years old, Eloctate should be given every 8 to 24 hours.[59] Many other long-acting factor VIII products are currently available.

Intermediate- and High-Purity Plasma-Derived Concentrates

Intermediate-purity plasma-derived concentrates are prepared from cryoprecipitated plasma or fresh-frozen plasma (FFP), from which factor VIII is further purified using precipitation, gel permeation, ion exchange, or affinity chromatography, often in combination. Specific factor VIII coagulant activity in these products ranges from 2 to more than 100 IU/mg of protein, and many of the methods used also copurify significant amounts of von Willebrand factor (vWF), making them useful for the treatment of some patients with von Willebrand disease (vWD; see later discussion on the treatment of vWD). More highly purified plasma-derived concentrates are produced using heparin ligand or immunoaffinity purification methods and have specific activities ranging from 140 to greater than 3000 IU/mg. To stabilize the factor VIII molecule, the majority of these products are formulated by adding human albumin before lyophilization: Alphanate (Grifols USA) and Koate-DVI (Talecris Biotherapeutics).

Emicizumab-kxwh (Hemlibra, Genentech)

Emicizumab is a humanized bispecific antibody that binds both IX and X, essentially mimicking the factor VIII function and is given subcutaneously. In 2017, the results of the phase 3 HAVEN-1 study demonstrated that weekly subcutaneous dosing in patients >12 years old with inhibitors had a significant reduction in annualized bleeding rate (ABR); group A patients were receiving bypass agents on demand and given weekly emicizumab; group B did not receive emicizumab and group C patients were receiving prophylaxis with bypass agents plus emicizumab. There was an 87% reduction in ABR in group A vs group B.[60] The treatment was well tolerated with the most common side effect being local injection site reactions (15%). However, three patients receiving high-dose activated prothrombin complex concentrate (aPCC) with emicizumab prophylaxis developed thrombotic microangiopathy (TMA). In the HAVEN-2 study, a phase 3 study of children 2 to 12 years old with hemophilia A and inhibitors, patients were randomly assigned to three different dosing schedules: group A received emicizumab 1.5 mg/kg weekly, group B 3 mg/kg every 2 weeks and Group C 6 mg/kg weekly monthly; ABR was 0.3, 0.2, and 2.2 respectively.[61] The most common side effects were local reactions and nasopharyngitis. There were no reports of TMA or thrombosis. Two patients developed anti-drug antibodies: in one patient there was a loss of drug efficacy and in the other, the antibody resolved without intervention. Patients without inhibitors have also benefited from emicizumab prophylaxis, as demonstrated in the HAVEN 3 study,

TABLE 136.2 Dosing Regimens for Traditional Factor Replacement in Bleeding and Prophylaxis in Hemophilia

Site	Factor Level (%)	Dose Hemophilia A (U/kg)	Dose Hemophilia B (U/kg)	Duration of Treatment	Comments
Joint	30–70	15–35	30–70	1–3 days	Splinting, temporary splinting, no weight bearing
Life threatening (e.g., intracranial, retropharyngeal, retroperitoneal)	80–100	40–50	80–100	1–14 days	Antifibrinolytic therapy with retropharyngeal bleeds
Soft tissue	30–50	15–25	30–50	2–5 days	Higher levels can be used for compartment syndrome
Surgery	80–100	40–50	80–100	10–14 days (or shorter for minor procedures)	Significant blood loss can occur into large muscles of the lower extremity and the iliopsoas
Oral	20–50	10–25	20–50	1–2 days	Antifibrinolytic therapy
Gastrointestinal[a]	30–100	15–50	30–100	2–3 days	Should be evaluated for source
Genitourinary[b]	30–50	15–25	30–50	1–2 days	Avoid antifibrinolytic therapy
Prophylaxis[c]	50	25	50	qod or 3×/week	

[a] Depending on severity.

[b] Painless spontaneous hematuria often requires no treatment other than fluid intake. Persistence requires treatment and evaluation.

[c] Use of a schedule of 25 U/kg qod and a dose of 40 U/kg with an interval of 2 days between the next dose may increase compliance by decreasing infusions to three per week.

qod, Every other day.

Data from DiMichele D. Hemophilia 1996: New approach to an old disease. *Pediatr Clin North Am.* 1996;43:709; Mannucci PM. Haemophilia treatment protocols around the world: towards a consensus. *Haemophilia.* 1998;4:421; and Lusher J. *Treatment of Congenital Coagulopathies*, AABB Press; 1999.

evaluating weekly (group A), every other week prophylaxis (group B), no emicizumab (group C), and weekly dosing with prophylactic factor VIII (group D); there was a 96% and 97% reduction in the ABR for groups A and B, with over 50% of participants not having any bleeds. Local reactions were the most common and there was no TMA, thrombosis, antidrug antibodies or inhibitors.[62] HAVEN-4 included patients with and without inhibitors receiving monthly emicizumab (a small cohort received 4 weekly doses prior to starting the monthly dosing) and the ABR was 2.4, with side effects being similar to those seen in HAVEN-3.[63] Emicizumab can be given from infancy to adults at a loading dose of 3 mg/kg weekly for four doses; thereafter it can be given weekly (1.5 mg/kg), every 2 weeks (3 mg/kg), or monthly (6 mg/kg). Since different vial sizes cannot be mixed and volume may exceed the maximum for a single injection, patients need to receive multiple injections for one dose but compared to 104 to 156 (twice–thrice weekly) IV administrations/year, patient satisfaction remains high. There are two black box warnings for emicizumab: TMA with the use of high-dose aPCC and thrombosis. For surgery or breakthrough bleeding, patients may need factor VIII replacement or a bypassing agent.

Clotting based coagulation tests, including activated partial thromboplastin time (aPTT), factor VIII levels (other factor levels), Bethesda assays, aPTT-based activated protein C resistance and activated clotting time will not be accurate in patients who are using emicizumab (PTT can be shortened-normal) and secondary to the long half-life of emicizumab, these abnormalities in clotting assays may persist for up to 6 months after the last dose; therefore, chromogenic (with bovine factor IXa and Xa) or immune-based assays for Factor VIII and Bethesda monitoring can be used.[64] In the HAVEN trials, drug monitoring levels or coagulation assays were not used for clinical decision making and using animal models, emicizumab approximates a factor VIII level of 10% to 20%. If an inhibitor is suspected, anti-drug antibodies may be sent (commercial test not available); if an emicizumab level is needed, emicizumab calibrators and controls are available from r^2 Diagnostics.[65]

Novel Direction for Factor VIII Deficiency

Many of the new products, like emicizumab, improve global hemostasis without the replacement of the Factor VIII product. Fitusiran, Sanofi, is in clinical trials and is a small inhibitory messenger RNA blocking antithrombin production and enhancing thrombin generation. This drug is given monthly, subcutaneously, and has been studied in patients with moderate or severe hemophilia A or B with or without inhibitors and has not yet been licensed. The Phase 1 study assessed pharmacokinetics and pharmacodynamics of weekly versus monthly dosing, demonstrating that there was a dose-dependent reduction in antithrombin with the monthly dosing; no thrombotic events were reported.[66] A Phase 2 study of fitusiran at 50 and 80 mg, showed promising results with an ABR of 0.84 and suppression of antithrombin.[67] Two thrombotic events were reported in patients using fitusiran: an atrial thrombosis and a fatal cerebral sinus venous thrombosis, in a patient receiving concurrent high-dose Factor VIII replacement; therefore, trials were temporarily halted and bleeding management guidelines for patients on fitusiran were published in December 2017. The current Phase 3 fitusiran trial was put on hold by Sanofi in October 2020 due to additional reports of thrombotic events.

Another novel therapeutic being evaluated in clinical trials in subjects with hemophilia A or B with or without inhibitors is concizumab, Novo Nordisk, a humanized monoclonal antibody to the K2 domain of tissue factor pathway inhibitor (TFPI), which impedes binding of TFPI to the active site of Factor Xa. In a Phase 2 trial, patients were given daily subcutaneous doses, with potential dose escalation if bleeding occurred; ABR was reduced by 78% in patients with inhibitors and three patients developed anti-drug antibodies without clinical correlations.[68] In March 2020, concizumab trials were halted due to three thrombotic events but trials resumed in August 2020.[69]

Gene Therapy for Factor IX Deficiency

A landmark paper was published in December 2011 describing a phase 1 trial of the first six patients with severe factor IX deficiency who received one peripheral IV injection of an adeno-associated virus (AAV) expressing a factor IX gene, at three different doses. This vector was selected as it does not integrate into the host genome and a capsid of AAV serotype 8 was added to avoid immunogenicity. Another advantage of using this serotype is the propensity for it to home to the liver. Sixty-seven percent of the patients in the trial no longer needed prophylaxis and the other 33% needed less factor. Patients who received the highest dose experienced a transient elevation of the alanine aminotransferase, between weeks 7 and 10, which resolved with prednisolone; this effect correlates with finding AAV8-capsid specific T cells in the peripheral blood.[70] These authors published an update on the long-term outcome of 10 men (22 to 64 years old) treated with gene therapy using the AAV8 construct; the additional four patients received the high dose of the vector and had on average 5% factor IX levels, with a decrease in bleeding episodes, sustained over 4 years.[71]

More recent trials in gene therapy take advantage of a point mutation in the factor IX gene, known as Factor IX Padua, which synthesizes about eightfold higher Factor IX than wild type; factor IX–R338L was engineered with a liver-specific promoter and infused at a dose of 5×10^{11} vector genomes/kg in 10 men with severe hemophilia B with ABR reduction from 11.1 to 0.4 after infusion and average factor IX levels of 33.7 ± 18.5%. Two patients had an asymptomatic elevation of liver enzymes, which resolved after a short course of prednisone.[72]

Gene Therapy for Factor VIII Deficiency

Due to the large size of the factor VIII gene, advances in gene therapy for hemophilia A have been much slower than for hemophilia B, with the first report for gene therapy in hemophilia A coming 8 years after the landmark hemophilia B publication. Nine men with severe hemophilia A received a single dose of AAV vector encoding a B domain deleted human factor VIII (AAV5-hVIII-SQ, BMN-280, BioMarin) at three doses with one receiving a low dose, one intermediate dose, and the remaining seven at a high dose, with the patients in the low and intermediate groups having factor VIII less than 3 IU/dL and 6/7 high-dose participants had >50 IU/dL, which persisted at 1 year. After the first patient in the high-dose group had an elevated ALT, the remainder of the group were given prophylactic prednisone. There were no neutralizing antibodies.[73] In 2020, there was a 3-year follow-up of 15 patients who had received a dose of AAV5-hVIII-SQ; 13 of the 15 patients at 2 to 3 years who received a dose of 2 or 4×10^{13} vector genomes/kg had factor VIII levels in the moderate range (mean 13% to 20%) with ABR of 0 and reduction of factor VIII from 139 to 155 infusions/year to 0 to 0.5.[74] This product is not yet licensed in the United States, awaiting further safety data from an additional 2-year follow-up.

1-Deamino 8-D Arginine Vasopressin

The preferred product for the treatment of patients with mild or moderate hemophilia A is the synthetic octapeptide DDAVP, a vasopressin analog. DDAVP causes a release of factor VIII (and vWF) from endothelial cells, raising plasma factor VIII by approximately threefold (range 2- to 12-fold) in patients with hemophilia in whom the disease is caused by decreased production or secretion of a functional protein or a protein that has decreased activity. To be effective, DDAVP relies on a partial quantitative deficiency of factor VIII; thus, patients with severe hemophilia will not benefit from its use if the causative mutation results in no synthesis, secretion, or a nonfunctional protein. In a retrospective study assessing response to a DDAVP challenge in mild or moderate hemophilia, 57% of patients with mild hemophilia had a positive response, and several who failed the initial challenge had a response after a mean of 6 years, increasing the response rate to 71% in the mild group.[75] The response to DDAVP in an individual patient is typically reproducible, and effective response must be documented before its routine use or as prophylaxis for bleeding in surgical procedures (see box on 1-Deamino 8-D Arginine Vasopressin Trial). IV and intranasal preparations are available. The IV product has been used in a subcutaneous route of administration. The intranasal preparation more easily allows a patient to administer the compound on an as-needed basis in a home therapy regimen. The phenomenon of tachyphylaxis, the decreased effectiveness of repeated doses of the same compound, occurs after several, typically three, consecutive doses.

Injectable DDAVP (Sanofi Aventis) is available in 4 μg/mL. The recommended dose is 0.3 μg/kg, mixed in 30 mL normal saline (for children <10 kg, 10 mL normal saline), infused IV slowly over 30 minutes. This dose can be repeated after 12 to 24 hours. DDAVP nasal spray Stimate (CSL Behring) is available in a metered-dose pump that delivers 0.1 mL (150 μg) per activation (spray). The dose is one activation for patients weighing less than 50 kg and two activations in separate nostrils for those weighing more than 50 kg. In general, only three consecutive doses of DDAVP should be used unless otherwise advised by an experienced hemophilia treater. Because DDAVP is a vasopressin analog, there is a risk of fluid retention with its use. Changes in fluid balance can result in hyponatremia and seizures, especially when DDAVP is used in individuals on nonfluid-restricted or salt-restricted diets (e.g., elderly or very young patients or surgical patients undergoing fluid replacement with solutions with concentrations <0.9% sodium). For this reason, DDAVP is not recommended for children younger than 2 years of age. Caution is advised with the use of DDAVP in patients at risk for arterial thrombosis because there have been reports of myocardial infarction and cerebral thrombosis with its use.[76]

1-DEAMINO 8-D ARGININE VASOPRESSIN TRIAL

1. Collect citrated plasma from the patient immediately before DDAVP infusion for testing with the post infusion blood specimen.
2. Administer DDAVP IV (0.3 μg/1 kg) in 25–50 mL normal saline.
3. Wait approximately 30 min after the infusion, carefully observing the patient for possible adverse side effects (increased blood pressure, facial flushing, signs or symptoms of hyponatremia).
4. Collect post-DDAVP infusion specimen in sodium citrate at 60, 120, and 240 min.
5. Compare the pre- and post-DDAVP factor VIII and vWF:Ag levels to confirm a therapeutic response, threefold increase from baseline (for mild or moderate hemophilia, response is defined as twofold increase in factor VIII: C levels or an absolute level above 0.31 U/mL at 1 h).[75]

Plasma/Cryoprecipitate

In communities where virally inactivated factor VIII concentrates are not available, cryoprecipitate provides an effective alternative to therapy with concentrates for hemophilia A and vWD patients. Cryoprecipitate is a small-volume product (10 to 15 mL) enriched in factor VIII, vWF, fibrinogen, fibronectin, and factor XIII. Dosing can be calculated assuming approximately 80 to 150 IU of factor VIII per bag of cryoprecipitate (derived from a 450-mL single whole blood donor collection unit). Thus, a typical 1750-IU dose (50% correction for a 70-kg patient) would require between 10 and 21 bags or units.

Products Available for Treatment of Factor IX Deficiency

Factor IX Concentrates

As with replacement therapy for factor VIII deficiency, intermediate- and high-purity products derived from plasma (Alphanine SD, Grifols; and Mononine, CLS Behring) and recombinant products for the treatment of factor IX deficiency are available. All of these concentrates also undergo at least one viral inactivation or exclusion step in manufacturing. The volume of distribution of factor IX is approximately twice the plasma volume. This can be explained in part by the affinity of factor IX for type IV collagen present in the extracellular matrix.[77] Recovery of factor IX after the infusion is therefore approximately 1%/IU/kg. The recovery observed with recombinant factor IX is approximately 20% lower than that observed with plasma-derived factor IX.[78] This is likely caused by differences in posttranslational modifications between recombinant factor IX and plasma-derived factor IX.

Intermediate-purity factor IX products are generally purified from plasma using anion-exchange chromatography or calcium or barium precipitate adsorption. These methods select proteins that contain highly negatively charged epitopes. The vitamin K-dependent (VKD) coagulation factors, by virtue of their gamma-carboxyglutamic acid–rich domains, are such proteins; thus, these techniques copurify varying amounts of the other VKD coagulation factors, factor VII, factor X, and prothrombin with factor IX. Hence, the products are referred to as *prothrombin complex concentrates* (PCCs). The levels of vitamin K proteins in these products vary and can be obtained from the manufacturer. In addition, the PCCs are contaminated with trace amounts of activated forms of VKD factors. The presence of these activated factors is the likely explanation for thromboses that have occurred with the use of these intermediate-purity products, typically in the setting of postoperative immobility or hepatic dysfunction.[79] To minimize the risk of thrombosis with the use of PCCs, it is advisable to achieve a peak factor IX level no higher than 50%.[80] Some clinicians add small amounts of heparin to infusions of these products to prevent thrombosis, and some manufacturers have formulated PCCs with heparin or antithrombin III.

High-purity factor IX products are produced from plasma using techniques of ligand affinity or immunoaffinity chromatography and typically have specific activities greater than 150 IU/mg. Three single high-purity recombinant factor IX products have been licensed in the United States (BeneFIX, Wyeth; Ixinity, Aptevo Biotherapeutics LLC; and Rixubis, Baxalta Incorporated). Because specific products have different recovery results, consulting the package insert and performing recovery studies are recommended; for example, 1 IU BeneFIX/kg will increase the circulating activity of factor IX by 0.8 ± 0.2 and 0.7 ± 0.3 IU/dL in adults and pediatric (younger than 15 years old) patients, respectively.[82] Also, the initial dose of BeneFIX should be given under direct medical supervision because the potential for an allergic reaction is significant.[81] Thrombotic complications have not been reported with these high-purity products; some thrombotic events have been associated with continuous administration, which is not an approved method.[81] In patients with a history of allergy and inhibitors, irreversible nephrotic syndrome has been reported during immune tolerance induction (ITI).[82,83]

In communities where factor IX concentrates are not available, plasma may provide a means of replacing factor IX in hemophilia B patients during bleeding episodes. Each unit of FFP derived from a 450-mL whole blood collection contains approximately 200 IU of factor IX. Replacement to therapeutic levels of factor IX with FFP is difficult because of the complication of volume overload. In some areas, S/D plasma provides a virally inactivated alternative to FFP.

There are three extended half-life recombinant factor IX products licensed in the United States (Alprolix, Biogen Inc, Idelvion, CSL Behring LLC and Rebinyn, Novo Nordisk). Alprolix, synthesized in a human embryonic kidney cell line and purified by nanofiltration is covalently linked to human immunoglobulin G1; this Fc fusion protein has extended the half-life of factor IX: in adults, almost 86.5 hours, 12 to 17-years old about 83.5 hours, 6 to 11 years old about 72 hours and 2 to 5 years old almost 66.5 hours.[84] Some patients with factor IX deficiency may only need factor IX twice a month with this product. It should be noted that kaolin-based assays may underestimate the factor IX level.[84]

Other Useful Adjuncts for Treatment of Bleeding in Hemophilia A and B

The antifibrinolytic agents tranexamic acid (oral–Lysteda, Ferring Pharmaceuticals Inc; IV Cyklokapron, Pfizer) and ε-aminocaproic acid (EACA) (Amicar, Xanodyne Pharmaceuticals) are sometimes used in conjunction with clotting factor replacement therapy or DDAVP in the treatment of bleeding that occurs with hemophilia and other bleeding disorders. These agents interact with the lysine-binding site of plasminogen and enhance its activation. The more important effect of lysine analogs is that their occupancy of this site inhibits binding of the zymogen, plasminogen, to fibrin, which is necessary for full fibrinolytic activity. Antifibrinolytics are useful in the setting of mucosal bleeding and may substantially reduce the need for clotting factor concentrates in the setting of oral mucosal bleeding with tooth extractions. These agents are administered preoperatively and continued postoperatively until wound healing occurs. Although tranexamic acid is more potent, it is less readily absorbed when given orally. Tranexamic acid is administered at 25 mg/kg orally or 10 mg/kg IV preoperatively, and therapy can be continued postoperatively using oral rinses with a 5% solution. EACA is used at a dose of 100 mg/kg preoperatively followed by 100 mg/kg every 6 hours either orally or IV (maximum dose, 24 g/day). The dosing of these medications should be reduced in patients with renal insufficiency.

INHIBITORS OF FACTOR VIII AND FACTOR IX

A major complication in the treatment of patients with hemophilia is the development of inhibitory antibodies against the infused factors that interfere with factor activity. Rarely, antibodies may develop that do not affect activity but increase the clearance of factor VIII or factor IX. The incidence of factor VIII inhibitors is approximately 30%, and in patients receiving recombinant products inhibitors typically develop within the first 20 exposures to replacement therapy.[85,86] Results of the Survey of Inhibitors in Plasma-Product Exposed Toddlers (SIPPET) trial showed that patients who received recombinant products were two-fold more likely to develop inhibitors than those treated with plasma-derived products.[87] In another analysis of the SIPPET data, inhibitor production was found to be the highest in the first 10 exposure days with recombinant products occurring earlier (first 5 exposure days) and lasting longer than for plasma-derived products (exposure days 6 to 10).[88]

Patients with low-titer, transient inhibitors can be managed with increased doses of factor VIII or novel agents. Recently, a prospective, longitudinal study of 25 patients with severe hemophilia A evaluated the immune response during the first 50 exposure days to Advate; four distinct signatures were seen: subgroup 1 had no antibodies to factor VIII; subgroup 2 had non-neutralizing IgG1 antibodies; subgroup 3 had transient IgG1 antibodies and subgroup 4 developed high-affinity IgG1 antibodies, followed by IgG3 which was the harbinger of persistent antibodies and production of IgG4 antibodies. The seven patients in subgroup 4 all had high or moderate risk factor 8 mutations.[89] Inhibitors to factor IX occur less frequently, with an estimated incidence of approximately 1% to 3%.[90] Patients with factor IX antibodies may have anaphylactic reactions when treated with high-purity products.[91,92]

Patients with high-titer inhibitors to either factor VIII or factor IX do not usually achieve hemostasis after factor replacement; however, in the era of new agents, there are alternatives that lead to enhanced thrombin generation without factors. Management of patients who develop inhibitors involves two approaches: (1) acute treatment of bleeding episodes and (2) ITI therapy, whereby the patient is treated frequently (often daily) with factor VIII or factor IX in an effort to suppress the production of inhibitors by the immune system (similar to allergic desensitization therapy).

Treatment of acute bleeding episodes can be accomplished by three methods. For patients with low-titer inhibitors (<5 Bethesda units [BU], a laboratory measurement of inhibitor activity), hemostasis can be accomplished with large doses of factor VIII or factor IX (e.g., as high as 200 IU/kg given at frequent intervals) in an effort to neutralize or "override" the circulating inhibitor. A neutralization approach is usually ineffective for patients with high-titer inhibitors (>5 to 10 BU) and is expensive because of the large amounts of the factor required. The peak inhibitor titers pre-immune tolerance therapy and during treatment are the most significant prognostic features.[93] These patients and patients with low-titer inhibitors who fail to respond to override therapy can be treated using products that act to "bypass" the inhibitor. There are three current bypass agents approved; one is aPCCs (FEIBA, Takeda Pharmaceutical Company Limited), which contain factors VII, X, and prothrombin in addition to factor IX that enhance the production of thrombin generation by activating the coagulation pathway at points further down than the factor VIIIa/factor IXa step.

The other two are recombinant activated factor VII (rFVIIa) (NovoSeven, Novo Nordisk) was licensed in Europe and the United States with an indication for use as a bypassing agent in the treatment of patients with hemophilia A and hemophilia B and inhibitors, or acquired hemophilia (also approved for bleeding and perioperative management in Glanzmann thrombasthenia, who are refractory to platelet transfusion and congenital factor VII deficiency) and SEVENFACT, HEMA Biologics). The dose of NovoSeven for patients with the inhibitor is 90 μg/kg every 2 hours. SEVENFACT is given every 3 hours compared with every 8 to 12 hours for PCCs or aPCCs. Thrombosis has also been reported with the use of rFVIIa[80,94,95] and PCCs.[83]

Despite the success achieved with ITI regimens (80% to 90%),[96] "bypass" agents are still needed in patients undergoing tolerization because an interval potentially as long as 2 to 3 years exists between the time that induction is initiated and the inhibitor is suppressed. Bleeding episodes that occur before the achievement of tolerance usually require treatment with one or another of the bypassing agents.

Leissinger et al. demonstrated in hemophilia A patients with high-titer inhibitors the superiority of prophylactic thrice-weekly FEIBA (Baxter) at 85 U/kg over on-demand therapy.[88] In a prospective, randomized, crossover study with a 3-month washout between the two arms, which were each 6 months, the prophylaxis regimen prevented the progression of joint disease in high-titer inhibitor patients; and is now recommended for prophylaxis in high-titer inhibitor patients (see box Treatment of Life-Threatening Bleeding Episodes in Patients With Inhibitors Against Factor VIII or Factor IX).

Treatment of life-threatening bleedings in the context of a high-titer inhibitor represents a significant challenge. The effect of non-factor VIII concentrates (bypass agents) when the inhibitor titer is greater than 10 BU (precluding the use of factor VIII), is difficult to monitor in the laboratory because plasma factor levels do not reflect hemostasis. Adjunctive therapies are frequently used in this setting to lower the titer of the antibody to allow for treatment of the patient with factor VIII concentrates. Aggressive regimens are used in which circulating antibodies are depleted using plasmapheresis or staphylococcal protein A immunoadsorption, and reduction of antibody production is attempted using immunomodulatory agents such as steroids, cyclophosphamide, and IV infusion of immunoglobulin G (IgG).[98–101] These strategies for acutely reducing antibody titers are also used by some hemophilia treaters at the outset of ITI. In a phase II trial, Leissinger et al. evaluated the safety and efficacy of rituximab, without concurrent ITI, to reduce high-titer inhibitor levels in hemophilia A patients,[102] although the study was designed to enroll 43 patients, only 23 were enrolled and the Data Safety Monitoring Board closed the study because of poor accrual over 4 years. Three of 16 (18.8%) had a major response (inhibitor titer <5 BU) and one with a minor response (initial inhibitor titer <5 BU but increased after factor VIII exposure).[103] Several case reports or series of patients with severe hemophilia have demonstrated a greater advantage from rituximab when used in conjunction with ITI.[104,105] In a recent review of inhibitor eradication with rituximab, Franchini and Mannucci concluded that the combination of ITI with rituximab in mild to moderate hemophilia is likely to be more beneficial[106] than when used without simultaneous factor VIII. Also, rituximab has been used successfully in the setting of acquired hemophilia A, mostly with concurrent immunosuppression.[105]

TREATMENT OF LIFE-THREATENING BLEEDING EPISODES IN PATIENTS WITH INHIBITORS AGAINST FACTOR VIII OR FACTOR IX

Concentrates

1. Factor VIII containing concentrates in high doses (as high as 150–200 IU/kg) if inhibitor titer is low (<5–10 BU). High-dose continuous infusion of factor VIII (≈10 IU/kg/h) after a high-dose bolus may be useful.
2. Recombinant factor VIIa—NovoSeven. Dose is 90 μg/kg (or a dose up to 320 μg/kg) administered every 2 h. Risk of thrombosis exists with this product.
3. Activated PCCs at a dose of 50–75 IU/kg every 8–12 h. Risk of thrombosis exists with this product.

Immunomodulation

1. Antibody depletion
   a. Plasmapheresis
   b. Extracorporeal immunoadsorption of plasma (staphylococcal protein A column therapy and other methods)
2. Suppression of antibody production
   a. High-dose steroids (equivalent of prednisone 80 mg/day)
   b. Cyclophosphamide (10–15 mg/kg load and 2–3 mg/kg/day)
   c. Intravenous immunoglobulin (1 g/kg daily for 2 days)
   d. More aggressive regimens that may include vincristine, azathioprine, cyclosporine, or interferon-γ

Conservative Measures

1. Immobilization
2. Compression
3. Local application of hemostatic agents
4. Antifibrinolytics
5. Avoid venipunctures, intramuscular injections, arterial puncture, and lumbar punctures
6. Avoid use of medications that inhibit platelet function (ASA, NSAIDs)
7. DDAVP may be effective in some patients with low-titer inhibitors

ASA, Aspirin; *BU*, Bethesda unit; *NSAID*, nonsteroidal anti-inflammatory drug; *PCC*, prothrombin complex concentrate.

Patients with inhibitors to factor VIII or factor IX can also be treated with novel agents for prophylaxis; although most treaters would try one attempt at ITI.[93]

VON WILLEBRAND DISEASE

vWD is an autosomal dominant bleeding disorder first described by Erik von Willebrand in 1926, who named this bleeding diathesis *pseudohemophilia*. vWD is relatively common, with a prevalence of up to 2% of the general population.[107] The penetrance and severity of the disease vary depending on the type of vWD (type 1, 2, or 3); the specific mutation; the number of affected genes; the patient's blood type; and numerous drug, hormonal, and stress-related parameters. These factors, particularly the subtype of vWD and the patient's response to DDAVP, influence the recommended treatment for acute bleeding episodes or prophylaxis against bleeding.

Although the disease had been described in the 1920s, the primary defect had earlier been attributed to either platelets or the vessel wall. An understanding of the missing protein in vWD and its relationship to factor VIII was not appreciated until the 1950s. Correction of the defect with transfusion of plasma, but not with platelet concentrates alone, defined the disease as one involving a missing plasma protein factor (vWF), not a platelet or vessel wall defect.[108] A correlation between vWD and factor VIII activity had previously been observed—the observation that a plasma fraction from patients lacking factor VIII (hemophilia A) could correct the defect in vWD in addition to the autosomal inheritance pattern, which helped further differentiate hemophilia A from vWD.[108] A more detailed discussion of the clinical features and pathophysiology of vWD and the molecular biology of vWF can be found in Chapter 133.

Transfusion Therapy for von Willebrand Disease

The specific treatment for vWD varies with the bleeding symptoms and signs and with the subtype of vWD (see Chapter 133). Treatment is guided further by laboratory results indicating the potential success of increasing vWF with DDAVP and the clinical experience with a particular patient and his or her natural biologic family members who have vWD. When possible, attempts should be made to treat the patient without exposing him or her to plasma-derived products.

Nonprotein-Based Treatment

DDAVP is a synthetic octapeptide homolog of vasopressin that results in the release of stored vWF from Weibel Palade bodies of the endothelium (see section on treatment of hemophilia A). DDAVP is often effective for type 1 disease and may be useful in certain patients with type 2 disease. It is not appropriate for use in patients with type 3 disease in whom no stores of vWF exist. Before the use of DDAVP, a DDAVP trial should be conducted to document its efficacy in an individual patient. The trial is performed as described for hemophilia A. The phenomenon of tachyphylaxis is also observed when DDAVP is used to treat vWD. For bleeding that does not respond to DDAVP or in patients in whom a poor response is observed with DDAVP, other modalities (typically protein based) must be used.

As described for hemophilia A, the antifibrinolytic agent EACA or tranexamic acid are often administered in the setting of dental surgery to inhibit fibrinolysis. Care should be taken when these agents are administered in patients with a predisposition to thrombosis.

Estrogens upregulate vWF synthesis and may be useful, especially in women. Therapy with estrogens should also help ameliorate menorrhagia in affected symptomatic patients.

Plasma Protein–Based Therapy

Factor VIII Concentrates

Some intermediate-purity factor VIII concentrates are manufactured from plasma using methods that copurify significant amounts of vWF. Many of the products listed in Table 136.3 contain vWF. Humate-P (CLS Behring GmbH) and Wilate (Octapharma), which is 1:1 vWF:RCo/factor VIII, are currently licensed for the treatment of vWD. The multimeric pattern of VWF in these concentrates varies, and no product has the pattern of multimers that is present in normal plasma.[109] Because many of these products are effective clinically, the importance of these differences in multimer pattern remains to be determined. In addition, when using multiple doses of these products, factor VIII and vWF:RCo should be monitored because there is an increased risk of thrombotic events with the accumulation of factor VIII.

von Willebrand Factor Concentrates (Plasma-Derived and Recombinant)

Several chromatography-purified plasma-derived concentrates enriched in vWF have been studied by manufacturers in Europe.[110,111] Preliminary reports suggest that these are amenable to viral inactivation steps and may be effective both in vitro and in vivo.[109] To date, none of these have been developed as widely licensed products. Recombinant vWF (VONVENDI, Takeda Pharmaceutical Company Limited.) which is albumin- and plasma-free and synthesized in Chinese hamster ovaries was approved in 2015. In patients with severe vWD, a phase 3 multicenter trial of recombinant vWF, given alone or with Advate, was effective in treating all 22 patients with bleeding episodes; no thrombosis or inhibitors occurred during the study.[112] This can be used for treatment, prophylaxis, or in the perioperative setting; by itself, recombinant vWF can raise plasma factor VIII levels by 40% within 6 hours, with some individual variability.[113]

Cryoprecipitate

Cryoprecipitate was the mainstay of plasma-based therapy for bleeding in patients with vWD until the availability of virally inactivated intermediate-purity factor VIII concentrates with preserved functional vWF protein. These factor VIII concentrates are the products of choice for the treatment of bleeding in patients with types 1 and 2 vWD who are unresponsive to DDAVP and for bleeding in patients with type 3 vWD. Owing to the small potential for viral contamination of cryoprecipitate, manufacture of which does not include steps to inactivate viral pathogens, cryoprecipitate is currently indicated only when virally safe concentrates containing vWF are unavailable.

ACQUIRED FACTOR VIII AND VON WILLEBRAND FACTOR DEFICIENCY

Antibodies that inhibit the activity of factor VIII can develop in previously normal patients. Most of these patients have no underlying disease; however, factor VIII antibodies can arise in the setting of autoimmune disorders or the postpartum period. Although approximately one-third of inhibitors disappear spontaneously, the mortality rate among affected patients is significant.

In adults, acquired vWD is a rare autoimmune disorder that can occur in association with other autoimmune disorders or lymphoproliferative disease. Antibodies may interact with the epitopes on vWF required for its normal activity or result in increased clearance of antibody–vWF complexes.

In children, acquired vWD is extremely rare but has been reported in the context of Wilms tumor, hypothyroidism, and congenital heart disease and some medications; with treatment of the underlying disorder, vWF normalizes.

Treatment

Therapy for those patients with relatively high inhibitor titers (>5 BU) includes bypassing agents (FEIBA or rFVIIa) to stop bleeding and immunosuppression to reduce inhibitor levels. Plasmapheresis or immunoadsorption can be used to reduce the circulating levels of inhibitors. Immunosuppressive agents and IV IgG are useful adjuncts to abrogate the production of the autoantibody. DDAVP can also be effective in some patients with low-titer inhibitors. Unlike inhibitors that develop with hemophilia A, exposure to factor VIII usually does not result in increased antibody titers.[114] Conservative measures to control hemorrhage should also be used in conjunction with the above, including immobilization and compression, topical or local hemostatic agents, and antifibrinolytic therapy. The use of venipunctures, intramuscular injections, and drugs with platelet inhibitory activity should be minimized or avoided.

OTHER COAGULATION PROTEIN DEFICIENCIES

Approximately 15% of inherited bleeding disorders are caused by deficiencies of coagulation factors other than factor VIII, factor IX, or vWF. Inherited deficiencies of fibrinogen and factors II, V, VII, X, XI, and XIII may result in bleeding, requiring treatment. The genes for these factors are not located on the X chromosome; thus two gene defects are typically required for symptomatic disease. Consanguinity is frequent in affected kindreds. The characteristics of these deficiencies are presented in Table 136.3. Hereditary deficiencies of factor

TABLE 136.3 **Other Coagulation Deficiencies**

Factor	Incidence	Inheritance	Chromosome	Half-Life	Target Plasma Level	Treatment Product[a]
I (fibrinogen)	$1–2/10^6$		4	2–4 days	50–100 mg/dL	Concentrates
Afibrinogenemia		AR				Cryoprecipitate
Hypofibrinogen		AR or AD				
Dysfibrinogen		AR or AD				
II (prothrombin)	$<1/10^6$	AD	11	3 days	30%	PCCs Plasma
V	$1/10^6$	AR	1	36 hours	25%	Plasma
VII	$2/10^6$	AR	13	3–6 hours	25%	rFVIIa Concentrates PCCs Plasma
X	$2/10^6$	AR	13	40 hours	10%–25%	Concentrate PCC Plasma
XI		AR or AD	4	80 hours	20%–40%	Concentrates Plasma
XIII	$<1/10^6$	AR	1.6	9 days	5%	Concentrates Cryoprecipitate Plasma

[a] Products are listed in order of viral safety.

AD, Autosomal dominant; *AR*, autosomal recessive; *PCC*, prothrombin complex concentrates.

Data from Cohen AJ, Kessler CM. Treatment of inherited coagulation disorders. *Am J Med.* 99:675, 1995.

XII, prekallikrein, and high-molecular-weight kininogen have not been described to result in bleeding diatheses.

The mainstays of therapy for these disorders are cryoprecipitate (for fibrinogen deficiency) and plasma. In some countries, concentrates enriched in the missing protein have been available. An S/D-treated pooled plasma product is also available in some regions. Pooled S/D-treated plasma has the advantage over FFP in that it is virally inactivated but has the drawback of exposing the patient to a large number of donors (2500) with each dose.

Fibrinogen Deficiency

Bleeding disorders can result from low to absent levels of fibrinogen (hypofibrinogenemia or afibrinogenemia) or a protein with abnormal function (dysfibrinogenemia). The inheritance pattern for the former is autosomal recessive and for the latter is autosomal dominant. Dysfibrinogenemias can result in bleeding or hypercoagulability. The gene for fibrinogen is located on chromosome 4. Because fibrinogen is required for the formation of a fibrin clot, it is surprising that afibrinogenemic patients survive gestation and birth. Diagnosis is made when patients present with bleeding from the umbilical stump, intracranial hemorrhage, or mucosal bleeding. Hemarthroses can occur but are less common than observed with the hemophilias. Wound healing may be delayed. Increased incidence of fetal wastage in patients with afibrinogenemia and hypofibrinogenemia is observed, and term gestation is rarely achieved without replacement of fibrinogen.[115–117] Because the substrate for clot formation, fibrinogen, is missing or deficient, the prothrombin time (PT), aPTT, thrombin clotting time (TCT), and coagulation assays that have fibrin formation as their endpoints are all prolonged. Replacement of fibrinogen is accomplished with cryoprecipitate with a goal of achieving a plasma level between 50 and 100 mg/dL and at least 60 mg/dL for maintenance of pregnancy.[117] (Each bag of cryoprecipitate contains approximately 200 to 300 mg of fibrinogen.) The biologic half-life of fibrinogen is between 2 and 4 days. Virally inactivated, highly purified fibrinogen concentrates are available in Europe, China, Japan, and the United States, RiaSTAP, CSL Behring and Fibryga, Octapharma, which is nano-filtered, are available. These fibrinogen concentrates offer many advantages over cryoprecipitate, including viral inactivation, standardized fibrinogen content, smaller infusion volume and expedited time to treat the patient as reconstitution is swift, since it is stored as a lyophilized powder, and there is no need for cross-matching.[118] Adverse reactions to treatment include the development of fibrinogen antibodies; allergic reactions; and, paradoxically, thrombosis.

Prothrombin Deficiency

Congenital prothrombin deficiency is a rare autosomal recessive disorder estimated to be present at a rate of 0.5 cases per million. The disease has been described with both homozygous and heterozygous defects (including compound heterozygotes). No reports of aprothrombinemia appear in the literature, suggesting that a complete lack of the protein is incompatible with normal development. Hemorrhagic symptoms include bruising; hemarthroses; intracranial, mucosal, and deep-tissue bleeding; and menorrhagia.[119] Correlation between bleeding and prothrombin levels is poor. Both the PT and the aPTT are prolonged, and the thrombin time is normal. Treatment of prothrombin deficiency includes plasma at a dose of 15 to 25 mL/kg followed by 3 mL/kg every 12 to 24 hours to achieve levels of approximately 30%. The half-life of prothrombin is approximately three days. PCCs contain prothrombin and other VKD factors and can be used to treat prothrombin-deficient patients who are undergoing major surgery or life-threatening bleedings. Caution should be exercised because these have been associated with thrombosis.

Factor V Deficiency

Inherited deficiency of factor V occurs in fewer than 1:1,000,000 people with an autosomal recessive inheritance pattern (homozygous or compound heterozygous), resulting in factor V levels less than 20%. Symptoms include bleeding from the umbilical stump and mucous membranes, ecchymoses, menorrhagia, postpartum bleeding, and intracranial hemorrhage. Hemarthroses can occur but are less common than severe hemophilia. The correlation between bleeding and factor V levels is poor. No factor V–enriched plasma concentrates are available. Because factor V is in the common pathway of coagulation, in deficiency states, both the PT and the aPTT are prolonged. Treatment of bleeding involves the infusion of plasma at 15 to 20 mL/kg with a goal of achieving levels of 20%. The half-life of factor V is approximately 36 hours. Because platelets contain stored factor V,[120] they have been used to treat bleeding. Platelet infusion may result in the production of platelet-specific antibodies.

Factor VII Deficiency

Factor VII deficiency occurs in approximately 1:500,000 people; it is autosomally recessive and of the rarely inherited coagulation disorders, factor VII deficiency is the most common. Severe bleeding occurs with levels below 1%, and symptoms in severely affected patients are similar to those observed with severe hemophilia. Intracranial hemorrhage may occur in up to 16% of cases and neonates after vaginal delivery. The PT is prolonged, but the aPTT and thrombin times are normal. PCCs contain factor VII and may provide a benefit over plasma because they are virally inactivated. As with the use of these products for factor VIII and factor IX inhibitors, thrombosis has been reported. Recombinant activated factor VII (NovoSeven, Novo Nordisk) concentrate is effective in the treatment of bleeding with a congenital factor VII deficiency.[121–124] This can be used at a dose of 10 to 40 μg/kg every 4 to 6 hours, which is much lower than the dose used for patients with hemophilia and inhibitors.[125] Inhibitors to factor VIIa have developed in patients with congenital factor VII deficiency.[121]

Factor X Deficiency

Congenital deficiency of factor X is a rare condition resulting from homozygous or compound heterozygous defects in the autosomal genes for factor X located on chromosome 13. Bleeding correlates with factor X levels, and symptoms include epistaxis, menorrhagia, hemarthrosis, intracranial or gastrointestinal hemorrhage, hematuria, and umbilical cord bleeding. Because factor X is a component of prothrombinase (the first step in the common pathway), diagnosis is suggested by both a prolonged PT and a prolonged aPTT but a normal TCT. Treatment is with plasma products (FFP or S/D-treated plasma) at approximately 15 to 25 mL/kg followed by 5 mL/kg every 24 hours with a goal of plasma factor X activity levels of 20%. PCCs can be used; however, they contain variable amounts of factor X. As with the use of PCCs for other indications, the risk of thrombosis is increased. Coagdex, Bio Products Laboratory, is a plasma-derived factor X concentrate, approved in 2015 for prophylaxis, treatment of bleedings and perioperative management in mild-moderate factor X deficiency. There is a registry study NCT03161626, which collects data about patients with severe factor X deficiency and major surgery. For prophylaxis, Coagdex can be given twice weekly (children <12, 40 units/kg, age ≥12, 25 units/kg) but levels should be monitored to assess individual response.[126]

Factor XI Deficiency

Congenital factor XI deficiency (sometimes called hemophilia C) is an autosomal disorder with a recessive pattern of inheritance and is particularly common in Ashkenazi Jews in whom two specific mutations account for the approximately 8% prevalence of an abnormal factor XI gene.[127] The factor XI gene is located on chromosome 4. Bleeding symptoms are variable and include postsurgical or traumatic bleeding or heavy menses in women. Spontaneous hemorrhage and musculoskeletal bleeding are not typical of the disorder, and these characteristics distinguish this disorder from hemophilia A and B. Plasma levels of factor XI do not correlate with bleeding symptoms unlike the factor levels in hemophilia A and B. The aPTT is prolonged with factor XI deficiency; PT and thrombin time are normal. The bleeding risk in patients with factor XI deficiency depends on the surgical site and the fibrinolytic activity, if low prophylaxis may not be needed.[128] Plasma (FFP and S/D-treated plasma) provides the mainstay of therapy, and dosing takes into consideration the long half-life of 60 to 80 hours; however, some patients may have difficulty tolerating the large fluid volume of FFP. Although the half-life of factor XI in S/D plasma is comparable to that of FFP, decreased levels of factor XI in the product (≈30% to 50%) have been reported.[129] Especially in those patients with absent factor XI protein, inhibitors have developed after exposure to factor XI products. Two virally reduced or inactivated factor XI concentrates have been developed using affinity chromatography or cation-exchange chromatography.[130] These two concentrates, licensed in France (Hemoleven, LFB Biomedicaments France) and England (FXI concentrate Bio Products Laboratory). Both concentrates have been demonstrated to be effective, but there have been reports of thromboembolic complications with their use, presumably because of contaminant activated factor IX. Both products are now formulated with antithrombin and heparin, but caution is advised with their use in elderly patients and in patients with preexisting cardiovascular disease. In addition, because of thromboembolic risk, when using factor XI concentrates, antifibrinolytics should not be used concurrently. The recommended dose of these concentrates is 10 to 15 IU/kg.[128] There are no recombinant XI products available.

Because bleeding occurs in patients with factor XI deficiency more often in settings in which fibrinolysis is more active (oral mucosa, urinary tract), antifibrinolytic agents can be useful adjuncts in the treatment of such bleeding episodes or used as sole agents to prevent bleeding with dental procedures. Fibrin glue can provide a useful adjunct or be used solely in topical bleeding (dental extractions, circumcisions). DDAVP has been reported as useful for the prevention of surgical bleeding in factor XI deficiency.[131] The mode of effect of the DDAVP is unclear but is likely caused by the coexistence of mild vWF deficiency.

Factor XIII Deficiency

Factor XIII is a transglutaminase that catalyzes the cross-linking of γ-glutamyl and ε-lysyl groups of fibrin monomers, stabilizing the forming clot by decreasing its susceptibility to fibrinolysis. Inherited deficiency of factor XIII is autosomal recessive and results from defects in the genes for the two subunits of factor XIII located on chromosome 1 (B subunit) and chromosome 6 (A subunit). The majority of reported defects involve the A subunit. Umbilical bleeding in homozygotes may be observed at birth. Soft tissue bleedings, hemarthroses, excessive intracranial bleeding (relative to other coagulation deficiencies), pseudotumors, and bleeding during surgery are observed in affected patients. Surgery is also complicated by poor wound healing. Affected male patients may have oligospermia, and female patients may have recurrent miscarriages. Coagulation screening test results (PT, aPTT, and TCT) are normal. Solubility of clots is increased with factor XIII deficiency; thus, the diagnosis can be made by incubating clots in the presence of solubilizing agents such as 5 M urea or 1% to 2% chloroacetic acid. This qualitative test fails to detect mild and moderate deficiency; therefore, it is not recommended to perform quantitative factor XIII testing when suspecting a deficiency. Factor XIII has a long half-life (9 to 15 days). Previously, FFP (2 to 3 mL/kg) or cryoprecipitate (1 bag/10 to 20 kg) were the only options for treating patients with factor XIII deficiency. However, in February 2011, the first plasma-derived factor XIII concentrate (Corifact, CSL Behring) was approved by the FDA for prophylaxis; this concentrate is given intravenously to maintain a trough level of 5% to 20% with the initial recommended dose being 40 IU/kg every 28 days.[132] Because of the long half-life of factor XIII, the replacement can be used on a prophylactic basis (dosing every 3 to 4 weeks) to prevent intracranial hemorrhage and other bleeding episodes. The United Kingdom Haemophilia Centre Doctors' Organisation's current guidelines recommend lifetime prophylaxis for those patients with a severe factor XIII deficiency and a personal or family history of bleeding.[125] Dosing with factor XIII concentrate is 10 to 20 IU/kg every 4 to 6 weeks, with lower doses for prophylaxis and higher doses for the treatment of bleeding episodes, as well as escalating the dose throughout pregnancy.[125]

Recombinant FXIII-A2 (Tretten, Novo Nordisk) was approved in 2013. For prophylaxis in patients with congenital factor XIII A–subunit deficiency, recombinant FXIII-A2 35 IU/kg can be given monthly, targeting a trough >10%; this product cannot be used for patients with a B-subunit deficiency.[133] During the phase 1 extension study, no patients developed inhibitors or had thrombotic complications; twelve patients who underwent minor surgery eight patients receiving recombinant FXIII-A2 within the last 7 days and four within the last 10 to 21 days, did not require additional doses of factor.[134]

OTHER PLASMA-DERIVED PROTEIN CONCENTRATES

As discussed in Chapter 115, plasma fractionation processes also allow for the isolation of plasma components other than the coagulation proteins. Immunoglobulins are isolated by a variety of techniques from the Cohn fraction II–III. α_1-Antitrypsin and antithrombin are produced from fraction IV. As with other VKD proteins, protein C may be isolated from Cohn fraction II.

Anticoagulant Proteins (Protein C and Antithrombin)

Brief mention should be made of plasma-derived concentrates enriched in protein C and recombinant antithrombin III (Thrombate III, Grifols). These products have been used for a variety of indications, but both are licensed for the treatment of congenital deficiencies that result in thrombosis. Protein C concentrate has also been used in the treatment of purpura fulminans with meningococcemia. Antithrombin III in combination with defibrotide has been used for the successful treatment of veno-occlusive disease in patients who develop this complication after undergoing bone marrow transplantation,[135] heparin resistance in patients undergoing cardiopulmonary bypass, extracorporeal membrane oxygenation (ECMO), and sepsis. In addition, antithrombin III has been used in patients with acute lymphoblastic leukemia who are receiving asparaginase. There is recombinant topical thrombin (Recothrom, Baxter) which has been used in the surgical setting.

Although early studies showed some efficacy in using activated protein C to treat sepsis.[136] a Cochrane review reported that in five randomized controlled trials, including 5101 patients, activated protein C did not decrease the risk of death and was associated with an increased risk of bleeding.[137] Ceprotin, Baxter, is protein C concentrate that has been used for patients with severe protein C deficiency.

Immunoglobulins

The use of immunoglobulins (both IV and hyperimmune products) for a variety of diseases is discussed elsewhere in this book.

α_1-Protease Inhibitor (Antitrypsin)

α_1-Protease inhibitor (or antitrypsin) concentrates (Prolastin-C, Grifols; Aralast, Bayer Corporation; Zemaira, CLS Behring) are available for the prophylactic treatment of people with congenital deficiency of α_1-antitrypsin. α_1-Antitrypsin inhibits neutrophil elastase, which is thought to be responsible for the alveolar damage resulting in emphysema. These replacement products, administered IV, are presumed to act to delay the progression of congenital emphysema associated with this protease inhibitor deficiency.

FUTURE DIRECTIONS

Long-acting factor products have now been approved and have improved quality of life while reducing the number of weekly infusions and limiting the need for venous access devices. Novel delivery methods and rebalancing therapies for hemophilia, such as monthly subcutaneous injections are now widely used, greatly enhancing the quality of life. The possibility of future treatment with an oral agent may become a reality. Alternatively, curative treatment with gene therapy or gene editing may drastically reduce the need for factor replacement or rebalancing therapies. This continues to be a most promising time for the management of patients with hemophilia and rare inherited factor deficiencies.

CHAPTER 137

DISSEMINATED INTRAVASCULAR COAGULATION

Marcel Levi

A variety of disorders, including infectious or inflammatory conditions and malignant disease, will lead to activation of coagulation. In many cases, this activation of coagulation will not lead to clinical complications and will not even be detected by routine laboratory tests, but can only be measured with sensitive molecular markers for activation of coagulation factors and pathways.[1,2] However, if activation of coagulation is sufficiently strong, the platelet count may decrease and global clotting times may become prolonged. In its most extreme form, systemic activation of coagulation is known as disseminated intravascular coagulation (DIC). DIC is characterized by the simultaneous occurrence of widespread (micro)vascular thrombosis, thereby compromising blood supply to various organs, which may contribute to organ failure.[3,4] Because of ongoing activation of the coagulation system and other factors, such as impaired synthesis and increased degradation of coagulation proteins and protease inhibitors, consumption of clotting factors and platelets may occur, resulting in diffuse bleeding.

In view of the multiple, often contrasting mechanisms that occur in patients with DIC, a consensual definition of DIC had been a matter of debate. In 2001, the subcommittee on DIC of the International Society on Thrombosis and Haemostasis proposed a definition that reflects the central role of the microvascular milieu (i.e., endothelial cells, blood cells, and the plasma protease system, in the pathogenesis of DIC). This definition of DIC reads as follows: “DIC is an acquired syndrome characterized by the intravascular activation of coagulation without a specific localization and arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction.”[5]

The diagnosis of DIC may be hampered by the non-specific nature of many indicators of coagulation activation, although newly developed scoring algorithms based on readily available routine laboratory parameters show promising diagnostic accuracy.[5] Owing to the complexity of the clinical presentation, the variable, and unpredictable course, and the multitude of therapies given to patients with DIC, properly conducted clinical trials are difficult to perform and even to devise. Management relies on limited evidence from clinical trials in combination with small studies employing surrogate outcome endpoints and experience from case series, as well as from an understanding of the underlying pathophysiologic mechanisms.[6]

EPIDEMIOLOGY

Activation of coagulation in concert with inflammatory activation can result in microvascular thrombosis, which contributes to multiple organ failure in patients with severe sepsis.[7] In support of this concept, postmortem findings in patients with coagulation abnormalities and DIC on the background of severe sepsis include diffuse bleeding, hemorrhagic necrosis of tissues, microthrombi in small blood vessels, and thrombi in mid-size and larger arteries and veins. Ischemia and necrosis were invariably the results of fibrin deposition in small and mid-size vessels. Importantly, intravascular thrombi appear to be the driver of the organ dysfunction. Fibrin deposition in various organs also is a characteristic finding in animal models of DIC. Thus, experimental bacteremia or endotoxemia causes intra- and extravascular fibrin deposition in the kidneys, lungs, liver, brain, and other organs. Amelioration of the hemostatic defect with various interventions in these models reduces fibrin deposition, improves organ function, and, in some cases, reduces mortality. Finally, the results of clinical studies also support the concept that the extent of activation of the coagulation system is an important determinant of clinical outcome. DIC has been shown to be an independent predictor of organ failure and mortality.[8] In a consecutive series of patients with severe sepsis, 43% of patients with DIC were compared with 27% without DIC. In this study, the severity of the coagulopathy was directly related to mortality.[9]

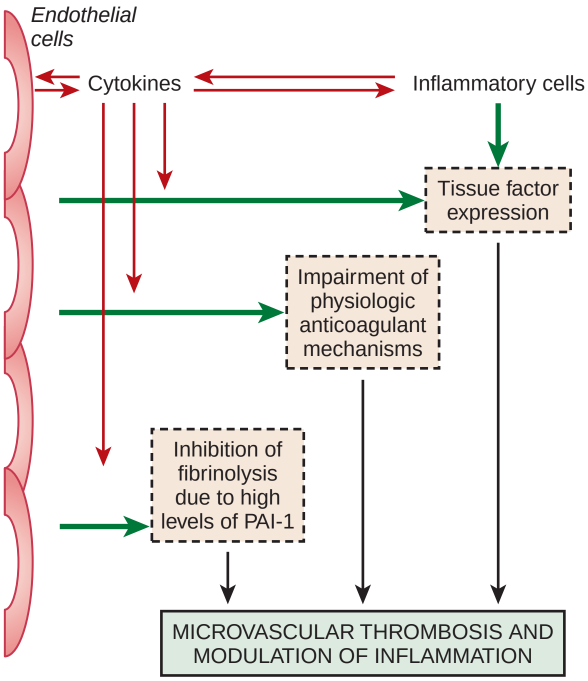
In addition to microvascular thrombosis and organ dysfunction, coagulation abnormalities may have other harmful consequences. Thrombocytopenia in patients with sepsis places them at increased risk of bleeding. For example, critically ill patients with a platelet count of less than 50×10^9/L have a four to fivefold higher risk for bleeding than those with higher platelet counts.[10] Although the overall risk of intracerebral bleeding in patients in the intensive care unit (ICU) is less than 0.5%, up to 88% of patients with this complication have platelet counts less than 100×10^9/L. The use of anticoagulants in patients with thrombocytopenia further increases the risk of bleeding. Regardless of the cause, multivariate analyses indicate that thrombocytopenia is an independent predictor of ICU mortality and increases the risk of death by 1.9- to 4.2-fold. In particular, thrombocytopenia that persists for more than 4 days after ICU admission, or a 50% or greater decrease in the platelet count during the ICU stay is associated with a four- to sixfold increase in mortality. In fact, the platelet count appears to be a stronger predictor of ICU mortality than composite scoring systems, such as the Acute Physiology and Chronic Evaluation (APACHE) II or Multiple Organ Dysfunction Score (MODS). Decreased levels of coagulation factors, as reflected by prolonged global coagulation times, also increase the risk of bleeding. Prolongation of the prothrombin time (PT) or activated partial thromboplastin time (aPTT) to over 1.5 times the control is associated with an increased risk of bleeding and mortality in critically ill patients.

PATHOBIOLOGY

Traditionally, DIC was thought to be the result of activation of both the extrinsic and intrinsic pathways of coagulation. The classical concept was that the extrinsic pathway was initiated by a tissue-derived component, which activated factor VII, leading to the direct conversion of prothrombin to thrombin. This process would proceed as long as there was tissue damage from systemic infection, trauma, placental abruption, or malignancy. In contrast, the intrinsic or contact pathway of coagulation was initiated by contact activation of factor XII which, together with its cofactors, kallikrein and kininogen, then activated factor XI with subsequent activation of factor IX. The initiators of contact activation were poorly understood until recently but were thought to include collagen and artificial surfaces. In recent years, the molecular mechanisms of coagulation pathways have been defined (Fig. 137.1) (see Chapters 120 and 124). This has provided new insight into the pathogenesis of DIC. In general, current thinking is that thrombin and fibrin generation in patients with DIC is largely driven via the extrinsic pathway; the role of the contact system is uncertain.

Tissue Factor-Factor VII(a) Pathway

The extrinsic pathway is initiated by the tissue factor (TF)-factor VIIa complex. TF is a membrane-bound 4.5 kD protein that is constitutively expressed on cells that are mostly in tissues not in direct contact



Endothelial cells
Cytokines
Inflammatory cells
Tissue factor expression
Impairment of physiologic anticoagulant mechanisms
Inhibition of fibrinolysis due to high levels of PAI-1
MICROVASCULAR THROMBOSIS AND MODULATION OF INFLAMMATION

Figure 137.1 PATHWAYS INVOLVED IN THE ACTIVATION OF COAGULATION IN DIC. Both perturbed endothelial cells and activated mononuclear cells may produce proinflammatory cytokines that induce tissue factor expression, thereby initiating coagulation. In addition, downregulation of physiological anticoagulant mechanisms and inhibition of fibrinolysis promotes intravascular fibrin deposition. *PAI-1*, Plasminogen activator inhibitor, type 1.

with blood, such as the adventitial layer of larger blood vessels. Subcutaneous tissue also contains substantial amounts of TF. When expressed on the cell surface, TF interacts with factor VII, either in its zymogen or activated form. The TF-factor VIIa complex catalyzes the activation of both factor IX and factor X. Factors IXa and Xa enhance the activation of factors X and prothrombin, respectively. In cells in contact with the blood, TF is induced by mediators such as cytokines, C reactive protein, and advanced glycosylation end products. Inducible TF is predominantly expressed by monocytes and macrophages. Monocyte TF expression is enhanced in the presence of platelets and granulocytes in a P-selectin-dependent manner. This may reflect nuclear factor-kappa B (NFκB) activation that occurs when activated platelets bind to neutrophils or mononuclear cells. These cell-cell interactions also stimulate the production of IL-1b, IL-8, monocyte chemotactic protein 1 (MCP-1), and TNFα. Under cell culture conditions, cytokines such as TNFα, and IL-1, can induce TF expression by vascular endothelial cells, but the in vivo relevance of this finding is uncertain. Studies in vivo suggest that IL-6 is the dominant inducer of TF expression by mononuclear cells.

Increased monocyte TF expression and procoagulant activity has been demonstrated in DIC associated with sepsis, cancer, or coronary disease. Expression of TF appears to be localized to certain organs and vascular beds, but it is uncertain whether its expression is under genetic control in an organ-specific manner. With trauma, such as extensive surgery, brain injury, or burns, it is likely that constitutively expressed TF at the site of injury is the primary source of procoagulant material, but direct support for this concept is lacking.

The Intrinsic Pathway

The role of the intrinsic pathway in the pathogenesis of DIC is uncertain. Negatively-charged substances, such as phospholipids, polyphosphates, and glycosaminoglycans, are potential activators of the contact pathway (see Chapters 120 and 124). Studies in patients with suspected DIC have identified elevated levels of markers of activation of the contact system. In patients with meningococcal septicemia, there was a negative correlation between plasma factor XII levels and the levels of factor XIIa-C1 inhibitor complexes. Although this finding implies consumption of factor XII and subsequent downstream activation of factor XI, an alternative explanation is that there is a negative acute-phase effect with reduced synthesis of factor XII in conjunction with thrombin-mediated activation of factor XI. However, blockade of the contact system with a factor XIIa-directed antibody failed to prevent DIC in a baboon model of *Escherichia coli* sepsis but diminished the development of lethal hypotension. These findings provide reasonable support for the current view that the contact pathway does not contribute to DIC but may play important roles in proinflammatory mechanisms related to vascular permeability, vascular proliferation (kininogen induces smooth muscle cell proliferation), and enhancement of fibrinolysis.[11]

Cytokines and Other Amplification Pathways

Activation of blood coagulation requires several cofactors (see Chapters 120 and 124). For the development of DIC, the surfaces of cell remnants or intact cells, inflammatory mediators, and coagulation proteins are required. The stimulus for activation depends on the underlying disease and may range from bacterial cell compounds, such as endotoxin, TF on host or cancer cells, other cancer cell procoagulants, TF, or fat or amniotic fluid. Each of these triggers interacts with other mediators: TF assembles on anionic phospholipid surfaces, which can be provided by activated platelets, leukocytes, or by cancer cells. Cytokines interact with receptors and induce signaling pathways that induce TF expression and other proinflammatory components via the NFκB complex.

Endotoxin is a lipopolysaccharide compound of gram-negative bacteria that induces the sepsis syndrome and DIC. Gram-negative bacteria liberate endotoxin from their membrane, which interacts with cell surfaces via various pathways. In blood, endotoxin directly binds to CD14 on monocytes and binds to endothelial cells after complexing with lipopolysaccharide-binding protein (LBP) and the Toll-like receptor 4 (TLR 4) complex. Through these interactions, endotoxin induces signaling pathways that culminate in NFκB activation and initiates the expression of proinflammatory cytokines and TF. Likewise, exotoxin such as lipoteichoic acid (LTA) from gram-positive bacteria can induce proinflammatory cytokine expression in a similar manner.

The molecular mechanisms underlying endotoxin-induced activation of coagulation have been studied in primates and baboons. In endotoxin or *E. coli* models of sepsis, inhibition of the TF pathway abolishes the activation of coagulation, thereby highlighting the importance of TF. IL-6 is an important mediator of procoagulant effects, whereas TNFα is involved in the fibrinolytic response to endotoxin. Inhibition of TF with tissue factor pathway inhibitor (TFPI) reduces IL-6 levels in the baboon model, suggesting that there is extensive crosstalk between coagulation and inflammatory mediators (see the following section). Monocytes that express TF bind factor VII(a), shed TF, or bind to the damaged vessel wall. After interacting with platelets, circulating monocytes can trigger DIC. Microvesicles may accelerate this process, and the complex interaction among cells, membrane fragments, soluble mediators, and plasma proteins may trigger the DIC syndrome. The severity and duration of the consumptive process are mainly determined by the potency of the triggers and the capacity of inhibitory mechanisms.

Coagulation Protease Crosstalk Promotes Inflammation

In addition to activating coagulation protein zymogens, coagulation proteases also interact with specific cell receptors and trigger signaling pathways that elicit proinflammatory mediators.[7] Factor Xa, thrombin, and the factor VIIa-TF complex have such effects. Factor Xa injection into rats induces localized inflammation, probably as a result of its interaction with effector-cell protease receptor-1 (EPR-1) and not because of thrombin generation. Exposure of cultured endothelial cells to factor Xa stimulates the production of MCP-1, IL-6, and IL-8 and upregulates the expression of adhesion proteins that tether neutrophils to the cell surface. Further evidence for the crosstalk between inflammation and coagulation comes from the observations that IL-6 and IL-8 elicit TF-dependent procoagulant activity in monocytes and the identification of IL-6 as the critical mediator of procoagulant activity either on its own or after endotoxin challenge in vivo. Therefore, cytokine production induced by factor Xa may be an important driver of coagulation in DIC.

In addition to its procoagulant functions, thrombin has a variety of non-coagulant effects. Thrombin induces the release of MCP-1 and IL-6 from fibroblasts, epithelial cells, and mononuclear cells in vitro. Thrombin also induces IL-6 and IL-8 production by endothelial cells, which has a procoagulant effect that is TF-dependent. Cell activation by thrombin is likely mediated by protease-activated receptors. The factor VIIa-TF complex also activates cells by binding protease-activated receptor-2 (PAR-2).

Direct evidence of the in vivo relevance of these phenomena comes from a study showing that recombinant factor VIIa infusion in volunteers induces an increase in plasma levels of IL-6 and IL-8. Although the concentrations of factor VIIa infused far exceed those found in patients with sepsis, it is possible that factor VIIa-induced cytokine production is of physiological importance. Thus, this information adds to the concept that several coagulation proteases induce proinflammatory mediators that augment procoagulant activity and amplify the consumptive process. Endogenous anticoagulant pathways are essential to regulate these proteases and prevent uncontrolled DIC.

Endogenous Anticoagulant Pathways in Disseminated Intravascular Coagulation

The development of DIC is counteracted by several mechanisms (see Chapters 120 and 124). First, coagulation inhibitors regulate the coagulation mechanism. These inhibitors include antithrombin (AT), the protein C pathway, and TFPI (Fig. 137.2).[7] AT, which complexes and inhibits thrombin and factor Xa, is one of the most important inhibitors, and reduced AT levels are a characteristic of DIC. Reductions in AT levels reflect a combination of reduced protein synthesis increased clearance through the formation of protease-AT complexes and AT degradation by neutrophil elastase. In addition, cytokines may impair proteoglycan synthesis in the vessel wall, thereby reducing the availability of heparan sulfate for the potentiation of AT activity.

In animal models of experimental bacteremia, AT concentrate infusion increases survival, reduces the severity of DIC, and lowers the levels of IL-6 and IL-8. Therefore, in addition to its anticoagulant function, AT may also have an anti-inflammatory effect.

Activated protein C and its cofactor protein S form a second line of defense. Thrombin binds to thrombomodulin on the endothelial cell surface, and the thrombin-thrombomodulin complex converts protein C to its active form, activated protein C (APC).[12] In addition, the thrombin-thrombomodulin complex converts thrombin activatable fibrinolytic inhibitor (TAFI) into its activated form, TAFIa. APC inactivates factors Va and VIIIa by proteolytic cleavage, thus down regulating the coagulation cascade. Endothelial cells, primarily those of large blood vessels, express endothelial protein C receptor (EPCR) on their surface. EPCR binds protein C and presents it to the thrombin-thrombomodulin complex for activation; a process that amplifies APC generation about 20-fold.

APC has anti-inflammatory effects on mononuclear cells and granulocytes, which may be distinct from its anticoagulant activity. Administration of APC prevents thrombin-induced thromboembolism in mice, mainly through its antithrombotic effect. In addition, several studies have demonstrated the anti-inflammatory effects of APC.

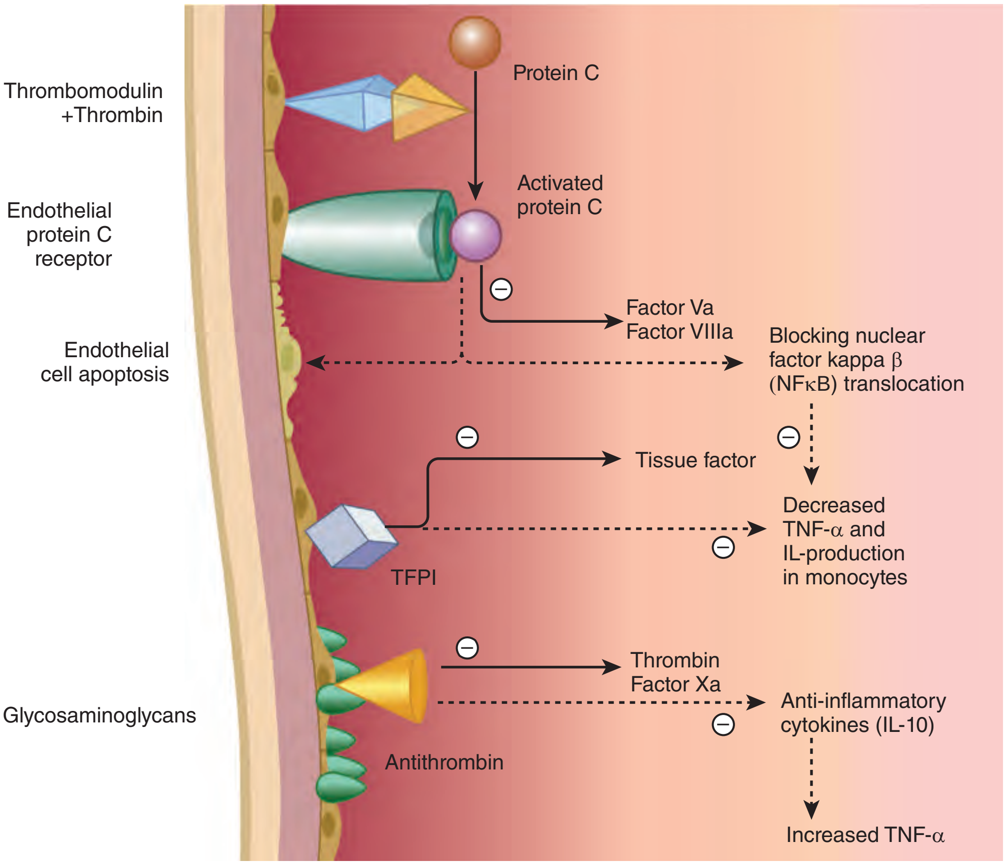


Figure 137.2 PHYSIOLOGICAL ANTICOAGULANT MECHANISMS IN DIC. Physiological anticoagulant mechanisms (activated protein C system, tissue factor pathway inhibitor *[TFPI]*, and antithrombin) are not only involved in blocking thrombin generation and thrombin activity but also affect inflammatory pathways.

Defects in the protein C pathway enhance the vulnerability to inflammatory reactions and DIC. In patients with DIC, lower levels of protein C and protein S are associated with increased mortality. Mice with one allele targeted disruption of the protein C gene, causing heterozygous protein C deficiency, have more severe DIC and a greater inflammatory response than wild-type mice. Blockade of the activity of protein C by infusion of C4 binding protein converted a sublethal model of *E. coli* in baboons into a lethal model. Blockade of EPCR with a neutralizing monoclonal antibody also increased mortality in the *E. coli* baboon model. In contrast, infusion of PC in the same model protected the baboons from fatal DIC. Thus, the protein C pathway appears to be an important host defense against sepsis and DIC.

With systemic inflammation, TNFα and interleukin-1 may down regulate the expression of thrombomodulin by endothelial cells as they do in cell culture experiments. Although thrombin upregulates EPCR expression, by activating metalloproteases, thrombin may also induce EPCR shedding from the endothelium.

Thrombomodulin plays a central role in the pathogenesis of DIC.[13] First, thrombomodulin is essential for the activation of protein C by thrombin; as such, thrombomodulin plays a key role in the anticoagulant and anti-inflammatory properties of the protein C system. Second, thrombomodulin binds thrombin, thereby preventing it from exerting prothrombotic and proinflammatory effects. Third, thrombomodulin-bound thrombin activates TAFI, which suppresses bradykinin activity and complement activation. In DIC, the expression of thrombomodulin is downregulated and activation of protein C is impaired.[14] Thus, histological analysis of skin biopsies from patients with meningococcal sepsis reveals decreased endothelial expression of thrombomodulin in vessels with and without thrombosis.

TFPI is another inhibitor of coagulation. TFPI, which can be either endothelial cell–associated or lipoprotein-bound in plasma, inhibits the TF factor VIIa complex by forming a quaternary complex in which factor Xa is the fourth component.

The importance of TFPI in sepsis is uncertain because the majority of patients with sepsis have normal levels of TFPI. The relevance of TFPI in DIC is illustrated by three lines of experimentation. First, depletion of TFPI sensitized rabbits to DIC induced by TF infusion. Second, TFPI infusion protected against the harmful effects of *E. coli* in primates. TFPI not only inhibited DIC in baboons challenged with lethal amounts of *E. coli* but prevented mortality and improved organ function. Third, TFPI infusion blocked the procoagulant effects of endotoxin in human volunteers.

Although normal levels and functions of coagulation inhibitors are important for protection against DIC, there is no evidence that patients with congenital deficiencies of coagulation inhibitors are at higher risk for DIC. Additional work is needed to examine the impact of these deficiencies on the interaction between coagulation and inflammation.

Fibrinolysis

In experimental models of DIC, there is an initial enhancement in fibrinolysis followed by marked impairment caused by the release of type 1 plasminogen activator inhibitor (PAI-1). The molecular mechanisms responsible for these findings include TNFα and IL-1 induced decrease in tPA release by endothelial cells and increase in PAI-1 production and TNFα-induced increase in urokinase-type plasminogen activator (uPA) production. Endotoxin and TNFα stimulate PAI-1 production in the liver, kidneys, lungs, and adrenal glands of mice. The net procoagulant state is illustrated by a late rise in fibrin breakdown fragments after *E. coli* challenge in baboons.

Experimental data also suggest that enhanced fibrinolysis clears fibrin from organs. Endotoxin-induced fibrin formation in the kidneys and adrenal glands occurs when PAI-1 levels increase. Furthermore, endotoxin does not induce fibrin formation in PAI-1 knockout mice, and fibrin deposition is increased in mice with functionally inactive thrombomodulin (TMProArg mutation). These experiments demonstrate that fibrinolytic action is required to reduce the extent of intravascular fibrin formation.

Fibrinolytic activity is regulated by PAI-1, the principal inhibitor of this system. Recent studies have shown that a functional mutation in the PAI-1 gene, the 4 G/5 G polymorphism, not only influences the plasma level of PAI-1 but was also linked to clinical outcomes in patients with meningococcal septicemia. Patients with the 4 G/4 G genotype had significantly higher plasma PAI-1 levels and an increased risk of death compared with those without this polymorphism. The PAI-1 polymorphism does not influence the risk of contracting meningitis, but likely increases the risk of fatal septic shock in patients with meningococcal infection. These studies provide the first evidence that genetically determined differences in fibrinolytic activity influence the risk of complications from gram-negative infection. In cohorts of patients with DIC, high levels of PAI-1 are one of the best predictors of mortality. These data suggest that DIC contributes to mortality in patients with sepsis. High levels of PAI-1 in such patients may contribute to mortality or may simply be a marker of severe inflammation because PAI-1 is an acute-phase protein.

CLINICAL MANIFESTATIONS

The clinical manifestation of DIC may vary depending on the underlying disorder. At one end of the spectrum is the acute severe DIC that often occurs in the setting of sepsis, major trauma, obstetric calamities, and severe immunologic responses. Diffuse multiorgan bleeding, hemorrhagic necrosis, microvascular thrombosis, and thrombi in medium and large blood vessels are common findings at autopsy. Occasionally, patients with unequivocal clinical and laboratory evidence of DIC do not have confirmatory postmortem findings. Conversely, some patients whose clinical and laboratory findings were not consistent with DIC have typical autopsy findings. The lack of correlation among clinical, laboratory, and pathologic findings may reflect partly postmortem changes in the blood (e.g., hyperfibrinolysis) in some cases but is mostly unexplained. Diffuse microthrombi are most frequently found in the lungs and kidneys, followed by the brain, heart, liver, spleen, adrenal glands, pancreas, and gut. Immunohistology and ultrastructural analysis indicate that most thrombi consist of fibrin and platelets. In addition, activated mononuclear cells and evidence of inflammation are frequently present. In cases of persistent DIC, organization and endothelialization of the microthrombi are often observed.

Acute tubular necrosis is more frequent than renal cortical necrosis in patients with DIC. Clinically, thrombotic occlusive events occur first as a result of microthrombi that obstruct the microcirculation of organs. These thrombi result from clots that form either in the circulation or *in situ* in arterioles, capillaries, or venules. Circulatory obstruction produces organ hypoperfusion and can lead to ischemia, infarction, and necrosis. The process is disseminated throughout the microcirculation; therefore, all organs are potentially vulnerable.

In contrast to acutely ill patients with severe DIC, some patients have mild or subclinical disease manifested only by laboratory abnormalities. Subacute or chronic DIC generally occurs in patients with malignancy, particularly those with mucin-producing adenocarcinomas or acute promyelocytic leukemia (see Chapters 60 and 63). Patients with acute promyelocytic leukemia frequently present with hemorrhage, whereas thrombotic manifestations predominate in those with adenocarcinoma. In addition, patients with solid tumors may develop nonbacterial endocarditis with subsequent systemic arterial embolism and infarction.

Another cause of subacute or chronic DIC is the retained dead fetus syndrome. These patients may be asymptomatic or may present with mild to moderate skin and mucous membrane bleeding.

It is important to stress that DIC is not a disease but is always secondary to an underlying disorder that causes the activation of coagulation. The underlying disorders most commonly associated with DIC are listed in Box 137.1 and are described in detail in the following section.

BOX 137.1 Clinical Conditions That Are Most Frequently Complicated by Disseminated Intravascular Coagulation

- Sepsis/severe infection
- Trauma/burn/heatstroke
- Malignancy
  - Solid tumors
  - Acute leukemia
- Obstetrical conditions
  - amniotic fluid embolism
  - Abruptio placentae
  - HELLP syndrome
- Vascular abnormalities
  - Kasabach-Merrit syndrome
  - Other vascular malformations
  - Aortic aneurysms
- Severe allergic/toxic reactions
- Severe immunologic reactions (e.g., transfusion reaction)

HELLP, hemolysis, elevated liver enzymes, and low platelet count.

Disseminated Intravascular Coagulation in Infectious Disease

Systemic infections are among the most common causes of DIC. Immunocompromised patients, asplenic patients whose ability to clear bacteria (particularly pneumococci) is impaired, and newborns whose anticoagulant systems are immature are particularly prone to infection-induced DIC. Infections may be superimposed on trauma or malignancy, which themselves are potential triggers of DIC. In addition, infections can aggravate bleeding and thrombosis by directly inducing thrombocytopenia, hepatic dysfunction, and shock, which can lead to diminished blood flow in the microcirculation.

Clinically overt DIC occurs in 30% to 50% of patients with gram-negative or gram-positive sepsis. Extreme examples of sepsis-related DIC are streptococcus A toxic shock syndrome and meningococcemia. Streptococcus A toxic shock syndrome is characterized by deep tissue infection, vascular collapse, vascular leakage, and multiple organ dysfunction. M protein released from streptococci forms complexes with fibrinogen which bind to β_2 integrins on neutrophils leading to their activation. Meningococcemia, a fulminant gram-negative infection, is characterized by extensive hemorrhagic necrosis, DIC, and shock. The most frequent gram-negative infections associated with DIC are caused by *Pseudomonas aeruginosa, E. coli*, and *Proteus vulgaris*. Patients with these infections may only have laboratory evidence of activated coagulation or they may present with severe DIC.

Activation of the coagulation system has also been documented with nonbacterial pathogens such as viruses, protozoa (malaria), and fungi. Common viral infections, such as influenza, varicella, rubella, and rubeola, are rarely associated with DIC. Some viral infections can cause "hemorrhagic fever" characterized by fever, hypotension, bleeding, and renal failure. Laboratory evidence of DIC can accompany Korean, rift valley, and dengue-related hemorrhagic fever. Protozoan infections, such as cerebral malaria, may be associated with overt DIC. In these cases, secondary deficiency of a disintegrin-like metalloprotease with thrombospondin type 1 repeats (ADAMTS-13), the von Willebrand cleaving protease, may occur.[15] Such deficiency may also complicate other types of sepsis-induced DIC and may enhance platelet-vessel wall interactions, thereby contributing to microvascular thrombosis.

An extreme form of DIC manifests as purpura fulminans, a severe, often lethal form of DIC in which extensive areas of the skin over the extremities and buttocks undergo hemorrhagic necrosis. The disease predominantly affects infants and children and is rare in adults. Diffuse microthrombi in small blood vessels leads to necrosis, and vasculitis may also be found in biopsies of skin lesions. The disorder can occur 2 to 4 weeks after mild infection, such as scarlet fever, varicella, or rubella, or can occur during an acute viral or bacterial infection in patients with acquired or hereditary deficiencies of protein C or protein S (see Chapters 120 and 137). The syndrome mimics neonatal homozygous protein C or protein S deficiency; where purpura fulminans, with or without extensive thrombosis, develops soon after birth.

Disseminated Intravascular Coagulation With Trauma, Brain Injury, Burns, and Heatstroke

The time interval between trauma and medical intervention correlates with the development and extent of DIC. Experience during battle reveals that fast evacuation and prompt medical care reduce the risk of DIC. Extensive exposure of TF to the blood and hemorrhagic shock are the likely triggers of DIC in patients with trauma. However, cytokines may also contribute because cytokine levels in trauma patients are similar to those in patients with sepsis.[16] Plasma levels of TNFα, IL-1β, PAI-1, TF, neutrophil elastase, and soluble thrombomodulin can be elevated in trauma patients with evidence of DIC and predictive of major organ dysfunction and death. Laboratory evidence of severe DIC, reduced fibrinolytic activity, and perhaps low AT levels are predictive of poor outcomes in such patients.

In patients with head injuries, DIC is associated with a high rate of mortality. A DIC score is predictive of prognosis in such patients and can add information beyond the Glasgow coma score. Brain injury likely triggers DIC because of the abundant TF in the brain. Specimens of contused brain tissue obtained during surgery in patients with head injury and autopsy specimens of liver, lungs, kidneys, and pancreas reveal microthrombi in arterioles and venules.

Bleeding, laboratory tests indicative of DIC, and microthrombi in biopsy specimens from undamaged skin have been described in patients with extensive burns. Studies using labeled fibrinogen or platelets indicate local consumption in burned areas as well as systemic consumption. TF at sites of burned tissue, systemic inflammatory response syndrome induced by the burn, and superimposed infections can all trigger DIC. Local activation of coagulation in the bronchoalveolar compartment may contribute to acute lung injury in these patients.

Severe hemorrhage and multiple organ failure, indicative of DIC, may accompany heatstroke.[17] Diffuse fibrin deposition and hemorrhagic infarction are found in fatal human cases. DIC associated with profound fibrin(ogen)olysis is evident in patients with heatstroke. The possible triggers of DIC in patients with heatstroke include endothelial cell damage and TF release from heat-damaged tissues. In a series of 18 critically ill patients with heatstroke during the 2003 heatwave in Western Europe,[17] high levels of IL-6 and IL-8 were noted along with activation of white blood cells, as evidenced by upregulation of β2-integrin and increased production of reactive oxygen species. All patients had evidence of systemic activation of coagulation and DIC was present in about one-third. The extent of activation of inflammation and coagulation was correlated with the severity of the heatstroke.

Disseminated Intravascular Coagulation With Obstetric Complications

Placental abruption occurs in 0.2% to 0.4% of pregnancies and is a leading cause of perinatal death.[18] Older multiparous women and those with hypertensive disorders of pregnancy are thought to be at highest risk. About 10% of women with placental abruption develop DIC. Amniotic fluid activates coagulation in vitro, and the degree of placental separation correlates with the extent of DIC, suggesting that leakage of thromboplastin-like material from the placental system is responsible for DIC. Only severe DIC results in shock and fetal death.

Amniotic fluid embolism is a rare but serious complication of pregnancy and delivery. A maternal mortality rate of 86% was reported in a 1979 review of 272 cases, but in a more recent population-based study, the maternal mortality was only 26%. Patients predisposed to amniotic fluid embolism are multiparous women whose pregnancies are postmature with large fetuses and women undergoing tumultuous labor after pharmacologic or surgical induction.

Amniotic fluid is introduced into the maternal circulation through tears in the chorioamniotic membrane, rupture of the uterus, and injury of uterine veins. TF in amniotic fluid is the likely trigger of DIC. Mechanical obstruction of pulmonary blood vessels by fetal debris, meconium, and other particulate matter in the amniotic fluid enhances local fibrin–platelet thrombus formation and fibrinolysis. Occlusion of the pulmonary arteries and an acute anaphylactoid response reminiscent of severe systemic inflammatory response syndrome induce the sudden onset of dyspnea, cyanosis, acute cor pulmonale, left ventricular dysfunction, shock, and convulsions. These symptoms are followed within minutes to several hours by severe bleeding in one-third of patients. Diffuse bleeding occurs from the atonic uterus, puncture sites, gastrointestinal tract, and other organs.

Some studies report activation of coagulation and DIC in women with preeclampsia and eclampsia. In a large series of patients, there was a correlation between the clinical severity of preeclampsia and eclampsia and the platelet count and level of fibrin(ogen) degradation products. Also consistent with DIC were results of assays of thrombin generation and activation of fibrinolysis, such as (thrombin-antithrombin) TAT complexes, D-dimer, and levels of Bβ1–42. Despite these observations, heparin is of uncertain benefit. HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) is another complication of pregnancy-induced hypertension. Liver biopsy evidence of fibrin deposition in hepatic blood vessels and laboratory tests are consistent with DIC, but HELLP syndrome is thought to be caused by thrombotic microangiopathy.

Disseminated Intravascular Coagulation With Malignancy

Patients with solid tumors are vulnerable to risk factors and additional triggers of DIC that can aggravate thromboembolism and bleeding.[19] Risk factors include older age, advanced cancer, and use of chemotherapy or antiestrogen therapy. Triggers include septicemia, immobilization, and impaired liver function because of metastatic disease. Microangiopathic hemolytic anemia frequently is induced by DIC in patients with cancer and is particularly severe in patients with widespread mucin-secreting adenocarcinomas. Solid tumor cells can express a variety of procoagulant molecules including TF and cancer procoagulant, a cysteine protease with factor X activating properties. In breast cancer, TF is expressed by vascular endothelial cells as well as tumor cells. TF also appears to be involved in tumor metastasis and angiogenesis.

Cancer procoagulant is an endopeptidase found in extracts of neoplastic cells and in the plasma of patients with solid tumors. The role of this enzyme in the pathogenesis of cancer-related DIC is unclear. Interactions of P- and L-selectins with mucin from mucinous adenocarcinomas can induce the formation of platelet microthrombi and provide a third mechanism for cancer-related thrombosis. Depending on the rate and quantity of exposure or influx of TF-bearing vesicles, DIC can be overt or covert.

There are numerous reports of DIC and hyperfibrinolysis in patients with acute leukemia. In 161 consecutive patients with acute myeloid leukemia, DIC was diagnosed in 52. In patients with acute lymphoblastic leukemia, DIC was diagnosed in 15% to 20% of patients.[20] In patients with acute promyelocytic leukemia (APL), DIC is found in more than 90% of patients at the time of diagnosis or with remission induction therapy. APL cells express TF and cancer procoagulant, which can initiate coagulation. In addition, they release IL-Iβ and TNFα, compromising the protein C anticoagulant pathway by downregulating thrombomodulin expression. APL cells also express large amounts of annexin II, augmenting the conversion of plasminogen to plasmin. The net result of these processes is DIC and hyperfibrinolysis that can lead to fatal bleeding. All-*trans*-retinoic acid, which is used for induction and maintenance therapy of APL, inhibits the deleterious effect of APL cells and reduces the risk of DIC and bleeding.

Disseminated Intravascular Coagulation With Vascular Disorders

Rarely, vascular anomalies can trigger DIC. Localized consumption of platelets and fibrinogen in large aortic aneurysms can lead to coagulation abnormalities and bleeding.[21] In a series of patients with aortic aneurysms, 40% had elevated levels of fibrin(ogen) degradation products, but only 4% had laboratory evidence of DIC or bleeding.[21] Factors that predispose such patients to DIC include large aneurysms, particularly those with dissection or expansion. Coagulation in these cases is likely triggered by the abundant TF in atherosclerotic plaques.

Kasabach and Merritt were the first to describe bleeding in association with giant cavernous hemangiomas, benign tumors found in newborns or children that can evolve into convoluted masses of abnormal vascular channels that sequester and consume platelets and fibrinogen. Localized pain may occur because of thrombosis within the hemangiomas and the consumptive process may lead to chronic DIC and bleeding after trauma or with surgery. Cavernous hemangiomas may regress spontaneously; some respond to radiation or laser therapy.

Disseminated Intravascular Coagulation With Liver Disease

The levels of most coagulation factors, endogenous anticoagulants, and components of the fibrinolytic system are reduced in patients with severe liver disease reflecting reduced synthesis. In addition, the capacity of the liver to clear factors activated clotting factors and t-PA is decreased. Thrombocytopenia is common because of hypersplenism and decreased hepatic production of thrombopoietin. The similarities between the hemostatic defects with liver disease and those with DIC have evoked controversy as to the contribution of DIC to the coagulopathy of liver disease. Several laboratory and clinical observations support the concept that DIC accompanies hepatic disorders. These include reduced half-life of radiolabeled fibrinogen that is reversed with heparin administration, failure of replacement therapy to significantly increase the levels of hemostatic factors suggesting ongoing consumption, and increased levels of markers of activation of coagulation. All these findings are consistent with increased thrombin generation. Against the DIC hypothesis is the observation that microthrombi are found in only 2% of the tissues from patients who die of liver disease, and the fact that the increase in fibrinogen turnover can be explained by extravascular accumulation. Current thinking is that DIC is rare in patients with liver disease but that such patients are sensitive to the triggers of DIC because of the decreased synthetic capacity of the diseased liver and its inability to clear activated clotting factors. In patients undergoing peritoneovenous shunting for severe ascites, those with underlying liver disease are more likely to develop DIC than those with normal liver function.

Disseminated Intravascular Coagulation With Toxic Reactions or Snake Bites

The venom of certain snakes, particularly vipers and rattlesnakes, can produce a DIC-like coagulopathy.[22] Prominent among these species are *Vipera, Echis* (*E. carinatus* or *E. coloratus*), *Aspis, Crotalus, Bothrops*, and *Agkistrodon*. Venoms of these snakes contain enzymes or peptides that: (1) release fibrinopeptide A (*Agkistrodon rhodostoma*); (2) activate prothrombin even in the absence of calcium (*E. carinatus*); (3) activate factors X and V (Russell viper venom); (4) degrade fibrinogen (*Agkistrodon acutus*); (5) induce platelet aggregation; (6) inhibit platelet aggregation because of the presence of arginine-glycine-aspartic acid-containing peptides; (7) activate protein C; and (8) damage endothelial cells, which leads to bleeding, tissue ischemia, and edema. Interestingly, victims of snake bites rarely have excessive bleeding or thrombosis despite the abnormal coagulation tests and DIC-like picture.

LABORATORY MANIFESTATIONS

Thrombocytopenia or a rapidly declining platelet count is a diagnostic hallmark of DIC. However, only 35% to 44% of critically ill patients develop thrombocytopenia (platelet count $<150 \times 10^9/L$). Consequently, the specificity of thrombocytopenia for the diagnosis of DIC is limited.[10] A platelet count less than $100 \times 10^9/L$ is seen in 50% to 60% of DIC patients, whereas 10% to 15% of patients have a platelet count less than $50 \times 10^9/L$. In surgical or trauma patients with DIC, over 80% have platelet counts less than $100 \times 10^9/L$.

Consumption of coagulation factors in DIC leads to reduced levels of coagulation factors. Impaired coagulation factor synthesis due to impaired liver function or vitamin K deficiency and loss of coagulation proteins as a result of massive bleeding may also contribute. Although the accuracy of one-stage clotting assays for the diagnosis of DIC has been challenged (because of the presence of activated coagulation factors), there is good correlation between the levels of coagulation factors and the severity of the DIC. A low level of coagulation factors is reflected by prolonged coagulation screening tests, such as the PT or aPTT. A prolonged PT or aPTT is found in 14% to 28% of intensive care patients and in more than 95% of patients with DIC.

Plasma levels of factor VIII are paradoxically increased in most patients with DIC, probably due to the massive release of von Willebrand factor from the endothelium in combination with the acute-phase behavior of factor VIII. Recent studies have pointed to a relative decrease in the von Willebrand cleaving protease ADAMTS-13, thereby causing high concentrations of ultra-large von Willebrand multimers in plasma, which may facilitate platelet-vessel wall interactions and lead to thrombotic microangiopathy and subsequent organ dysfunction.[15]

Although measurement of fibrinogen levels has been advocated as a useful tool for the diagnosis of DIC, the levels are not helpful in many cases.[23] Fibrinogen is an acute-phase protein, and plasma levels can remain within the normal range despite ongoing consumption. In a consecutive series of patients with DIC, a low fibrinogen level had a sensitivity of only 28% for the diagnosis of DIC, and only patients with severe DIC had low levels.

Markers of Fibrin Generation and Degradation

Plasma levels of fibrin degradation products (FDP) are frequently used for the diagnosis of DIC. Increased levels of FDP were found in 42% of consecutive patients in the intensive care unit, in 80% of trauma patients, and in 99% of patients with sepsis and DIC. FDP can be quantified by rapid turnaround ELISA or latex agglutination assays. None of the available FDP assays discriminates between degradation products of fibrinogen and crosslinked fibrin, which may cause spuriously high results. The specificity of high levels of FDP for DIC is therefore limited and elevated FDP levels may be found in many other conditions including trauma, recent surgery, inflammation, and venous thromboembolism. Because FDP are metabolized in the liver and cleared via the kidneys, FDP levels are influenced by liver and kidney function.

The D-dimer assay better differentiates between degradation of crosslinked fibrin and fibrinogen than the FDP assay because D-dimer is exclusively derived from crosslinked fibrin (see Chapter 126). Fibrin is crosslinked by factor XIII that is activated by thrombin (see Chapters 120 and 124). Therefore, D-dimer is a marker of both fibrin formation and degradation.

Although D-dimer levels are high in patients with DIC, they are also elevated in patients with venous thromboembolism, recent surgery, or inflammatory conditions. Theoretically, measurement of soluble fibrin or fibrin monomers could be helpful to diagnose intravascular fibrin formation in DIC. Indeed, initial clinical studies suggest that an increase in the concentration of soluble fibrin above a defined threshold is diagnostic of DIC. Unfortunately, the problem so far is that a reliable test is not routinely available for quantitating soluble fibrin in plasma.

Endogenous Coagulation Inhibitors

Plasma levels of physiological coagulation inhibitors such as protein C and antithrombin may be useful indicators of ongoing activation of coagulation.[24] Low levels of these coagulation inhibitors are found in 40% to 60% of critically ill patients and in 90% of those with DIC.

Levels of protein C correlate with the severity of the DIC, and low levels are a predictor of poor outcome. In patients with meningococcal septicemia, protein C levels are markedly reduced, which may explain why such patients are prone to purpura fulminans. The decrease in protein C levels in such patients reflects reduced protein C activation because of downregulation of thrombomodulin and reduction in the levels of free protein S as well as protein C consumption.

Antithrombin levels also are a predictor of outcome in patients with sepsis and DIC. Antithrombin levels are reduced in such patients because of impaired synthesis (negative acute-phase response), increased consumption, and degradation by neutrophil elastase.

Fibrinolytic Markers

Fibrinolytic activity in DIC can be monitored by measuring plasma levels of plasminogen and α2-antiplasmin. Low levels may indicate consumption of these proteins. Plasmin generation is best assessed by measuring the levels of plasmin-α2-antiplasmin (PAP) complexes, which are moderately elevated in patients with DIC. However, because the concentration of α2-antiplasmin is half of that of plasminogen, plasmin can be generated in concentrations that overwhelm its major inhibitor. Under these circumstances, backup inhibitors such as α2-macroglobulin, α1-antitrypsin, and C1-inhibitor take over. The apparent insufficient fibrinolytic activity in patients with DIC is attributed to high levels of the inhibitor of plasminogen activation, PAI-1. Indeed, plasma levels of PAI-1 are often elevated in patients with DIC and are strongly correlated with an unfavorable outcome. A functional mutation in the *PAI1* gene, the 4 G/5 G polymorphism, is associated with increased levels of PAI-1 and a worse outcome in patients with meningococcal septicemia and associated DIC.

Point of Care Tests

Thromboelastography (TEG) can be done at the bedside and is popular in acute care settings.[25] The theoretical advantage of TEG over conventional coagulation assays is that it also provides an index of platelet function and fibrinolytic activity. TEG is increasingly employed in critically ill patients with hypercoagulable states, including DIC.[25] Procoagulant and anticoagulant states identified by TEG in patients with DIC are correlated with organ dysfunction and survival,[26,27] although it remains uncertain whether TEG offers advantages over the usual coagulation assays.[28] In a systematic review that included two randomized controlled trials and 16 observational studies in patients with sepsis, TEG was helpful for correctly identifying an endogenous fibrinolytic state.[29] The authors also found a correlation between hypocoagulability and mortality. The use of TEG for the diagnosis of DIC has not been rigorously evaluated although supporters believe that the assay may help appraise the state of coagulation in patients with critical illness.[30,31] However, TEG appears overly sensitive to interventions such as the administration of fibrinogen, and the therapeutic benefit of which is uncertain.

Diagnostic Algorithm for Disseminated Intravascular Coagulation

A simple scoring system for the diagnosis of DIC has been developed by the subcommittee on DIC of the International Society on Thrombosis and Haemostasis (ISTH) (Box 137.2).[5] The score can be calculated using routinely available laboratory tests (i.e., platelet count, PT), a fibrin-related marker (usually D-dimer), and fibrinogen. Tentatively, a score of 5 or more is compatible with DIC, whereas

BOX 137.2 Diagnostic Algorithm for the Diagnosis of Overt Disseminated Intravascular Coagulation[a]

1. Presence of an underlying disorder known to be associated with DIC (see Table 130.2)
   (no = 0, yes = 2) ☐
2. Score global coagulation test results
   - platelet count *(>100 = 0; <100 = 1; <50 = 2)*
   - level of fibrin markers (e.g., D-dimer, fibrin degradation products) ☐
   - (no increase: 0; moderate increase: 2; strong increase: 3)[b] ☐
   - prolonged prothrombin time
   - *(<3s. = 0; >3s. but <6s. = 1; >6s. = 2)* ☐
   - fibrinogen level
     (>1.0g/L = 0; <1.0g/L = 1) ☐
3. Calculate score
4. If ≥5: compatible with overt DIC; repeat scoring daily
   If <5: suggestive (not affirmative) for non-overt DIC; repeat next 1–2 days; ☐

[a] According to the Scientific Standardization Committee of the International Society of Thrombosis and Haemostasis.[5]

[b] Strong increase >5 × upper limit of normal; moderate increase is > upper limit of normal but <5 × upper limit ©of normal.

a score of less than 5 may be indicative but is *not* affirmative for non-overt DIC. More refined scoring systems have been developed for the diagnosis of non-overt DIC and are now being evaluated. A recent study showed that the INR can be used in place of PT prolongation, further facilitating international exchange and standardization. By using receiver-operating characteristic curves, the optimal cut-off for D-dimer was identified, thereby optimizing the sensitivity and the negative predictive value of the score. Prospective studies show that the DIC score has a sensitivity of 93% and a specificity of 98%. Studies in a series of patients with specific underlying disorders causing DIC (e.g., cancer or obstetric complications) show similar results. The severity of DIC according to this scoring system is related to mortality in patients with sepsis.[9] Linking prognostic determinants from critical care measurement scores such as APACHE-II to DIC scores is an important means of assessing prognosis in critically ill patients. Similar scoring systems have been developed and evaluated in Japan. The major difference between the international and Japanese scoring systems is a slightly higher sensitivity of the Japanese algorithm, which may reflect differences in the patient population because the Japanese series include more patients with hematological malignancies.

DIFFERENTIAL DIAGNOSIS

The diagnosis of DIC is complicated because patients with DIC may have other causes for coagulation abnormalities. For example, septic patients with DIC may have liver failure and vitamin K deficiency.

The differential diagnosis of thrombocytopenia in patients with suspected DIC is shown in Table 137.1. Sepsis itself is a risk factor for thrombocytopenia in critically ill patients, and the severity of sepsis correlates with the extent of thrombocytopenia. The principal factors that contribute to thrombocytopenia in patients with sepsis are impaired platelet production, increased consumption or destruction, or sequestration of platelets in the spleen or along the endothelial surface. Impaired production of platelets in the bone marrow may seem contradictory in view of the high levels of platelet production-stimulating proinflammatory cytokines, such as TNFα and IL-6, and the high concentrations of thrombopoietin in patients with sepsis. However, hemophagocytosis, phagocytosis of megakaryocytes and other hematopoietic cells by monocytes and macrophages, is common in severe sepsis and may be a result of high levels of macrophage colony-stimulating factor (M-CSF).

TABLE 137.1 Differential Diagnosis of Thrombocytopenia in Suspected Disseminated Intravascular Coagulation

Differential Diagnosis	Additional Diagnostic Clues
DIC	Prolonged aPTT and PT, increased FDP or D-dimer, low levels of antithrombin or protein C
Sepsis without DIC	Positive (blood) cultures, positive sepsis criteria, hemophagocytosis observed on bone marrow examination
Massive blood loss	Severe bleeding, low hemoglobin, prolonged aPTT, and PT,
Thrombotic microangiopathy	Schistocytes observed on blood smear, Coombs negative hemolysis, fever, neurologic symptoms, renal insufficiency, coagulation tests usually normal, ADAMTS-13 levels decreased
Heparin-induced thrombocytopenia	History of heparin use, venous or arterial thrombosis, positive HIT test (usually immunoassay for heparin-platelet factor 4 antibodies), increase in platelet count after cessation of heparin; coagulation tests usually normal
Immune thrombocytopenia	Antiplatelet antibodies, normal or increased number of megakaryocytes in bone marrow aspirate, thrombopoietin *(TPO)* level decreased; coagulation tests usually normal
Drug-induced thrombocytopenia	Decreased number of megakaryocytes in bone marrow aspirate or detection of drug-induced antiplatelet antibodies, increase in platelet count after cessation of the drug; coagulation tests usually normal

aPTT, Activated partial thromboplastin time; *FDP*, fibrin degradation products; *HIT*, heparin-induced thrombocytopenia; *PT*, prothrombin time.

Heparin-induced thrombocytopenia (HIT) is another cause of a low platelet count and thrombosis in critically ill patients (see Chapter 130). In a consecutive series of critically ill patients receiving heparin, HIT occurred in 1%. The risk of HIT is higher with unfractionated than with low-molecular-weight heparin (LMWH). Thrombosis may occur in 25% to 50% of patients with HIT (with fatal thrombosis in 4% to 5%). The diagnosis of HIT is based on the detection of HIT antibodies in combination with the occurrence of thrombocytopenia in a patient receiving heparin, with or without concomitant arterial or venous thrombosis.

Thrombocytopenia is a hallmark of thrombotic microangiopathies include syndromes such as thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome, malignant hypertension, chemotherapy-induced microangiopathic hemolytic anemia, and the HELLP syndrome (see Chapter 131). A common feature of these disorders is endothelial damage, triggering platelet adhesion and aggregation, thrombin generation, and impaired fibrinolysis. The consequences of severe endothelial dysfunction include thrombocytopenia, mechanical fragmentation of red cells with hemolytic anemia, and thrombotic occlusion of the microvasculature of organs such as the kidney and brain leading to renal failure and neurologic dysfunction, respectively.

Drug-induced thrombocytopenia is another frequent cause of thrombocytopenia in critically ill patients (see Chapter 129). Thrombocytopenia may be caused by drug-induced myelosuppression, such as caused by cytostatic agents, or by immune-mediated mechanisms. The diagnosis of drug-induced thrombocytopenia is complicated in patients suspected of having DIC because they often are taking multiple medications and have numerous potential causes for thrombocytopenia. Drug-induced thrombocytopenia is often diagnosed based upon the timing of initiation of a new agent in relation to the development of thrombocytopenia, after exclusion of other causes of thrombocytopenia. Rapid normalization of the platelet count after discontinuation of the suspected agent is highly suggestive of drug-induced thrombocytopenia.

Prolongation of global coagulation tests may reflect a deficiency of one or more coagulation factors (Table 137.2). In addition, but more rarely, it may reflect the presence of an inhibiting autoantibody

TABLE 137.2 Differential Diagnosis of Prolonged Activated Partial Thromboplastin Time and/or Prothrombin Time in Suspected Disseminated Intravascular Coagulation

Test Result	Cause
PT prolonged, aPTT normal	Factor VII deficiency Mild vitamin K deficiency Mild liver insufficiency Low doses of vitamin K antagonists
PT normal, aPTT prolonged	Factor VIII, IX, or XI deficiency Unfractionated heparin Inhibitory antibody and/or antiphospholipid antibody Factor XII or prekallikrein deficiency
PT and aPTT prolonged	Factor X, V, II or fibrinogen deficiency Severe vitamin K deficiency Vitamin K antagonists Global clotting factor deficiency • Decreased synthesis: liver failure • Increased loss: massive bleeding, DIC

aPTT, Activated partial thromboplastin time; *PT*, prothrombin time.

(see Chapter 134). Factor deficiency can be distinguished from an inhibitory by mixing patient plasma with control plasma. If the addition of control plasma corrects the abnormal test, coagulation factor deficiency is likely, whereas if there is no correction, an inhibiting antibody is likely to be present (see Chapter 126). The lupus anticoagulant can prolong the aPTT, and antiphospholipid syndrome may be associated with thrombocytopenia and thrombosis (see Chapter 138).

In general, acquired deficiencies of coagulation factors may be due to impaired synthesis, massive loss, or increased turnover (consumption). Impaired synthesis is often due to liver disease or vitamin K deficiency. Vitamin K deficiency may be caused by poor nutrition in combination with the use of antibiotics that affect intestinal flora. The PT is sensitive to both conditions because this test is dependent on plasma levels of factor VII (the vitamin K-dependent coagulation factor with the shortest half-life). Liver failure may be differentiated from vitamin K deficiency by measuring the level of factor V, which is not vitamin K dependent. In fact, factor V levels are incorporated into scoring systems for acute liver failure.

Uncompensated loss of coagulation factors may occur after massive bleeding, for example, trauma patients or patients undergoing major surgical procedures. This is particularly common when crystalloid, colloid, and red cells replacement is given without concomitant administration of plasma and cryoprecipitate. Depletion types of coagulopathy may exacerbate the bleeding and massive transfusion may trigger systemic activation of inflammatory pathways, thereby exacerbating the coagulopathy. In hypothermic patients (e.g., trauma patients), global coagulation tests may underestimate the extent of derangement in coagulation because the assays are performed at 37°C.

THERAPY

Management of DIC depends on the treatment of the underlying disorder that triggered the DIC. For sepsis-induced DIC, treatment includes aggressive use of intravenous organism-directed antibiotics and source control (e.g., by surgery or drainage). Other examples of treatment of the underlying condition include cancer surgery or chemotherapy, uterus evacuation in patients with abruptio placentae, resection of an aortic aneurysm, and debridement of crushed tissue in cases of trauma. In addition to treating the underlying cause of DIC, supportive treatment aimed at coagulopathy may be helpful (Box 137.3).[6]

BOX 137.3 Mainstays of Supportive Treatment of Disseminated Intravascular Coagulation

Modality	Details	Expectations/Rationale
Treating the underlying disorder	Dependent on the primary diagnosis	Inhibit or block the trigger of disseminated intravascular coagulation (DIC)
Antithrombotic agents	Prophylactic heparin to prevent venous thromboembolism (Low dose) therapeutic heparin in case of confirmed thromboembolism or if the clinical picture is dominated by (micro) vascular thrombosis and associated organ failure	Risk of venous thromboembolism is increased in critically ill patients, trauma patients, or patients with cancer Prevent fibrin formation; tip the balance within the microcirculation toward anticoagulant mechanisms and physiologic fibrinolysis; allow reperfusion of the skin, kidneys, and brain
Transfusion	Infuse platelets, plasma, and fibrinogen (cryoprecipitate) if there is overt bleeding or a high risk of bleeding	Bleeding should be controlled over the course of hours Platelet count, coagulation tests, and fibrinogen should return toward normal
Anticoagulant factor concentrates	Recombinant human activated protein C may be effective in sepsis and DIC (24 μg/kg/h for 4 days)	Restore anticoagulation in the microvascular environment and may have anti-inflammatory activity
Fibrinolytic inhibitors	Tranexamic acid (e.g., 500–1000 mg—q8–12 h or ε-aminocaproic acid 1000–2000 mg q8–12 h)	May be useful if there is hyperfibrinolysis; Bleeding ceases, but there is a risk of microvascular thrombosis and renal failure

Platelet and Plasma Transfusion

Low levels of platelets and coagulation factors increase the risk of bleeding. However, plasma or platelet substitution therapy should not be given on the basis of laboratory results alone; such therapy is only indicated if there is bleeding or if an invasive procedure is needed.[6] The presumed efficacy of treatment with plasma, fibrinogen concentrate, cryoprecipitate, or platelets is not based on randomized controlled trials but is rational therapy in patients with or at risk of bleeding. The concept that the administration of blood components "adds fuel to the fire" has never been proven.

Replacement therapy for thrombocytopenia consists of 5 to 10 units of platelet concentrate to increase the platelet count to 20 to 30 × 10^9/L, or to 50 × 10^9/L in patients requiring invasive procedures. Major problems with the administration of fresh-frozen plasma in patients with DIC who are bleeding are volume overload and capillary leak, which can lead to pulmonary edema, predispose patients to adult respiratory distress syndrome (ARDS), and induce ascites. Coagulation factor concentrates, such as prothrombin complex concentrate, may overcome the problem of volume overload but do not contain essential factors, such as factor V. Moreover, caution is advocated with the use of prothrombin complex concentrates in DIC because traces of activated factors may trigger thrombosis. Specific deficiencies of coagulation factors, such as fibrinogen, can be corrected by the administration of purified coagulation factor concentrates.

Cryoprecipitate can be used to rapidly raise the levels of fibrinogen and von Willebrand factor when DIC is accompanied by bleeding and the fibrinogen level is less than 1 g/L. Cryoprecipitate has at least four to five times more fibrinogen per mL than fresh-frozen plasma. Nonetheless, fresh-frozen plasma contains fibrinogen in sufficient amounts for treatment of mild to moderate hypofibrinogenemia.

Anticoagulant Treatment

Heparin therapy in patients with DIC remains controversial. Experimental studies suggest that heparin can at least partially inhibit the activation of coagulation in DIC. However, a beneficial effect of heparin in patients with DIC has not been demonstrated in controlled clinical trials. Also, the safety of heparin is debatable in DIC patients who are prone to bleeding. A large trial in patients with severe sepsis showed a non-significant benefit of low dose heparin on 28-day mortality and no major safety concerns.[32]

There is consensus that heparin is beneficial in some categories of DIC, such as metastatic carcinomas, purpura fulminans, and aortic aneurysm (prior to resection). Heparin also is indicated for treating thromboembolic complications in large vessels and before surgery in patients with chronic DIC. Heparin administration may be helpful in patients with acute DIC when intensive blood component replacement fails to control bleeding or when thrombosis threatens to cause irreversible tissue injury (e.g., acute cortical necrosis of the kidney or digital gangrene).

Heparin should be used cautiously. In patients with chronic DIC because of metastatic carcinoma or aortic aneurysm, infusion of unfractionated heparin at a dose of 500 to 750 U/hour without a bolus injection has been advocated. If no response is obtained within 24 hours, escalating dosages can be used. In hyperacute DIC cases, such as amniotic fluid embolism, septic abortion, and purpura fulminans, an intravenous heparin bolus of 5000 to 10,000 U heparin may be given along with replacement therapy. Some experts, however, do not administer a bolus dose of heparin even under these circumstances. Continuous heparin infusion of 500 to 1000 U/hour may be necessary to maintain the benefit until the underlying disease responds to treatment. Apart from these considerations, current guidelines dictate the universal use of prophylactic doses of heparin or low-molecular-weight heparin to prevent venous thromboembolic events in critically ill patients.[6]

Theoretically, the best anticoagulant for the treatment of DIC would be directed against TF. To this end, agents such as recombinant TFPI, inactivated factor VIIa, and recombinant nematode anticoagulant protein c2 (NAPc2) have been evaluated. Phase II trials of recombinant TFPI in patients with sepsis showed promising results, but phase III trials in patients with severe sepsis or severe pneumonia and organ failure did not show an overall survival benefit with TFPI.[33]

Recombinant human soluble thrombomodulin binds thrombin to form a complex that activates protein C (see Chapters 120 and 124). In a phase III randomized double-blind clinical trial in patients with DIC, soluble thrombomodulin had a better effect on bleeding and coagulation parameters than heparin. A systematic review and meta-analysis of mostly retrospective studies of soluble thrombomodulin in severe sepsis demonstrated a pooled relative risk of 0.81 (95% confidence interval [CI] 0.62 to 1.06) in three trials that included a total of 838 patients, and a relative risk of 0.59 (95% CI 0.45 to 0.77) in nine observational studies that included 571 patients.[34]

In a double-blind, placebo-controlled, phase III study, 816 patients with severe sepsis-associated coagulopathy were randomized to soluble thrombomodulin or placebo.[35] The absolute risk reduction in 28-day mortality with thrombomodulin was 26.8%, which was 2.55% lower (95% CI, −3.68 to 8.77) than the mortality with placebo. The benefit of thrombomodulin was greatest in patients with high levels of thrombin generation or D-dimer; a finding that needs prospective validation.

Physiological Anticoagulant Factor Concentrates

Restoration of the levels of physiological anticoagulants in DIC may be a rational approach.[36,37] Based on successful preclinical studies, the use of AT concentrate\s and heparin in patients with DIC was evaluated in patients with sepsis, septic shock, or both. The trials have shown some benefit in terms of improvement of laboratory parameters, shortening of the duration of DIC, or improvement in organ function. In several small clinical trials, high dose AT produced a modest, but not significant. reduction in mortality. A large randomized controlled trial also showed no significant reduction in mortality with AT concentrate in patients with sepsis,[38] although a post-hoc subgroup analysis suggested some benefit in patients who did not receive concomitant heparin. In a small randomized trial in patients with burns and DIC, AT administration decreased mortality, reduced multiple organ failure, and improved coagulation parameters compared with placebo.

Because abnormalities of the protein C system contribute to the pathogenesis of DIC, therapy with APC was predicted to be beneficial.[39] A dose-ranging study suggested that an APC dose of 24 μg/kg per hour was optimal, as evidenced by a decrease in D-dimer levels. A subsequent phase III trial comparing APC with placebo in patients with sepsis was stopped early because all-cause mortality at 28 days was reduced from 31% to 25% with APC. Patients with "overt DIC" (see Diagnosis) benefited more from APC than those without overt DIC[9] with relative risk reductions in mortality of 38% and 18%, respectively. Despite these findings, meta-analyses of published literature concluded that the evidence supporting the use of APC, even in patients with severe disease, was not strong. A subsequent series of negative trials in specific populations of patients with severe sepsis and the fact that APC administration increases the risk of bleeding led to the withdrawal of APC from the market.[40]

Fibrinolytic Inhibitors

Most guidelines recommend against the use of anti-fibrinolytic agents, such as ε-aminocaproic acid or tranexamic acid, in patients with DIC. This is because these drugs block already suppressed endogenous fibrinolysis and may further compromise tissue perfusion. In support of this concept, there are reports of severe thrombosis in DIC patients treated with these agents. However, in patients with DIC accompanied by primary hyperfibrinolysis, as can occur with acute promyelocytic leukemia, giant cavernous hemangioma, heatstroke, and metastatic carcinoma of the prostate, the use of fibrinolytic inhibitors can be considered if there is serious bleeding that does not respond to replacement therapy and evidence of hyperfibrinolysis. In these situations, it is important to replace depleted blood components before initiating treatment with fibrinolytic inhibitors.

CHAPTER 138

HYPERCOAGULABLE STATES

Julia A. M. Anderson and Jeffrey I. Weitz

Arterial and venous thromboses are common problems for all clinicians. Some patients with thrombosis have an underlying hypercoagulable state. These hypercoagulable states can be divided into three categories: inherited disorders, acquired disorders, and those that are mixed in origin.

Inherited hypercoagulable states, also known as thrombophilic disorders, can be due to loss of function of natural anticoagulant pathways or gain of function in procoagulant pathways (Table 138.1). Acquired hypercoagulable states represent a heterogeneous group of disorders in which the risk for thrombosis appears to be higher than that in the general population. These include such diverse risk factors as a prior history of thrombosis, obesity, pregnancy, cancer and its treatment, antiphospholipid antibody syndrome, drug-induced thrombosis such as heparin-induced thrombocytopenia or thrombosis associated with chemotherapeutic agents, or myeloproliferative disorders. The pathogenesis of thrombosis in these situations is likely multifactorial in origin. Mixed disorders are those with both inherited and acquired components, for example, hyperhomocysteinemia. Although severe hyperhomocysteinemia and associated homocystinuria are rare genetic disorders, most cases of mild to moderate hyperhomocysteinemia result from acquired folate and/or vitamin B_{12} deficiency superimposed on common genetic mutations in biochemical pathways involved in methionine metabolism.

Genetic hypercoagulable states and acquired risk factors combine to establish an intrinsic risk for thrombosis for each individual. This risk can be modified by extrinsic or environmental factors, such as surgery, immobilization, or hormonal therapy, which also increase the risk for thrombosis. When the intrinsic and extrinsic forces exceed a critical threshold, thrombosis occurs (Fig. 138.1). Appropriate thromboprophylaxis can prevent the thrombotic risk from exceeding this critical threshold, but breakthrough thrombosis can still occur if procoagulant stimuli overwhelm protective mechanisms.

This chapter describes the inherited, acquired, and mixed hypercoagulable states, details their laboratory evaluation, and provides practical advice for the management of these conditions.

INHERITED HYPERCOAGULABLE STATES

Inherited disorders are found in up to half of patients who present with venous thromboembolism before the age of 40, particularly those whose event occurred either in the absence of well-recognized risk factors, such as surgery or immobilization, or with minimal provoking factors, such as minor trauma, long-distance flight, or estrogens. Patients with inherited thrombophilic disorders often have a family history of thrombosis. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis. Patients who present with venous thrombosis in unusual sites, such as the cerebral or mesenteric veins, those with recurrent thrombosis, and patients who develop skin necrosis upon initiation of warfarin therapy should also be suspected of having an inherited hypercoagulable state.

From a pathophysiologic perspective, inherited hypercoagulable states fall into two categories. First are those associated with loss of function of endogenous anticoagulant proteins. These include deficiencies of antithrombin, protein C, and protein S. The second category involves gain of function in procoagulant pathways. These disorders include factor V Leiden and the FIIG20210A mutation, as well as increased levels of procoagulant proteins, such as factors VIII, IX, and XI. Each of these conditions will be briefly described.

Loss of Function of Endogenous Anticoagulants

Antithrombin Deficiency

Antithrombin, a single-chain glycoprotein with a molecular weight of 52,000 Da, is a member of the serine proteinase inhibitor (serpin) superfamily. Antithrombin is synthesized in the liver and endothelial cells and plays a critical part in regulating coagulation by forming a 1:1 covalent complex with thrombin, factor Xa, and other activated clotting factors. Once covalent complexes are generated, they are cleared from the circulation via the liver. The rate of antithrombin interaction with its target proteases is accelerated by heparin by 1000-fold. Heparan sulfate proteoglycan, which coats the vasculature, is the physiologic counterpart of medicinal heparin.

Newborn infants have approximately 50% of normal adult antithrombin levels, and much lower levels are found in preterm infants because of liver immaturity; adult levels are attained at 6 months.

Antithrombin deficiency can be inherited or acquired, and congenital deficiency of antithrombin was the first reported inherited risk factor for venous thromboembolism. Congenital antithrombin deficiency is relatively rare, occurring in about 1 in 2000, and can be one of two types (Table 138.2), both of which are inherited in an autosomal-dominant fashion and affect both sexes equally. Type I deficiency, which represents the classic deficiency state, is the result of reduced synthesis of biologically normal antithrombin. Heterozygotes with this condition have parallel reductions in antithrombin antigen and activity with levels reduced to about 50% of normal. A heterogeneous group of nonsense mutations, small deletions, insertions, or single-base substitutions are the molecular cause of most cases, although gene deletions can also be responsible. An antithrombin mutation database compiled by members of the Plasma Coagulation Inhibitors Subcommittee of the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis summarizes the mutations and can be accessed on the Imperial College London website (https://www.imperial.ac.uk/immunology-inflammation/research/haematology/haemostasis-and-thrombosis/database/#database) or in the human gene mutation database (www.hgmd.cf.ac.uk).

Type II antithrombin deficiencies are characterized by normal levels of antithrombin with impaired functional activity due to the presence of a variant protein. This condition is mainly caused by missense mutations that result in single amino acid substitutions. The clinical consequences of type II antithrombin deficiency depend on the location of the mutation, which may involve the reactive center loop or the heparin-binding domain. For example, some mutations in the reactive center loop of antithrombin slow its interaction with target proteases and are characterized by reduced antithrombin activity in the absence or presence of heparin. In contrast, mutations in the heparin-binding domain are associated with reduced antithrombin activity in the presence of heparin but normal activity in its absence. Unlike other inherited forms of antithrombin deficiency, which are embryonic lethal in the homozygous state, mutations in the

TABLE 138.2 Types of Inherited Antithrombin Deficiency

Type	Antigen	Activity (No Heparin)	Activity (With Heparin)
I	Low	Low	Low
II (active site defect)	Normal	Low	Low
II (heparin-binding site defect)	Normal	Normal	Low

heparin-binding domain only have clinical consequences in individuals homozygous for these mutations and do not increase the risk for thrombosis in the heterozygous state.

Because of the wide variety of heritable forms of antithrombin deficiency, functional antithrombin assays are the preferred method for screening. Most functional assays use synthetic substrates to monitor the rates at which added thrombin or factor Xa are inhibited in patient plasma. However, the assays differ in terms of whether bovine or human thrombin is used and whether heparin is added. Defects in the heparin-binding domain of antithrombin will be detected only in the presence of heparin. When antithrombin deficiency is identified with functional assays, immunologic assays are performed to distinguish between type I and type II deficiency.

Congenital antithrombin deficiency can be associated with spontaneous venous thromboembolism, but thrombosis often occurs in the setting of pregnancy and the puerperium; with the use of estrogen-containing oral contraceptives; or after major trauma or surgery. Thrombotic events are rare in children, with events typically occurring from mid to late teenage years and into the early twenties. The European Prospective Cohort on Thrombophilia (EPCOT) study compared the risks of a first episode of venous thromboembolism in asymptomatic individuals with antithrombin, protein C, or protein S deficiency with that in subjects with factor V Leiden over a 6-year period. The annual incidence of venous thromboembolism was highest in those with antithrombin deficiency.[1] Likewise, in a cohort of Italian patients, the risk of venous thrombosis was higher with antithrombin deficiency than with other thrombophilic defects.[2] The most common sites for venous thrombosis in patients wit antithrombin deficiency are the deep veins of the leg, but thrombosis can occur in mesenteric veins, as well as the renal and retinal veins. The risk for recurrence is high,[3] particularly in those with lower antithrombin levels,[4] and the risk varies depending on the subtype of antithrombin deficiency.

Acquired antithrombin deficiency can reflect decreased antithrombin synthesis, increased consumption, or enhanced clearance (Table 138.3). Decreased synthesis can occur in patients with severe hepatic disease, particularly cirrhosis, or in those given L-asparaginase, the latter because of drug-induced retention of antithrombin within the endoplasmic reticulum. Increased thrombin generation can result in antithrombin consumption. Disorders associated with excessive thrombin generation include acute thrombosis, disseminated intravascular coagulation (DIC), severe sepsis, polytrauma, disseminated malignancy, extensive burns, or prolonged extracorporeal circulation. Heparin treatment can reduce antithrombin levels up to 20% by enhancing its clearance. Severe antithrombin deficiency can also occur in some patients with nephrotic syndrome because of the loss of protein in the urine.

Users of oral contraceptive pills or hormone replacement therapy may have moderate reductions in antithrombin levels; during pregnancy, the antithrombin levels do not fall significantly but decreases are found in preeclampsia and pregnancy-induced hypertensive illnesses.

TABLE 138.3 Causes of Acquired Antithrombin Deficiency

Decreased Synthesis	Increased Consumption	Enhanced Clearance
Hepatic cirrhosis	Major surgery	Heparin
Severe liver disease	Acute thrombosis	Nephrotic syndrome
L-asparaginase	Disseminated intravascular coagulation Severe sepsis Multiple trauma Malignancy Prolonged extracorporeal circulation	

Protein C Deficiency

The protein C pathway is an important natural anticoagulant pathway. This on-demand pathway is activated when thrombin is generated (Fig. 138.2). Thrombin binds to thrombomodulin, a transmembrane thrombin receptor found on the surface of endothelial cells. Once bound to thrombomodulin, the substrate specificity of thrombin is altered so that it no longer serves as a procoagulant enzyme, but becomes a potent activator of protein C, a vitamin K–dependent glycoprotein. Thus, thrombin bound to thrombomodulin activates protein C 1000-fold more efficiently than free thrombin. The endothelial cell protein C receptor (EPCR), another transmembrane receptor on the endothelial cell surface, binds protein C and presents it to the thrombin-thrombomodulin complex for activation, thereby producing an additional 20-fold increase in the rate of protein C activation. The physiologic importance of thrombomodulin and EPCR is highlighted by the fact that deficiency of either receptor results in embryonic lethality in mice.

Activated protein C (APC) dissociates from this activation complex and serves as an anticoagulant by proteolytically degrading and inactivating factors Va and VIIIa, thereby attenuating thrombin generation. For efficient inactivation of factors Va and VIIIa, APC must bind to protein S, its cofactor. This interaction facilitates APC binding to activated cell surfaces, particularly the platelet surface, where factors Va and VIIIa are localized.

APC has a half-life in the circulation of about 15 minutes, whereas thrombin has a half-life of about 10 seconds. APC is inhibited by protein C inhibitor and α_1-proteinase inhibitor (α_1-antitrypsin), both of which are relatively slow inhibitors. Only the activity of protein C inhibitor is enhanced by heparin, but both inhibitors appear to contribute to APC inhibition in vivo.

Protein C deficiency can be inherited or acquired. Like antithrombin deficiency, protein C deficiency is inherited in an autosomal-dominant fashion and has a proven association with venous thrombosis.[5] Based on studies in healthy blood donors, heterozygous protein C deficiency can be found in 1 in 200 to 500 of the adult population, but many of these individuals do not have a history of thrombosis. Thus, the phenotypic expression of hereditary protein C deficiency is highly variable and may depend on other, as yet unrecognized, modifying factors. In contrast to antithrombin deficiency in which the homozygous state is embryonic lethal, homozygous or doubly heterozygous protein C deficiency can occur. The prevalence of homozygous protein C deficiency is estimated to be 1 in 160,000 to 360,000 births. Newborns with these disorders may present with purpura fulminans characterized by widespread thrombosis.

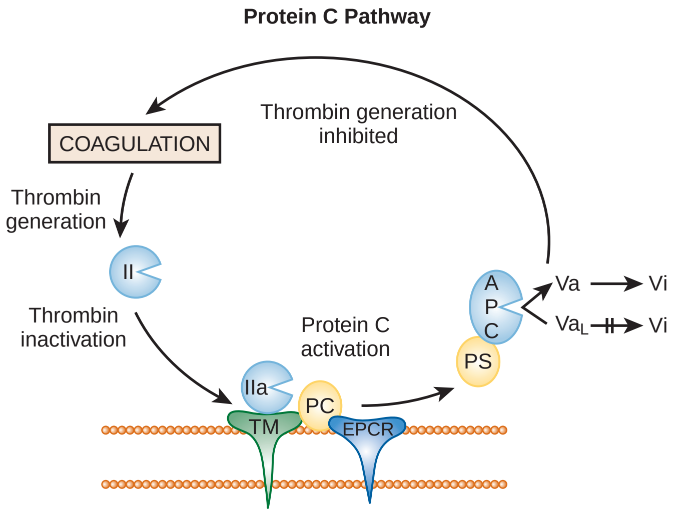

Figure 138.2 PROTEIN C PATHWAY. Activation of coagulation triggers thrombin (IIa) generation. Excess thrombin binds to thrombomodulin *(TM)* on the endothelial cell surface. Once bound, the substrate specificity of thrombin is altered so that it no longer acts as a procoagulant but becomes a potent activator of protein C *(PC)*. Endothelial protein C receptor *(EPCR)* binds PC and presents it to thrombomodulin-bound thrombin, where it is activated. Activated protein C *(APC)*, together with its cofactor, protein S *(PS)*, binds to the activated platelet surface and proteolytically degrades factor Va *(Va)* into inactive fragments *(Vi)*. Because factor Va is a critical component of the prothrombinase complex, factor Va inactivation by APC attenuates thrombin generation. Because factor Va Leiden *(FVa$_L$)* is resistant to inactivation by APC, patients with the factor V Leiden mutation have reduced capacity to regulate thrombin generation. *(From Anderson JA, Weitz JI. Hypercoagulability and uncommon vascular diseases. In: Jaff MR, White CJ, eds. Vascular Disease: Diagnostic and Therapeutic Approaches. Minneapolis, MN: Cardiotext Publishing; 2011.)*

Individuals with heterozygous protein C deficiency can develop skin necrosis upon initiation of treatment with vitamin K antagonists, such as warfarin. Typically, skin lesions are found on the extremities, breasts, or trunk. Starting as erythematous macules, the central regions of the cutaneous lesions become purpuric and then necrotic over a period of hours unless protein C is administered. Biopsies reveal fibrin thrombi within the vessels of the skin associated with interstitial hemorrhage. The skin lesions are clinically and histologically similar to those seen in infants with purpura fulminans and are attributable to the transient hypercoagulable state that is induced by warfarin, thereby explaining why they occur early during the course of warfarin therapy. The half-life of protein C is short and similar to that of factor VII. Starting warfarin in patients with protein C deficiency causes a further reduction in protein C levels, particularly if loading doses of warfarin are given. Thus, the activity of the natural anticoagulant protein C pathway is compromised before warfarin lowers the levels of vitamin K–dependent procoagulant proteins, particularly prothrombin and factor X, into the range required for its antithrombotic effects. Warfarin-induced skin necrosis has also been reported in association with acquired deficiency of protein C.

Hereditary protein C deficiency can be further delineated into two subtypes using immunologic and functional assays (Table 138.4). Most functional assays use Protac, a protease isolated from the venom of the copperhead snake, to activate protein C in plasma. The enzymatic activity of APC can then be determined directly using an APC-directed synthetic substrate, or it can be indirectly quantified by measuring the extent of prolongation of the activated partial thromboplastin time (aPTT). The most common form of hereditary protein C deficiency is the classic or type I deficiency state. This disorder reflects the reduced synthesis of a normal protein and is characterized by a parallel reduction in protein C antigen and activity, resulting in a quantitative deficiency due to reduced synthesis or stability of protein C. A variety of genetic defects can produce type I protein C deficiency, including promoter mutations, splice-site abnormalities, in-frame deletions, frameshift deletions, in-frame insertions, and frameshift insertions in the protein C gene *(PROC)*, but missense or nonsense mutations are the most common.

Type II protein C deficiency reflects synthesis of a dysfunctional protein and is characterized by normal protein C antigen with reduced functional activity, a qualitative deficiency. Most type II protein C deficiency states are caused by point mutations. Mutations in the active site of APC reduce its activity against synthetic substrates and decrease its capacity to prolong the aPTT. In contrast, mutations that affect other protein C domains essential for its activity may reduce its anticoagulant activity but may not affect its capacity to cleave synthetic substrates activity. Therefore, coagulation-based functional assays are preferred when screening patients for protein C deficiency.

Diagnosis of protein C deficiency is complicated. Protein C circulates in human plasma at an average concentration of 4 μg/mL.

TABLE 138.4 **Types of Inherited Protein C Deficiency**

Type	Antigen	Activity
I	Low	Low
II	Normal	Low

Plasma protein C antigen levels are widely distributed in healthy adults such that 95% of the values range from 70% to 140%. Furthermore, protein C levels increase with age, particularly in postmenopausal women.[6] The wide range of values renders the establishment of a normal range difficult. Levels less than 55%, however, are likely to reflect deficiency, whereas those between 55% and 70% are considered borderline and may be consistent with a deficiency state or the lower end of the normal distribution. Acquired causes of protein C deficiency must be excluded, and to document the presence of protein C deficiency, it is necessary to repeat the testing. Family studies may also be helpful to highlight the autosomal-dominant pattern of inheritance.

Acquired protein C deficiency can be due to decreased synthesis or increased consumption. Decreased synthesis can occur with liver disease or with warfarin therapy. Warfarin decreases functional activity more than immunologic activity. Newborns have protein C levels 20% to 40% lower than those of adults, and premature infants have even lower levels. Protein C consumption can occur with severe sepsis, with DIC, and after surgery. Reduced protein C levels have also been reported in cancer patients receiving cyclophosphamide, methotrexate, 5-fluorouracil, or L-asparaginase. A particularly severe form of acquired protein C deficiency has been described in association with meningococcal septicemia. In contrast to antithrombin, which is excreted in the urine of patients with nephrotic syndrome, the levels of protein C are normal or elevated in patients with nephrotic syndrome.

Protein S Deficiency

Protein S serves as a cofactor for APC and enhances its capacity to inactivate factors Va and VIIIa. In addition, protein S may have direct anticoagulant activity by inhibiting prothrombin activation through its capacity to bind anionic phospholipid, factor Va, or factor Xa, components of the prothrombinase complex. The importance of the direct anticoagulant activity of protein S is uncertain.

In the circulation, about 60% of total protein S is bound to C4b-binding protein, an acute phase complement component. Because only 40% of the protein S that is free is functionally active, only patients with low free protein S levels are prone to venous thrombosis. Therefore, the diagnosis of protein S deficiency requires measurement of both free and bound forms of protein S. Total protein S levels can be measured immunologically under conditions that dissociate protein S from C4b-binding protein. The free fraction can then be quantified with a monoclonal antibody that only recognizes free protein S, while the functional activity of protein

S can be measured using an APC cofactor assay. This assay depends on the prolongation of the aPTT when diluted patient plasma is added to protein S–depleted plasma containing APC and factor Va.

Protein S deficiency can be inherited or acquired. Heterozygous protein S deficiency is inherited in an autosomal-dominant manner; the prevalence varies between 1% and 7% among patients with thrombotic events. There is an association with unprovoked venous thromboembolism.[7] Based on measurements of total and free protein S antigen and protein S activity, three subtypes of inherited protein S deficiency have been identified (Table 138.5). Type I or classic deficiency results from the decreased synthesis of a normal protein and is characterized by reduced levels of total and free protein S antigen together with reduced protein S functional activity. Molecular analysis of protein S deficiency is complicated because there are two homologous protein S genes, one of which is likely a pseudogene. Nonetheless, most cases of type I protein S deficiency are caused by partial gene deletions, missense mutations, base pair insertions or deletions, premature stop codons, or mutations affecting a splice site in the gene encoding protein S *(PROS1)*. Type II protein S deficiency is characterized by normal levels of total and free protein S associated with reduced protein S activity. This type of deficiency is uncommon, and most of the causative mutations encode protein S domains involved in its interaction with APC.

TABLE 138.5 **Types of Inherited Protein S Deficiency**

Type	Total Protein S	Free Protein S	Protein S Activity
I	Low	Low	Low
II	Normal	Normal	Low
III	Normal	Low	Low

Type III protein S deficiency is characterized by normal levels of total protein S, but low levels of free protein S are associated with reduced protein S activity. The molecular basis of this type of deficiency appears to be similar to that of the type I deficiency states. In fact, type I and type III protein S deficiency are likely to be manifestations of the same disease because they often coexist in families. Thus, younger family members present with type I deficiency, whereas older family members have type III deficiency because protein S levels increase with age.

Acquired protein S deficiency can be due to decreased synthesis, increased consumption, loss, or shift of free protein S to the bound form. Decreased synthesis can occur in patients with severe liver disease, in those given L-asparaginase, and in patients given vitamin K antagonists. Increased consumption of protein S occurs in patients with acute thrombosis or in those with DIC. Patients with nephrotic syndrome can lose free protein S in their urine, causing decreased protein S activity. Total protein S levels in these patients are often normal because the levels of C4b-binding protein increase, shifting more protein S to the bound form. C4b-binding protein levels also increase in pregnancy and with the use of oral contraceptives. This shifts more protein S to the bound form and lowers the levels of free protein S and protein S activity. The pathophysiologic consequences of this phenomenon are uncertain. An association between antiphospholipid antibodies and acquired protein S deficiency has been reported in patients with severe forms of varicella zoster virus infection complicated by purpura fulminans. In healthy neonates, the total protein S antigen levels are 15% to 30% of normal, and the C4b-binding protein is significantly reduced to less than 20%, such that the free form of protein S predominates and the functional levels are only slightly reduced compared with normal adult levels.

Gain of Function Mutations

Gain of function mutations include factor V Leiden, FIIG20210A, elevated levels of procoagulant proteins, and other less well-characterized genetic disorders. Gain of function mutations are more prevalent in the general population than those associated with loss of function.

Factor V Leiden

In 1993, Dahlback and colleagues described three families with a history of venous thromboembolism. Affected family members exhibited limited prolongation of the aPTT when APC was added to their plasma. Accordingly, this phenotype was designated APC resistance (APCR). Bertina and colleagues demonstrated that APCR co-segregated with the factor V gene and was due to a single-base substitution, guanine to adenine at position 1691, that produced an Arg 506 Gln mutation at one of the APC cleavage sites on factor Va. This mutation, which is designated factor V Leiden, endows activated factor V Leiden with a 10-fold longer half-life in the presence of APC than its wild-type counterpart.

The factor V Leiden mutation is responsible for most cases of APCR. Other causes are mutations at Arg 306, another APC cleavage site. Arg 306 is replaced by a Gly residue in factor V Hong Kong and by a Thr residue in factor V Cambridge. Neither of these mutations is strongly associated with thrombosis.

The factor V Leiden mutation is inherited in an autosomal-dominant fashion. The prevalence of the mutation ranges from 2% to 5% in Whites but it is rare in Asians and Africans. This racial difference likely reflects a founder effect with the mutation arising 20,000 to 30,000 years ago, after the divergence of non-African from African and Caucasoid from Mongoloid subpopulations. The prevalence of factor V Leiden homozygosity is about 1 in 2500. The risk for thrombotic complications is lower with factor V Leiden than it is with deficiencies of antithrombin, protein C, or protein S;[8] and in the heterozygous state, factor V Leiden does not appear to be a strong risk factor for recurrent venous thrombosis.[9] The risk for thrombosis is higher in homozygotes than in heterozygotes. Acquired APC resistance may be caused by hormonal changes during pregnancy or by the administration of estrogens, such as oral contraceptive pills or hormone replacement therapy.

A diagnosis of APCR is established using a functional assay based on the ratio of the aPTT after APC addition divided by that determined before APC addition. Second-generation tests, which add dilute patient plasma to factor V-deficient plasma, are more specific for factor V Leiden. A normal functional test excludes factor V Leiden; a positive functional test for APCR should be confirmed with a genetic test for the factor V Leiden mutation. Some laboratories only use the genetic test for the diagnosis of factor V Leiden.

FII G20210A Mutation

After extensive screening of 28 families with unexplained venous thromboembolism, Poort and colleagues identified a heterozygous G to A nucleotide transition at position 20210 in the 3′-untranslated region of the prothrombin gene in five of the probands. This mutation, FII G20210A, results in elevated levels of prothrombin. Elevated levels of prothrombin, in turn, may increase the risk for thrombosis by enhancing thrombin generation or by inhibiting factor Va inactivation by APC.

The mechanism by which the FII G20210A mutation causes increased prothrombin levels appears to vary. Enhanced protein synthesis may result from more efficient 3′-end formation, increased messenger RNA stability, increased translation efficiency, or some combination of these mechanisms. An intronic FII gene polymorphism, A19911G, which influences splicing efficiency, may modulate the effect of the FII G20210A mutation such that heterozygous carriers of both mutations have a greater risk for thrombosis than those with only the FII G20210A mutation.

Like the factor V Leiden mutation, the prevalence of the FII G20210A mutation is higher in whites and low in Asians, American Indians, and African Americans. A founder effect likely explains the higher prevalence in whites. The mutation may have provided a survival advantage based on a protective effect with childbirth or severe sepsis.

FII G20210A is found in 1% to 6% of Whites. The mutation is more common in southern Europe than in northern Europe, a gradient opposite to that of factor V Leiden. Rare individuals homozygous for the FII G20210A mutation have been identified. In the Leiden Thrombophilia Study, 6.2% of venous thrombosis patients and 2.3% of healthy matched controls had the FII G20210A mutation.[10] The mutation independently confers a 2.8-fold increased risk for venous thrombosis, with no gender bias; a risk lower than that with antithrombin, protein C, or protein S deficiency. The abnormality confers a weaker increased risk of venous thrombosis than protein C, protein S, or antithrombin deficiencies.

Laboratory diagnosis of FIIG 20210 A depends on genetic screening after PCR amplification of the 3′-untranslated region of the FII gene. Although FII G20210A heterozygotes have 30% higher levels of prothrombin than non-carriers, the wide range of prothrombin levels in healthy individuals precludes the use of this phenotype to identify carriers.

Elevated Levels of Procoagulant Proteins

Elevated levels of factor VIII and other coagulation factors, including factors XI, IX, and VII, have been implicated as independent risk factors for thrombosis. Although the molecular bases for the high levels of these coagulation factors have yet to be identified, genetic mechanisms are likely responsible because the hereditability of these quantitative abnormalities is high.

Other Hereditary Disorders

The dysfibrinogenemias represent a heterogeneous group of disorders characterized by abnormal fibrinogen structure and are diagnosed by low functional and/or immunologic levels of fibrinogen, in association with prolonged thrombin and reptilase times. Acquired causes of dysfibrinogenemia, such as liver disease, must be excluded in the diagnostic work-up. Most congenital dysfibrinogenemias are asymptomatic and are often identified as incidental findings when coagulation testing is performed for other reasons. Up to 40% of the known dysfibrinogenemias are associated with a bleeding diathesis. Approximately 15 variant fibrinogens, which represent less than 10% of known dysfibrinogenemias, have been reported to be associated with thrombotic complications, including fibrinogen Marburg, Caracas V, Chapel Hill III, Hannover II, Nijmegen, New York I, Christchurch II and III, and Milano III. The exact mechanism by which these dysfibrinogenemias increase the risk for thrombosis depends on the nature of the fibrinogen defect. Most affect the C-terminal domain of the Aα chains or the thrombin cleavage site on the Bβ chains. Some biochemical defects have been further characterized, such as defects in the release of fibrinopeptides A or B by thrombin, impaired binding of thrombin or tissue plasminogen activator to fibrin, or resistance to lysis by plasmin. It is likely that acquired and/or other hereditary factors contribute to the thrombosis that occurs in patients with dysfibrinogenemia.

ACQUIRED HYPERCOAGULABLE STATES

Acquired hypercoagulable states include antiphospholipid syndrome and cancer, as well as pregnancy and estrogen therapy (oral contraception or hormone replacement therapy). These disorders can occur in isolation or can be superimposed on hereditary hypercoagulable states. Heparin-induced thrombocytopenia is an immune-mediated adverse drug reaction and is a strong, independent risk factor for arterial and venous thrombosis.

Lupus Anticoagulants and the Antiphospholipid Syndrome

First described in a study by Wasserman and colleagues in 1906 among patients with positive serologic tests for syphilis, antiphospholipid antibodies are a heterogeneous group of autoantibodies directed against proteins that bind phospholipid. Antibodies can be categorized into those that prolong phospholipid-dependent coagulation assays, known as the lupus anticoagulant (LA), or anticardiolipin antibodies (ACLs), which target cardiolipin. A subset of ACL recognizes other phospholipid-bound proteins, particularly β_2-glycoprotein I.

Patients who have thrombosis in association with an LA and/or ACL (antibodies of the immunoglobulin [Ig]G or IgM subclass directed against cardiolipin or β_2-glycoprotein 1) are diagnosed with antiphospholipid syndrome (APS). The criteria for diagnosis of APS were updated in 2006.[11] APS is considered primary when it occurs in isolation and secondary when it is associated with autoimmune disorders, such as systemic lupus erythematosus or other connective tissue diseases. Clinical manifestations of APS include one or more episodes of thrombosis, one or more unexplained fetal deaths at 10 or more weeks of gestation, or three or more first-trimester miscarriages (less than 10 weeks of gestation); placental thrombosis is hypothesized to be the cause of the pregnancy-related complications that characterize APS. Intrauterine growth retardation, preeclampsia, and eclampsia have also been associated with APS. APS can also occur with cancer, with some infections, and with drugs such as phenothiazines, phenytoin, hydralazine, or amoxicillin. Thrombosis in APS patients can be arterial, venous, or placental.

To make the diagnosis of APS, at least one clinical criterion and one laboratory criterion must be met.[12] Laboratory diagnosis of APS requires the presence of LA or ACL on tests taken 12 weeks apart. Tests for LA are well standardized, and an LA is associated with a higher risk of thrombosis than ACL.

The LA is detected using phospholipid-dependent clotting tests. Most screening assays are based on the aPTT. aPTT reagents differ in their sensitivity for detection of LA, and many laboratories have adopted less sensitive aPTT reagents for routine aPTT testing. LA is suspected when the aPTT is prolonged. To explore the cause of the prolonged aPTT, patient plasma is mixed with normal plasma, and LA is suspected if the aPTT remains prolonged. The diagnosis is confirmed by demonstrating that the addition of excess hexagonal-phase phospholipid normalizes the aPTT, thereby documenting the phospholipid dependence of the abnormal test result.[13] In addition to the aPTT, a battery of phospholipid-dependent clotting tests is often used for the diagnosis of LA. These include the dilute Russell viper venom time and kaolin clotting time.

ACL antibodies are detected using immunoassays. Only ACL of medium to high titer and of the IgG or IgM subclass are associated with thrombosis, and the risk is higher with antibodies against β_2 glycoprotein-1 than against cardiolipin. For ACL, the amount of IgG or IgM antibody binding to cardiolipin-coated platelets is expressed in standardized GPL or MPL units, with 1 unit representing the cardiolipin-binding capacity of 1 μg/mL affinity-purified antiphospholipid antibody from reference sera. The extent of antibody binding is influenced by both the titer of the antibody and its affinity for cardiolipin. The lack of standardization of ACL assays renders it difficult to compare results between laboratories.

ACL antibodies are found in 3% to 10% of healthy individuals. They also are common with certain infections (such as coronavirus-19 [COVID-19], mycobacterial pneumonia, malaria, or parasitic disorders) and after exposure to some medications. Often, these antibodies are of low titer and are transient. ACL antibodies are detected in about 30% to 50% of patients with systemic lupus erythematosus. Of these, 10% to 20% also have LA.

The mechanism by which antiphospholipid antibodies trigger thrombin generation is unclear. In cell cultures, these antibodies can directly activate endothelial cells and induce the expression of adhesion molecules that can tether tissue factor-bearing leukocytes or microparticles onto their surface. Antiphospholipid antibodies also have been shown to (a) activate platelets, (b) interfere with the protein C pathway, (c) inhibit antithrombin catalysis by vessel wall heparan sulfate, (d) impair fibrinolysis, and (e) enhance transmigration of oxidized low density lipoprotein (LDL) into the vessel wall, thereby promoting atherothrombosis. Whether these mechanisms are operative in vivo has yet to be established. In contrast to most hypercoagulable states, APS can be associated with spontaneous arterial thrombosis, as well as with venous thromboembolism. Arterial thrombosis can manifest as an ischemic stroke or transient ischemic attack. Thrombosis of the sagittal sinus or other cerebral veins, a form of venous thrombosis, is another cause of stroke in these patients.

Heparin-Induced Thrombocytopenia

A clinicopathologic syndrome, heparin-induced thrombocytopenia (HIT) is diagnosed based on clinical features[14] and laboratory detection of HIT antibodies (see Chapter 131). The risk for HIT is higher with unfractionated heparin than with low-molecular-weight heparin (LMWH) and almost never occurs with fondaparinux. HIT is more common in surgical patients than in medical patients and occurs more frequently in women.

Typical clinical features of HIT include thrombocytopenia and thrombosis (arterial or venous). Less common features include necrotic skin lesions at the site of subcutaneous heparin injection, acute systemic reactions to heparin, and rarely, DIC (see Chapter 137).[15] Thrombocytopenia is the most common finding, occurring in 90% of patients. Typically, the platelet count falls 5 to 10 days after heparin is started.[16] However, thrombocytopenia can occur earlier if the patient has been exposed to heparin in the past 3 months. Rarely, the onset of HIT is delayed and occurs several days after stopping heparin.

HIT is an autoimmune-like disorder and is caused by heparin-dependent, platelet-activating antibodies of the IgG subclass. These antibodies are directed against neoantigens that are exposed on platelet factor 4 (PF4) when it forms a complex with heparin. By binding to FcγII receptors on platelets, these antibodies trigger platelet activation. Activated platelets and platelet-derived microparticles provide an anionic phospholipid surface on which coagulation factors assemble and promote thrombin generation. This produces an aggressive hypercoagulable state and explains why 30% to 70% of HIT patients develop thrombosis.

The diagnosis of HIT is supported by assays that capitalize on the platelet-activating properties of HIT antibodies. Functional assays, such as the platelet serotonin release assay or heparin-induced platelet activation assay, detect antibody-induced platelet activation in the presence of heparin and are the gold standard for diagnosis of HIT. In contrast, although enzyme immunoassays for the detection of antibodies against PF4/heparin complexes are more sensitive than functional assays, they are less specific because only a small subset of these antibodies has the capacity to produce HIT. Consequently, a negative immunoassay is useful to exclude the diagnosis of HIT, but a positive test should be confirmed with a functional assay.

When the diagnosis of HIT is established, heparin must be stopped, and an alternative anticoagulant should be given. Options include direct thrombin inhibitors (such as argatroban or bivalirudin) or parenteral factor Xa inhibitors (such as fondaparinux or danaparoid) or oral factor Xa inhibitors (such as rivaroxaban or apixaban). Treatment with parenteral agents should be continued until the platelet count returns to baseline levels, at which point an oral factor Xa inhibitor or warfarin can be initiated.

Cancer and Its Treatment

About 25% of patients who present with venous thromboembolism have cancer. Cancer patients who develop venous thromboembolism have reduced survival compared with those without this complication. Patients with brain tumors, pancreatic cancer, and advanced ovarian, lung, gastrointestinal tract, or prostate cancer have particularly high rates of venous thromboembolism.[17] Treatment with chemotherapy, hormonal therapy, and biologic agents, such as erythroid stimulating agents and antiangiogenic drugs, and surgery further increases the risk for venous thromboembolism. Additional risk factors include indwelling central venous catheters and major abdominal, pelvic, or orthopedic surgery.

The pathogenesis of thrombosis in cancer patients is multifactorial in origin and represents a complex interplay among the tumor, patient characteristics, and the host hemostatic system. Tumors can initiate coagulation by expressing tissue factor or cysteine proteases on their surface or by shedding tissue factor-bearing microparticles. In addition to its role in coagulation, tissue factor also acts as a cell-signaling molecule that promotes tumor proliferation and spread.

Patient factors that contribute to venous thromboembolism include immobility and venous stasis secondary to extrinsic compression of major veins by tumor. Surgical procedures, indwelling central venous catheters, and chemotherapy can produce vessel wall injury. In addition, tamoxifen, selective estrogen receptor modulators (SERMs), L-asparaginase, and other drugs may induce an acquired hypercoagulable state by reducing the levels of natural anticoagulant proteins.

L-Asparaginase and combination chemotherapeutic regimens, such as breast cancer regimens of cyclophosphamide, methotrexate, and 5-fluorouracil increase the risk for thrombosis. The incidence of thromboembolic events in children receiving L-asparaginase for treatment of acute lymphocytic leukemia ranges from 1.1% to 36.7% depending on whether catheter-related events are included. The mechanism likely involves the decreased synthesis of antithrombin, protein C, and protein S, in addition to the retention of antithrombin within the endoplasmic reticulum.

Patients with multiple myeloma and other plasma cell dyscrasias are at increased risk for arterial and venous thrombosis. The reason for this is unclear but may include acquired activated protein C resistance, elevated levels of factor VIII and/or von Willebrand factor, and the influence of the paraprotein on blood viscosity and fibrinolysis. Patients treated with thalidomide or lenalidomide are at high risk for venous thromboembolism, particularly when these drugs are given in combination with dexamethasone. Current guidelines recommend low-dose aspirin or LMWH thromboprophylaxis for patients receiving these agents.[18,19] Rivaroxaban or apixaban may be an alternative to LMWH in these patients.

Although a proportion of patients who present with unprovoked venous thromboembolism have occult cancer, extensive screening for cancer is not recommended.[20] A careful history should be taken to identify any symptoms suggestive of underlying cancer. If such symptoms are present, further investigation is warranted. If there are no symptoms suggestive of underlying cancer, patients should be encouraged to undergo age-appropriate screening tests for breast, cervical, colon, or prostate cancer.

Myeloproliferative Disorders

The most common Philadelphia chromosome-negative (Ph-neg) myeloproliferative disorders, essential thrombocythemia (ET) and polycythemia vera (PV), are associated with an increased risk for thrombosis, especially arterial thrombosis, and venous thrombosis affecting the splanchnic vessels, including the hepatic and portal veins, which can lead to the Budd–Chiari syndrome, or the mesenteric veins. Thrombosis involving the microcirculation is common in patients with ET, and patients may complain of erythromelalgia, characterized by burning pain, redness and swelling of the fingers and toes, transient visual defects, or recurrent headache. Although ET and PV may evolve to myelofibrosis or transform into acute myeloid leukemia, fatal cardiovascular events are a leading cause of mortality. The reported cumulative risk for thrombosis ranges from 2.5% to 5.0% per patient-year in PV and from 1.9% to 3% per patient-year in ET, depending on the patient risk category. Age over 60 years and a previous history of thrombosis are risk factors for serious thrombosis, whereas usual cardiovascular risk factors, such as hypertension, diabetes, dyslipidemia, and smoking, may place patients at intermediate risk.

The pathogenesis of thrombosis in patients with myeloproliferative disorders is multifactorial in origin and includes leukocytosis, leukocyte activation, rheologic abnormalities due to raised red cell mass in PV, enhanced platelet activation, and a prothrombotic endothelial phenotype.

An acquired point mutation in the Janus kinase 2 gene (*JAK2* V617F) is found in up to 95% of patients with Ph-neg PV and in 50% to 60% of those with ET. The *JAK*2 gene encodes a cytoplasmic tyrosine kinase that is critical for signaling between type 1 cytokine receptors and intracellular proliferation mechanisms. Clinical observations, supported by laboratory studies, suggest an association between the *JAK*2 mutation and increased leukocyte and platelet activation, particularly in reticulated platelets, and there is a correlation between the burden of the mutant allele and thrombin generation. Acquired activated protein C resistance secondary to a reduction in free protein S levels has also been demonstrated in patients with ET and PV. Overall, there is little to support routine *JAK*2 screening unless splenomegaly or an elevated hemoglobin, white blood cell, and/or platelet count raises the possibility of an underlying myeloproliferative disorder. However, it may be justifiable to check for the *JAK*2 mutation in patients with unexplained splanchnic or mesenteric vein thrombosis, even in the absence of these findings.

Current management of PV and ET is aimed at the prevention of major cardiovascular events and is based on the patient's risk category. Low-risk patients with PV are managed with phlebotomy, whereas high-risk patients are given cytoreductive therapy. Low-dose aspirin (75 to 100 mg daily) is recommended for all PV patients regardless of risk category, and such therapy is highly effective for the treatment of the microcirculatory disturbances in patients with ET.

Paroxysmal Nocturnal Hemoglobinuria

A rare but serious disorder, paroxysmal nocturnal hemoglobinuria (PNH) is associated with intravascular hemolysis and cytopenia. PNH is caused by the clonal expansion of a hematopoietic stem cell that has a somatic mutation in the X-linked *PIG-A* gene, which encodes cell surface proteins that serve as phosphatidylinositol anchors (see Chapter 32). Patients with PNH may have life-threatening thrombosis that can be difficult to recognize when it affects the splanchnic or cerebral veins. Severe persistent abdominal pain or headache in patients with PNH should prompt appropriate radiologic investigations to exclude thrombosis. Although patients with PNH who have documented thrombosis should be treated with anticoagulants, eculizumab, a monoclonal antibody complement inhibitor, is highly effective and the only licensed treatment for PNH.[21]

Pregnancy

Pregnancy is an independent risk factor for venous thromboembolism: the risk for venous thromboembolism in pregnant women is up to six-fold higher than that in age-matched nonpregnant women. About 1 in 1000 pregnancies are complicated by venous thromboembolism, and the risk is highest in the postpartum period. Thus, venous thromboembolic disease is the leading cause of maternal morbidity and mortality and is estimated to account for 12% of the fatalities in pregnancy.[22]

The individual risk for venous thromboembolism in pregnancy and the puerperium, defined as the 6-week period after delivery, is influenced by patient-related factors. These factors include age over 35 years, body mass index over 29, cesarean delivery, prolonged immobilization, obesity, and thrombophilia or family history of venous thromboembolism. Multiparity, ovarian hyperstimulation, and a past history or family history of venous thromboembolism are other risk factors.

Over 90% of deep vein thrombosis in pregnancy occurs in the left leg because the enlarged uterus further compresses the left iliac vein by placing pressure on the overlying right iliac and ovarian arteries. A similar mechanism likely explains the isolated left iliofemoral thrombosis that can occur in pregnancy.

Hypercoagulability of the blood occurs in pregnancy and reflects a combination of venous stasis and changes in the hemostatic system. The enlarging uterus reduces venous blood flow from the lower extremities. This is not the only mechanism responsible for venous stasis because blood flow from the lower extremities begins to decrease by the end of the first trimester, likely reflecting hormonally induced venous dilatation. Systemic factors also contribute to hypercoagulability. Thus, the levels of circulating procoagulant proteins increase in the third trimester of pregnancy. These include factor VIII, fibrinogen, and von Willebrand factor, among others. Coincidentally, suppression of natural anticoagulant pathways and decreased fibrinolytic activity occur. Thus, there is an acquired resistance to activated protein C that is related, at least in part, to reduced levels of free protein S. The net effect of these changes is enhanced thrombin generation, in addition to the release of tissue factor from the uteroplacental circulation, as evidenced by elevated levels of prothrombin fragments and thrombin/antithrombin complexes. Platelet activation and increased platelet turnover occur, and mild thrombocytopenia, likely secondary to consumption, occurs in 8.3% of women at term. The altered levels of hemostatic proteins normalize 4 to 6 weeks after delivery.

About half of the episodes of venous thromboembolism in pregnancy occur in women with thrombophilia. The risk for venous thromboembolism in women with thrombophilic defects depends on the type of abnormality and the presence of other risk factors. The risk appears to be highest in women with a positive family history of venous thromboembolism who are homozygous for the factor

V Leiden or FIIG 20210 A mutation. There is also an increased risk in women with antithrombin, protein C, or protein S deficiency and a positive family history and a lower risk in those who are heterozygous for the factor V Leiden or FIIG 20210 A mutation. The risk of venous thromboembolism during pregnancy is similar in all three trimesters and begins in early pregnancy. In general, the daily risk is higher in the postpartum period than it is during pregnancy. Therefore, if thromboprophylaxis is given during pregnancy, it must be administered throughout the pregnancy and continued for at least 6 weeks postpartum.

Assisted Conception and Ovarian Hyperstimulation Syndrome

The overall risk for venous thrombosis in women undergoing ovarian hyperstimulation is small (estimated as 0.1% per treatment cycle). Often, thrombosis affects veins of the upper extremities or the jugular veins; the explanation for this phenomenon remains unclear. Thrombophilia testing is not routinely recommended in women undergoing ovarian stimulation because the predictive value is low.

Hormonal Therapy

Oral contraceptives, estrogen replacement therapy, and SERMs are all associated with an increased risk for thrombosis. The relatively high risk for venous thromboembolism associated with early oral contraceptives prompted the development of low-dose formulations containing reduced doses of estrogen and progestin. Currently available low-estrogen combination oral contraceptives contain 20 to 50 μg of ethinylestradiol and one of several different progestogens. Even these low-dose combination contraceptives are associated with a three- to four-fold increased risk for venous thromboembolism compared with the risk in non-users. In absolute terms, this translates to an incidence of 3 to 4 per 10,000. In contrast, progesterone-only methods of contraception, including pills, cutaneous implants, and progesterone-releasing intrauterine devices, are associated with little or no risk of thrombosis.[23]

Although smoking increases the risk for myocardial infarction and stroke in women taking oral contraceptives, it is unclear whether smoking affects the risk for venous thromboembolism. In contrast, obesity increases the risk for both arterial and venous thrombosis, and the risk of venous thrombosis increases steeply in those over the age of 40 years. The risk for venous thromboembolism is highest during the first 3 months of oral contraceptive use and persists only for the duration of use.

Case-control studies suggest that the risk for venous thromboembolism is 20- to 30-fold higher in women with inherited thrombophilia who use oral contraceptives than the risk for non-users with thrombophilia or users without these defects. Despite the increased risk, however, routine screening for thrombophilia is not indicated in women considering the use of oral contraceptives. Based on the estimated incidence and case fatality rate of thrombotic events, it is estimated that 400,000 women would need to be screened to detect 20,000 carriers of factor V Leiden. Oral contraceptives would need to be withheld in all these women to prevent a single death. For less prevalent thrombophilic defects, even larger numbers of women would need to be screened. Based on these considerations, routine screening cannot be recommended.

Oral contraceptive pills may cause prothrombotic side effects by inducing modest increases in levels of procoagulant factors (such as factors VII, VIII, X, prothrombin, and fibrinogen) and decreases in the levels of anticoagulant proteins (such as antithrombin and protein S). Acquired APC resistance is an almost universal finding in women taking oral contraceptives; the clinical significance of this phenomenon is uncertain.

There is good evidence that oral hormonal replacement therapy with conjugated equine estrogen (with or without a progestogen) increases the risk for myocardial infarction, ischemic stroke, and venous thrombosis. Carriers of the factor V Leiden mutation receiving hormone replacement therapy have a significantly increased risk for venous thromboembolism. Data from the Heart and Estrogen Replacement Study (HERS) and the Estrogen Replacement and Atherosclerosis Trial indicate that heterozygous carriers of the factor V Leiden mutation who were taking hormone replacement therapy had a 14-fold higher risk for venous thromboembolism compared with non-carriers receiving placebo. Based on this information, the use of oral hormone replacement preparations has markedly decreased. Use of transdermal hormone replacement therapy does not appear to increase the risk of venous thrombosis.[24]

SERMs are estrogen-like compounds. The prototypical SERM is tamoxifen, which serves as an estrogen antagonist in the breast, but has an estrogen agonist effect in other tissues, such as bone and uterus. Like estrogens, tamoxifen increases the risk for venous thromboembolism three- to fourfold. The risk is higher in postmenopausal women, particularly when they are receiving systemic combination chemotherapy.

Aromatase inhibitors are replacing tamoxifen for the treatment of estrogen receptor-positive breast cancer. These agents are associated with a lower risk for venous thromboembolism than is tamoxifen. Raloxifene, a SERM used to prevent osteoporosis, increases the risk for venous thromboembolism threefold compared with placebo. Therefore, this agent is contraindicated for the prevention of osteoporosis in women with a prior history of venous thromboembolism.

Prior History of Venous Thromboembolism

A history of previous venous thromboembolism places patients at risk for recurrence. Those with unprovoked venous thromboembolism have a particularly high risk for recurrence when anticoagulant treatment is stopped. Their risk for recurrence is about 10% at 1 year and 30% at 5 years. This risk occurs regardless of whether there is an underlying thrombophilic defect, such as factor V Leiden or the FIIG 20210 A mutation.

The risk for recurrent venous thromboembolism is lower in patients whose incident event occurred in association with a well-recognized and transient risk factor, such as major surgery or prolonged immobilization. These patients have a risk for recurrence of about 4% at 1 year and 10% at 5 years. Patients at highest risk for recurrence are those homozygous for factor V Leiden or the FII G20210A mutation and those with APS, advanced malignancy, or inherited deficiencies of antithrombin, protein C, or protein S. The risk for recurrence in such patients is likely to be 15% at 1 year and up to 50% at 5 years.[25]

COMBINED INHERITED AND ACQUIRED HYPERCOAGULABLE STATES

Hyperhomocysteinemia is the prototypical hypercoagulable state that occurs due to a combination of inherited and acquired factors. Homocysteine is an intermediate sulfur-containing amino acid that acts as a methyl group donor during the metabolism of methionine, an essential amino acid derived from the diet. The interconversi of 5-methyltetrahydrofolate, a methyl group donor, vitamin B_{12} and folate, cofactors in the interconversion, and the enzyme methionine synthase. Increased levels of homocysteine can be the result of increased production or reduced metabolism. Severe hyperhomocysteinemia and cysteinuria are rare and are usually caused by deficiency in the enzyme, cystathione β-synthetase. More common is mild to moderate hyperhomocysteinemia. This can be caused by genetic mutations in methyltetrahydrofolate reductase (MTHFR) when they are accompanied by the nutritional deficiency of folate, vitamin B_{12}, or vitamin B_6. Common polymorphisms in MTHFR, C677T, and A1298C are associated with reduced enzymatic activity and increased thermolability. The cofactor requirements are therefore increased with these mutations.

Hyperhomocysteinemia also can be associated with certain drugs, such as methotrexate, theophylline, cyclosporine, and most anticonvulsants, as well as some chronic diseases, such as end-stage renal disease, severe hepatic dysfunction, and hypothyroidism.

A fasting serum homocysteine level over 15 mmol/L is considered elevated. Although elevated levels were a common finding, routine fortification of flour with folic acid has resulted in lower homocysteine levels in the general population. Elevated serum levels of homocysteine have been associated with an increased risk for arterial thrombosis (myocardial infarction, stroke, and peripheral arterial disease) and venous thromboembolism.

Elevated levels of homocysteine can be reduced by the administration of folate with vitamin B_{12} and vitamin B_6. Randomized trials, however, have shown that the reduction of homocysteine levels with vitamin therapy does not reduce the risk for recurrent cardiovascular events in patients with coronary artery disease or stroke, nor does it lower the risk for recurrent venous thromboembolism; whether reduction of homocysteine levels is of benefit in peripheral artery disease with bypass grafts is less certain. Nonetheless, based on these negative trials and the declining incidence of hyperhomocysteinemia, the enthusiasm for screening for hyperhomocysteinemia has waned.

CLINICAL EVALUATION OF PATIENTS WITH HYPERCOAGULABLE STATES

A carefully taken history is essential to evaluate a patient with a history of thrombosis. The patient's age at the time of thrombosis, the location of the thrombosis, and results of objective diagnostic tests should be recorded. A historical record of previous thromboses and sites, and potential risk factors, such as recent surgery, trauma, prolonged immobility, pregnancy, or estrogen use should be noted. A family history of thrombosis, especially in first-degree relatives, may point to a heritable thrombophilic defect; systemic symptoms, such as anorexia, weight loss, change in bowel habits, or gastrointestinal bleeding, may suggest an underlying malignant condition.

A full physical examination should be conducted with attention to abdominal or pelvic masses, lymphadenopathy, and skin changes such as skin necrosis and livedo reticularis. Basic investigations are necessary to exclude acquired causes of thrombosis and to assess the patient's general health and tolerance to anticoagulation (see box on Routine Investigations to Evaluate a Patient with Venous Thrombosis).

THROMBOPHILIA SCREENING

In the past, the indications for thrombophilia screening were somewhat controversial, and the implications of such tests were often misinterpreted. It is now apparent that testing for heritable thrombophilia does not predict the likelihood of recurrence in unselected patients with symptomatic venous thrombosis. For patients with a first episode of venous thromboembolism, thrombophilia screening is indicated only if the results influence the duration of treatment or have an impact on family counseling regarding the use of estrogen-containing compounds. It is reasonable to screen patients whose first episode of thrombosis occurred before the age of 40 years, patients with thrombosis in an unusual site, such as cerebral or mesenteric veins, and those with two or more first-degree relatives, with unprovoked thrombosis; retinal vein thrombosis is not an indication for such screening. Screening should not be done when patients are taking an anticoagulant. If indefinite anticoagulation therapy is planned, screening is generally not required. Neonates and children with purpura fulminans should be urgently tested for protein C or S deficiency, as should adults who develop skin necrosis in association with vitamin K antagonists (see box on When to Perform a Thrombophilia Screen).

ROUTINE INVESTIGATIONS TO EVALUATE A PATIENT WITH VENOUS THROMBOSIS

Test	Abnormality	Diagnostic Information
Complete blood count	Elevated hematocrit Increased white count Increased platelet count Leukopenia Thrombocytopenia	Myeloproliferative disorder (e.g., essential thrombocythemia, polycythemia vera); cytopenias may be found in paroxysmal nocturnal hemoglobinuria; if thrombocytopenia associated with heparin administration, consider heparin-induced thrombocytopenia
Blood film	Leukoerythroblastic changes	Underlying neoplasm invading bone marrow
Liver function tests	Abnormal tests	May point to malignancy
Renal function	Impaired renal function	Assess prior to anticoagulation with heparin or low-molecular-weight heparin or direct oral anticoagulants
Urinalysis	Proteinuria	Nephrotic syndrome; may be associated with venous thromboembolism or renal vein thrombosis
PT and aPTT	Prolonged PT and aPTT	To enable safe anticoagulation to proceed if required Need to exclude lupus anticoagulant

aPTT, Activated partial thromboplastin time; *PT*, prothrombin time.

WHEN TO PERFORM A THROMBOPHILIA SCREEN

Clinical Scenario

- First episode of unprovoked venous thromboembolism in individuals younger than 40 years of age
- Thrombosis in an unusual site (e.g., cerebral or mesenteric vein thrombosis)
- Two or more first-degree relatives with unprovoked thrombosis
- Three or more early pregnancy losses, or one or more fetal deaths after 10 weeks, gestation

LABORATORY EVALUATION OF THROMBOPHILIA

Screening should include functional assays for antithrombin and protein C, an immunoassay for free protein S, testing for activated protein C resistance using the modified APC sensitivity ratio with DNA testing for the factor V Leiden mutation if the screening test is positive, DNA testing for the FIIG 20210 A gene mutation, and phospholipid-based clotting tests to detect an LA and enzyme immunoassay for ACL (see box on Essential Tests for Thrombophilia Screening). The benefits and potential harms of thrombophilia testing should always be discussed in advance with the patient because the psychological impact of knowing that they are a carrier of a genetic defect is one of the disadvantages of testing and because test results may also impact the cost of life insurance.

The timing of thrombophilia screening is critical. Levels of natural anticoagulants may be lower at the time of an acute thrombotic event; additionally, heparin can reduce the level of antithrombin, while vitamin K antagonists, such as warfarin, reduce the levels of protein

ESSENTIAL TESTS FOR THROMBOPHILIA SCREENING

- Basic coagulation screen
  - International normalized ratio (INR): to exclude the warfarin effect—warfarin will lower protein C and S levels
  - Activated partial thromboplastin time (aPTT): to exclude the heparin effect—heparin will lower antithrombin levels
- Functional assay for antithrombin (with heparin to detect type II defects)
- Functional assay for protein C
- Functional assay for protein S (immune assays for total and free protein S)
- APC resistance assay: with the genetic test for factor V Leiden for confirmation of abnormal results
- Genetic test for FIIG 20210A gene mutation
- Anticardiolipin and β_2-glycoprotein-1 antibodies (IgG and IgM) and lupus anticoagulant assay

C and protein S. Therefore, testing is best performed well after the acute event and when anticoagulant treatment has been discontinued. During pregnancy, protein S levels fall, complicating the diagnosis of protein S deficiency.

MANAGEMENT OF THROMBOSIS IN PATIENTS WITH HYPERCOAGULABLE STATES

Thrombosis treatment is usually divided into two overlapping stages, initial treatment, and extended therapy. The impact of hypercoagulable states on these two stages is discussed separately, as is their impact on the duration of anticoagulant therapy and recommendations for the prevention of recurrence.

Initial Treatment

With few exceptions, the management of initial thrombotic events in patients with hypercoagulable states is no different from the management of these events in patients without underlying hypercoagulable disorders. The exceptions are purpura fulminans in newborns with homozygous protein C or protein S deficiency, warfarin-induced skin necrosis, heparin-induced thrombocytopenia, and thrombosis in patients with severe antithrombin deficiency. Newborns with purpura fulminans require protein C or protein S concentrates or enough fresh frozen plasma to increase the levels of protein C or protein S.

Patients with antithrombin deficiency can usually be managed with LMWH or unfractionated heparin, although higher doses may be needed to achieve therapeutic anticoagulation. As an alternative, oral factor Xa inhibitors such as apixaban or rivaroxaban can be considered. Patients with severe antithrombin deficiency may require antithrombin concentrates to increase plasma levels of antithrombin to a point where heparin or LMWH can be used for treatment. Antithrombin concentrates are commercially available in plasma-derived and recombinant forms. The aim of treatment with antithrombin concentrate is to initially increase antithrombin activity to greater than 120% of the normal level (based on an expected 1.4% increase above baseline activity level per IU/kg of antithrombin administered) and to then maintain antithrombin activity at over 80% of the normal level. Plasma antithrombin levels need to be monitored to ensure that levels over 80% are maintained; antithrombin has a half-life of 2 to 4 days.

Treatment of heparin-induced thrombocytopenia involves discontinuation of heparin (including all forms of heparin such as heparin flushes of indwelling central venous catheters) and the initiation of an alternative anticoagulant, such as argatroban, fondaparinux, or an oral factor Xa inhibitor. Once the platelet count returns to its baseline level in those given a parenteral anticoagulant, the patient can be given either a vitamin K antagonist at a low initiating dose or a direct oral anticoagulant.

In patients with triple positive antiphospholipid antibody syndrome (LA, ACL, and antibody against β2-glycoprotein 1), or those with APS complicated by arterial thrombosis, direct oral anticoagulants such as rivaroxaban have been found to be less effective than vitamin K antagonists.[26–28] For those with single or dual positive APS, there is insufficient data to guide advice on the optimal anticoagulant to use initially and longer term. However, in 2019, the European Medicines Agency (EMA) and the MHRA (UK) advised against the use of all direct oral anticoagulants in people with APS of any type. Initial treatment is usually with LMWH or fondaparinux, followed by extended use of a vitamin K antagonist.

In asymptomatic subjects with laboratory evidence of ACL or LA, but no history of venous or arterial thrombosis, appropriate thromboprophylaxis should be given at the time of thrombotic challenge, such as major surgical procedures, prolonged immobilization, or pregnancy and the puerperium. There is no indication for primary preventive treatment with anticoagulants or antiplatelet agents in such individuals.

Extended Therapy

Extended treatment of thrombosis in patients with hypercoagulable states is like that of patients without these underlying disorders. Caution is needed when starting patients with protein C or protein S deficiency on warfarin or other vitamin K antagonists to prevent skin necrosis. Warfarin should not be started in these patients until therapeutic anticoagulation has been fully achieved with heparin or LMWH. Once started, low doses of warfarin should be given to prevent precipitous decreases in the levels of protein C or protein S; the heparin or LMWH should only be stopped when the international normalized ratio (INR) has been therapeutic for at least two consecutive days.

In patients with APS, randomized trials have shown that usual-intensity warfarin (target INR of 2.0 to 3.0) is as effective as higher-intensity warfarin. The risk for major bleeding is lower with usual-intensity warfarin than it is with higher-intensity regimens. A target INR of 2.5 with an INR range from 2.0 to 3.0 is appropriate for patients with other hypercoagulable states.

For patients with cancer-associated thrombosis, compared with warfarin, LMWH reduces the risk for recurrent venous thromboembolism without increasing bleeding,[29] lacks interactions with chemotherapy and other medicines, and holds favorable pharmacokinetics for with-holding prior to invasive procedures. The major drawbacks of LMWH have been cost and its requirement for parenteral administration. Direct oral anticoagulants appear to be efficacious and may take over as the mainstay of treatment for patients with cancer-associated thrombosis; evidence from clinical trials demonstrate non-inferiority compared to LMWH, although there are several outstanding issues, such as drug-drug interactions, and bleeding risk in certain tumor types.[30–32]

Duration of Treatment

The presence of a hypercoagulable state has no influence on the duration of anticoagulant treatment in patients whose venous thromboembolic event occurred in the setting of a well-recognized and transient risk factor, such as major surgery or prolonged immobilization due to medical illness. These patients are treated with anticoagulants for a minimum period of 3 months.

For those with unprovoked venous thromboembolism, a minimum of 3 months of anticoagulation treatment is recommended, at which point individualized assessment of the risk of recurrence without anticoagulation and the risk of bleeding with anticoagulation should be undertaken. Unless the risk of bleeding is high, most patients should receive extended anticoagulation therapy. Heterozygosity for factor V Leiden or the FIIG20210A mutation does not influence the risk for recurrence. In contrast, patients with deficiency of antithrombin, protein C, or protein S or those homozygous for factor V Leiden or the FII G20210A mutation appear to be at higher risk for recurrence and likely should receive longer-term anticoagulation treatment. Likewise, patients with APS with a persistent ACL or LA are also at high risk for recurrence and require extended treatment with a vitamin K antagonist.

The decision to continue anticoagulation indefinitely requires consideration of the site and severity of the first episode of venous thromboembolism, information on whether or not the event was provoked, assessment of the risk for anticoagulant-related bleeding, and other risk factors such as an elevated D-dimer level after stopping anticoagulant therapy.[25] There is mounting evidence that patients with VTE provoked by minor transient risk factors such as a flight or a brief period of immobilization and those with minor persistent risk factors such as obesity or inflammatory bowel disease have a risk of recurrence of up to 8% at one year if anticoagulation therapy is stopped. Therefore, extended anticoagulation may need to be considered in such patients taking into account adherence and patient preference.

Treatment and Prevention of Thrombosis During Pregnancy

Thrombophilic disorders have no influence on the treatment of venous thrombosis during pregnancy. Due to its better bioavailability and longer half-life, LMWH is the anticoagulant of choice; fondaparinux is reserved for women with an allergy to heparin. LMWH can be given once or twice daily in a weight-adjusted fashion. The need for dose adjustments and monitoring during the course of pregnancy has been a controversial area, but consensus-based recommendations advise against the need for monitoring anti-factor Xa levels. Direct oral anticoagulants and vitamin K antagonists should not be used in pregnancy because these drugs have the potential to cross the placenta.

No studies have addressed the optimal duration of anticoagulation for pregnancy-related venous thrombosis. In total, treatment should be given for 3 to 6 months from the time of diagnosis. Warfarin and LMWH can be safely administered in nursing mothers, with no detectable anticoagulant effect in breast milk. In contrast, direct oral anticoagulants should not be used in nursing mothers because low levels of drugs have been detected in breast milk.

Women with a past history of unprovoked or recurrent venous thromboembolism, those homozygous for factor V Leiden or the FII G20210A mutation, and those with deficiencies of antithrombin, protein C, or protein S and a family history of venous thrombosis should receive antepartum prophylaxis with LMWH. Postpartum, LMWH or warfarin should be given for 6 weeks. Postpartum treatment with LMWH or warfarin for 6 weeks is likely adequate for women with a history of venous thrombosis secondary to a well-defined risk factor. Prophylaxis during pregnancy, as well as postpartum, should be considered for women who developed venous thromboembolism after taking oral contraceptives, particularly if they have underlying thrombophilia. Women with thrombophilic defects but no prior history of venous thromboembolism or family history of the same likely do not require antepartum prophylaxis or postpartum treatment, but definitive data are lacking. A summary of these recommendations is provided in Table 138.6.[33]

TABLE 138.6 Management of Women With a History of Venous Thrombosis During Pregnancy and the Puerperium

Clinical History	Thrombophilia	Antepartum	Postpartum[a]
Prior VTE due to a transient risk factor	No	Surveillance	Yes
Prior VTE due to pregnancy or estrogens	Yes or no	Prophylactic LMWH	Yes
Prior idiopathic VTE	Yes or no	Prophylactic LMWH	Yes
Recurrent VTE	Yes or no	Treatment dose LMWH	Resume long-term anticoagulation
No prior VTE Positive family history	Antithrombin deficiency; homozygous FII G20210A; or Factor V Leiden; or dual heterozygosity for both mutations	Prophylactic or intermediate dose LMWH	Yes

[a]Postpartum prophylaxis involves a 6-week course of prophylactic doses of LMWH or dose-adjusted warfarin (target INR: 2.0–3.0).
LMWH, Low-molecular-weight heparin; *VTE*, venous thromboembolism.

Thrombophilia and Fetal Loss

About 30% of women have at least one fetal loss, and approximately 5% of women of reproductive age experience recurrent fetal loss. Women with hereditary or acquired thrombophilia have a two- to five-fold increased risk for fetal loss. Screening for APS is recommended if there is a history of three or more miscarriages before 10 weeks' gestation. Although once-daily LMWH in prophylactic doses, with or without aspirin, is often prescribed for women with recurrent fetal loss on the background of an underlying thrombophilic defect, such therapy is of no benefit and is costly and potentially harmful.

CONCLUSIONS AND FUTURE DIRECTIONS

Inherited or acquired hypercoagulable states can now be identified in up to 50% of patients with venous thromboembolism thanks to an increased understanding of the regulation of coagulation. The role of these disorders in the pathogenesis of arterial thrombosis is less clear, and further research is necessary to identify those individuals vulnerable to arterial thrombosis after plaque rupture. Despite an improved ability to diagnose hypercoagulable states, the impact of this information on clinical decisions remains limited. Common congenital hypercoagulable states increase the risk for a first thrombotic episode but appear to have little impact on the risk for recurrence. Identification of biomarkers for patients at risk for recurrent thrombosis and elucidating new hypercoagulable states are goals for the future.

CHAPTER 139

ANTIPHOSPHOLIPID SYNDROME

Lucia R. Wolgast and Jacob H. Rand

Antiphospholipid (aPL) syndrome (APS) is an autoimmune thrombophilic syndrome for which definitive disease mechanisms have not been established. The condition is defined and diagnosed by a constellation of clinical and laboratory criteria, detailed below. This chapter reviews the current understanding of pathogenic mechanisms, the current diagnostic tests for the condition, its clinical manifestations, and treatment approaches.

DEFINITION OF ANTIPHOSPHOLIPID SYNDROME

APS is an autoimmune thrombophilic condition in which patients develop antibodies against plasma proteins that bind to phospholipids. Diagnostic criteria (referred to as the Sydney criteria, detailed in Table 139.1) have been developed to provide consistency for clinical trials. These require that patients have documented evidence of vascular thrombosis and/or obstetric complications attributable to placental vascular insufficiency along with persistent abnormalities of one or more of aPL laboratory tests. The latter include elevated anticardiolipin (aCL) IgG or IgM antibodies, anti-β_2-glycoprotein I (anti-β2GPI) IgG or IgM antibodies, and positive lupus anticoagulant (LA) tests. The diagnosis is established only after the laboratory abnormalities have been confirmed 12 or more weeks after initial testing.

It is important for clinicians to realize that these formal criteria were intended to provide a uniformly rigorous definition of APS for standardizing clinical research. In real-world clinical practice settings, some patients may be diagnosed with presumptive APS without meeting the strict investigational criteria.

Patients with systemic lupus erythematosus (SLE) may develop APS, in which case they are considered to have **secondary APS**, while other patients may have a "stand-alone" form of the disorder, **primary APS**. Occasional patients will present with **catastrophic APS (CAPS)**, which manifests as disseminated thrombosis in large and small vessels with resulting multiorgan failure (criteria detailed in Table 139.2).

ANTIGENIC SPECIFICITIES OF ANTIPHOSPHOLIPID ANTIBODIES

The complexity of this autoimmune disorder is readily apparent by the observation that the addition of APS plasma to artificial phospholipid membranes results in the formation of proteinaceous complexes. This phenomenon has been visualized using atomic force microscopy (Fig. 139.1). Analysis of the composition of these complexes has revealed the presence of aPL antibodies and a variety of bound plasma proteins. It remains to be established whether the protein targets of the antibodies vary depending on patient manifestations.

The major protein recognized by aPL antibodies is β_2-glycoprotein I (β2GPI), a 50 kDa glycoprotein member of the complement control protein (CCP) superfamily. The protein consists of five homologous CCP domains, each consisting of ~60–amino acids, with a fifth domain that includes a phospholipid-binding site near the carboxy-terminus of the protein (Fig. 139.2). β2GPI binds to membranes via cationic residues, which interact with the anionic polar heads of membrane phospholipids adjacent to a hydrophobic loop that inserts into the lipid bilayer. β2GPI bound to phospholipid has a "J-shaped" fishhook conformation with the binding site for phospholipid in domain V, near the carboxy-terminus "barb" of the hook. The domain I epitope, which is cryptic in the unbound conformation of the protein, is exposed when β2GPI binds to phospholipid bilayers. Elevated levels of IgG antibodies against the domain I Gly40-Arg43 epitope have been correlated with an increased risk for thrombosis.

Several additional proteins have been identified as targets for autoantibodies in APS patients. These include prothrombin (factor II), factor V, protein C, protein S, annexin A2, annexin A5, tissue factor pathway inhibitor (TFPI), high and low molecular weight kininogen, factor VII/VIIa, plasmin, vimentin, and others. APS antibodies that bind to acidic glycosphingolipids known as sulfatides have also been described.

PATHOGENIC EFFECTS OF ANTIPHOSPHOLIPID ANTIBODIES

Multiple pathogenic mechanisms have been postulated to explain the thrombotic and pregnancy complications in APS (Table 139.3).

Activation of Complement

There is convincing evidence that complement activation plays a role in the APS disease process. When incubated with APS plasma, phospholipid vesicles activate more complement than when incubated with control plasma, as evidenced by more C5a and sC5b-9 generation (Fig. 139.3). Complement activation likely reflects the formation of APS macro-immune complexes on these vesicles. The modified Ham test has also been used to demonstrate complement activation; 69% of APS sera collected within 1 year of a thrombotic event and 86% of CAPS sera tested positive, whereas only 6.8% of SLE sera were positive. Complement activation is induced by anti-β2GPI antibodies, primarily through the classical pathway and germline variants in complement regulatory genes have been found in patients with thrombotic APS and CAPS. The role of complement activation is buttressed by findings in a mouse model of APS antibody-induced pregnancy loss where genetic deletion of C3 or treatment of wild-type mice with a C3 convertase inhibitor protected against pregnancy complications.

Inhibition of Anticoagulant and Fibrinolytic Mechanisms

aPL antibodies accelerate coagulation reactions on endothelial cells and trophoblasts by disrupting the antithrombotic shield provided by annexin A5. Annexin A5 forms a two-dimensional crystalline array over phospholipid bilayers, which shields anionic phospholipids on cell membranes and blocks coagulation proteins from binding and assembling on the cell membrane, thereby preventing phospholipid-dependent coagulation enzyme reactions. Annexin A5 is highly expressed by endothelial cells and localizes to the apical membrane of

TABLE 139.1 Sydney Investigational Criteria for the Diagnosis of the Antiphospholipid Syndrome

Clinical

- Vascular thrombosis (one or more episodes of arterial, venous, or small vessel thrombosis). For histopathologic diagnosis, there should be no evidence of inflammation in the vessel wall.
- Pregnancy morbidities attributable to placental insufficiency, including: (1) three or more otherwise unexplained recurrent spontaneous miscarriages before 10 weeks of gestation, (2) one or more fetal losses after the 10th week of gestation, (3) stillbirth, and (4) episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios that are otherwise unexplained.

Laboratory

- Medium or high titer aCL or anti-β2GPI IgG and/or IgM antibody present on two or more occasions, at least 12 weeks apart, measured by standard ELISAs.
- Lupus anticoagulant, on two or more occasions, at least 12 weeks apart, detected according to the guidelines of the ISTH SSC Subcommittee on Lupus Anticoagulants and Phospholipid-Dependent Antibodies.

Adapted from Miyakis S, Lockshin MD, Atsumi T, et al. International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *Thromb Haemost.* 2006;4:295–306.
"Definite APS" is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met.
aCL, Anticardiolipin; *aPL*, antiphospholipid; *β2GPI*, *β*2-glycoprotein I; *ELISA*, enzyme-linked immunosorbent assay; *Ig*, immunoglobulin.

TABLE 139.2 Proposed Criteria for the Classification of Catastrophic Antiphospholipid Syndrome

1. Evidence of involvement of three or more organs, systems and/or tissues[a]
2. Development of manifestations simultaneously or in less than a week
3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue[b]
4. Laboratory confirmation of the presence of antiphospholipid antibodies (lupus anticoagulant and/or anticardiolipin antibodies)[c]

Definite catastrophic APS

- All four criteria

Probable catastrophic APS

- All four criteria, except for only two organs, systems and/or tissues involvement
- All four criteria, except for the absence of laboratory confirmation at least 6 weeks apart due to the early death of a patient never previously tested for aPL prior to the catastrophic APS event
- Criteria 1, 2, and 4
- Criteria 1, 3, and 4 and the development of a third event in more than a week but less than a month, despite anticoagulation.

[a] Usually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension (N180/100 mmHg) and/or proteinuria (N500 mg/24 h).
[b] For histopathological confirmation, significant evidence of thrombosis must be present, although, in contrast to Sydney criteria, vasculitis may be present.
[c] If the patient had not been previously diagnosed as having an APS, the laboratory confirmation requires that the presence of antiphospholipid antibodies must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of definite APS.
aPL, Antiphospholipid; *APS*, antiphospholipid syndrome.
Adapted from Asherson RA, Cervera R, de Groot PG, et al. Catastrophic antiphospholipid syndrome: international consensus statement on classification criteria and treatment guidelines. *Lupus.* 2003;12:530–534.

placental syncytiotrophoblasts where maternal blood interfaces with fetal cells. Pregnant mice treated with anti-annexin A5 antibodies develop placental necrosis, fibrosis, and pregnancy loss, while pregnant annexin A5-null mice experience placental infarction and have reduced litter sizes. Anti-β2GPI IgG/β2GPI immune complexes disrupt the annexin A5 antithrombotic shield by competitively displacing the protein from the surfaces of cell membranes (Fig. 139.4). A mechanistic assay has been developed to assess disruption of annexin A5 anticoagulant activity.

aPL antibodies inhibit several steps in the protein C pathway. These include: (1) reducing protein C activation by the thrombomodulin-thrombin complex, (2) inhibiting assembly of the protein C complex, (3) inhibiting activated protein C (APC) directly or via its cofactor protein S, (4) binding to factors Va and VIIIa and protecting them from proteolysis by APC, and (5) reducing levels of protein C and protein S. Some aPL antibodies bind protein C or S. APC resistance has been described in APS plasmas and has been correlated with anti-β2GPI domain I antibodies.

Autoantibodies directed against TFPI have also been reported in APS patients; these antibodies may inhibit the capacity of TFPI to downregulate activation of factor IX and factor X by the factor VIIa-tissue factor complex. TFPI has a thrombogenic role by serving as a cofactor for promoting aPL-mediated expression of tissue factor by monocytes.

aPL antibodies impact fibrinolytic mechanisms in multiple ways including (1) binding to annexin A2 and reducing its capacity to serve as a receptor for tissue plasminogen activator (t-PA) and plasminogen, (2) reducing the catalytic activity of plasmin or t-PA, (3) increasing the levels of plasminogen activator inhibitor-1, (4) inhibiting autoactivation of factor XII, and (5)reducing plasmin generation because antibodies against β2GPI attenuate its capacity to serve as a cofactor for t-PA-mediated activation of plasminogen.

Activation of Platelets, Monocytes, and Neutrophils

Recent evidence from a mouse model suggests that aPL-induced thrombosis results from platelet activation that promotes endothelial activation and fibrin formation. aPL antibodies can induce platelet aggregation, an effect that may be promoted via signaling through apolipoprotein E receptor 2′ (ApoER2′) with the β2GPI binding site for ApoER2′ on platelets localized to its domain V. Since β2GPI has a dampening effect on platelet adhesion by interfering with the platelet–von Willebrand factor interaction, aPL antibodies increase platelet adhesion in flow systems by interfering with this dampening. Additionally, proteomic studies support a role for platelet disulfide isomerase family members in promoting aPL-mediated thrombosis.

aPL antibodies increase the expression of tissue factor and other cytokines by monocytes—a process that occurs through activation of the p38MAPK and MEK-1/ERK pathways. A recent unexpected finding was that TFPI primes the monocytes for the aPL-mediated signaling that results in tissue factor expression. aPL antibodies may also promote mitochondrial dysfunction and oxidative stress in monocytes, thereby inducing a proinflammatory state.

Finally, anti-β2GPI/β2GPI complexes can promote neutrophils to undergo NETosis, because neutrophil extracellular traps (NETs) can initiate clotting (see Chapter 121). The activation of the TLR4/MyD88/MAPKs axis was shown to be involved in the formation of NETs, which then promoted coagulation via tissue factor expression on the NETs along with platelet aggregation. This mechanism was further supported by the proteomic studies.

Effects on Vascular Endothelium

aPL antibodies can bind to, injure, and/or activate cultured vascular endothelial cells. Antibody binding to β2GPI on the endothelial surface may trigger signaling cascades that promote the expression of tissue factor and adhesion molecules.

Figure 139.2 Models for proposed β2GPI structures. By X-ray crystallography, β2GPI exhibits a J-shaped structure. However, small angle X-ray scattering (SAXS) of β2GPI in solution reveals an S-shaped conformation with a carbohydrate chain at the interface between domains I and II. In contrast to the SAXS structure, transmission electron microscopy of negatively stained unbound β2GPI mounted on grids exhibits a circular conformation, whereas it exhibits a "J" shaped structure when bound to phospholipid. The arginine 39-arginine 43 epitope on domain I recognized by thrombogenic aPL antibodies is cryptic in the proposed free-β2GPI conformations and is exposed when the protein binds to phospholipid. *(From de Laat B, de Groot PG. Autoantibodies directed against domain I of beta2-glycoprotein I. Curr Rheumatol Rep. 2011;13(1):70–76.)*

TABLE 139.3 **Proposed Pathogenic Mechanisms of Antiphospholipid Syndrome**

- I. Activation of Complement
    - A. Stimulated by formation of antiphospholipid syndrome (APS) macro-immune complexes
    - B. Augmented by germline variants of complement proteins.
- II. Inhibition of Anticoagulant and Fibrinolytic Mechanisms
    - A. Disruption of the annexin A5 anticoagulant shield
    - B. Inhibition of the protein C pathway—via reduced activation of protein C, inhibition of assembly of protein C complex, direct inhibition of proteins C and/or S, protecting factors Va and VIIIa from proteolysis, reduction of protein C and/or S levels, or prevention of protein C and EPCR binding
    - C. Interference with tissue factor pathway inhibitor (TFPI)
    - D. Interference with fibrinolysis via blocking of annexin A2, direct inhibition of plasmin, increase of PAI-1, or autoactivation of XIIa, inhibiting β2GPI cofactor activity
- III. Activation of Platelets, Monocytes and Neutrophils
    - A. Activation of platelets via ApoER2’
    - B. Interference of β2GPI in regulating von Willebrand factor (vWF)–mediated platelet adhesion
    - C. Activation of monocytes/macrophages, with increased tissue factor and cytokine expression
    - D. Activation of monocytes causes mitochondrial dysfunction and oxidative stress
    - E. Release of neutrophil extracellular traps (NETosis)
- IV. Effects on Vascular Endothelium
    - A. Direct injury and subsequent anti-β2GPI binding on endothelial cells
    - B. Signaling via annexin A2/TLR4/ApoER2 inducing proadhesive prothrombotic phenotype
    - C. Induction of adhesion molecules and tissue factor on endothelial cells and cytokine release
    - D. mTORC pathway-mediated vasculopathy
    - E. Release of procoagulant microparticles by endothelial cells and platelets
- V. Effects on Trophoblasts and Endometrial Cells
    - A. Abnormal trophoblast proliferation, migration and invasiveness, increased trophoblast apoptosis, and reduced secretion of HCG and adhesion molecules
    - B. Disruption in the differentiation of decidual endometrial cells
    - C. Disruption of maternal spiral artery transformation and maturation

Like its role in activating platelets, ApoER2′ expressed on the endothelial surface may also be a target for anti-β2GPI/β2GPI complexes to trigger tissue factor and adhesion molecule expression. Evidence from ApoER2′$^{-/-}$ knockout mice supports a role for the protein in mediating APS thrombosis.

Annexin A2 is an endothelial surface receptor for t-PA and plasminogen which serves as a receptor for β2GPI on vascular endothelium. In addition to aPL antibody-mediated inhibition described above, annexin A2 may play a role in mediating the effects of aPL antibodies on the signaling steps that promote thrombosis. Annexin A2 is not a transmembrane protein and so the signaling co-receptors, Toll-like receptor-2 (TLR2) and Toll-like receptor-4 (TLR4), have been implicated as triggers of the signaling cascade. Downstream signaling appears to involve tumor necrosis factor receptor-associated factor 6 (TRAF6) and myeloid differentiation factor 88 (MyD88). Tissue factor expression is mediated by p38 mitogen-activated protein kinase (MAPK). This mechanism is supported by the finding that a mutation in murine TLR-4 that disrupts lipopolysaccharide (LPS) binding attenuated the prothrombotic state in mice injected with aPL antibodies.

aPL antibodies may contribute to other vascular lesions by stimulating the mammalian target of the rapamycin complex (mTORC) pathway. Endothelial cells and platelets activated by aPL antibodies release microparticles containing procoagulant proteins and nucleic acids.

Effects on Trophoblasts and Endometrial Cells

In mice, in addition to disruption of the annexin A5 anticoagulant shield at the maternal-fetal interface, aPL-mediated promotion of tissue factor expression induces trophoblast injury and fetal death. Tissue factor contributed to the C5a-induced oxidative burst in neutrophils that promoted trophoblast and fetal injury in APS.

aPL antibodies may induce trophoblast proliferation, migration, and invasiveness, increase trophoblast apoptosis, and reduce the secretion of human chorionic gonadotropin (HCG) and adhesion molecules. Activation of MYD88 by TLR4 has been linked to increased levels of proinflammatory cytokines (IL-8, IL-1β, monocyte chemoattractant proteins) that influence trophoblast survival. Downregulation of signal transducer and activator of transcription 3 (STAT3) phosphorylation decreases IL-6 expression and reduces trophoblast migration. aPL antibodies have been implicated in the disruption of maternal spiral artery transformation and maturation, as well as differentiation of decidual endometrial cells through activation of signaling pathways such as nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB). Defective placentation may result in impaired blastocyte implantation, thereby leading to fetal loss.

Genetic and Proteomic Studies in Antiphospholipid Syndrome

Genetic factors appear to play a role in the development of aPL antibodies even though familial APS is rare. One study of seven families, which included 30 individuals who met consensus criteria for APS, concluded that the inheritance pattern of aPL antibodies appeared to be autosomal dominant, however no specific linkages could be identified. A study done with peripheral blood mononuclear cells from aPL antibody-positive patients found a gene expression pattern that appeared to correlate with a predisposition for thrombosis. Some of the identified genes encoded proteins that are known to be involved in thrombosis, including apolipoprotein E (ApoE), factor X, and thromboxane. Other genes were not connected with the disease process, such as hypoxia-inducible factor-1alpha (HIF-1α), zinc finger proteins, matrix metalloproteinase 19 (MMP19), interleukin 22 (IL22) receptor, and hematopoietic progenitor cell antigen (CD34) precursor. As mentioned above, germline variants of complement proteins have recently been associated with thrombotic APS and CAPS.

Proteomic studies have revealed a series of proteins that are differentially expressed in monocytes of APS patients with a history of thrombosis. These include annexin A1, annexin A2, ubiquitin Nedd8, Rho A protein, protein disulfide isomerase, and Hsp60. Proteomic analysis of platelets and plasmas from LA-positive patients with a history of thromboembolism supports the role of PDI and NETosis in APS-associated thrombosis. PDI family members were upregulated in platelets and plasma of these patients compared with controls. Leukocyte elastase inhibitor (SERPINB1), an antagonist of NET formation, was decreased and citrullinated histone H3, a NET-specific marker, was increased.

ANTIPHOSPHOLIPID ASSAYS

Paths to Development

The recognition of APS stemmed from observations of two laboratory anomalies. One of these, the biologic false-positive serologic test for syphilis (STS), caused by antibodies against cardiolipin

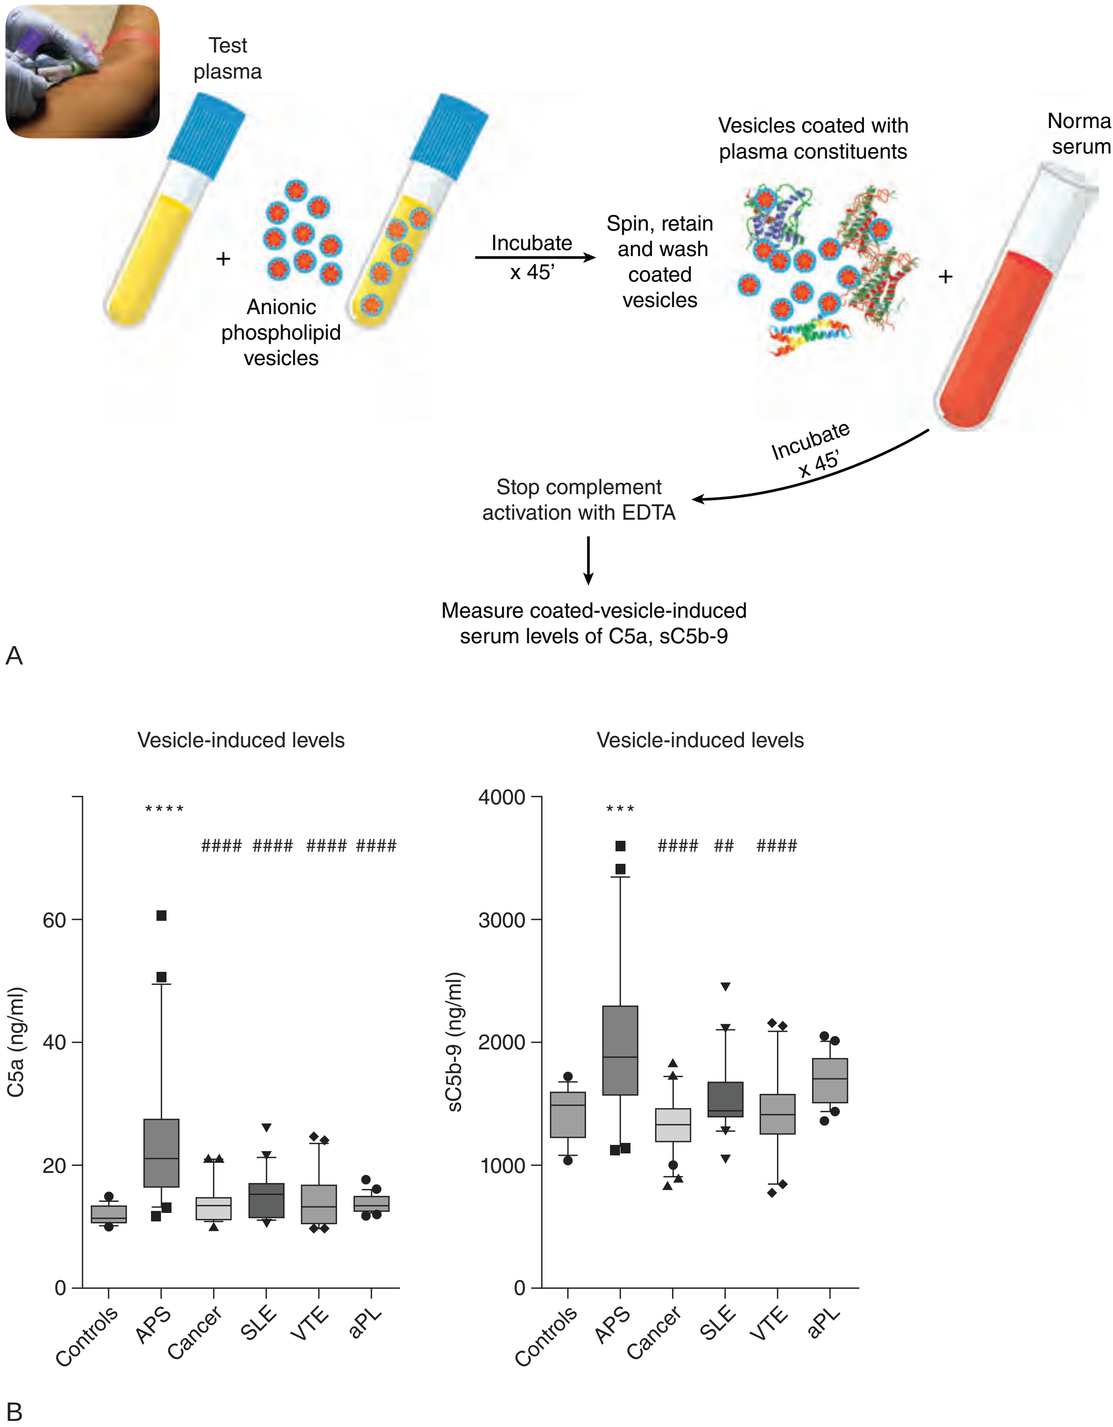

Figure 139.3 Two-stage assay for detecting complement activation in antiphospholipid syndrome (APS). (A) Pictorial representation of a method to measure complement activation generated in serum by phospholipid vesicles pre-incubated with patient plasmas. (B) Complement activation after exposure of patient plasma-coated vesicles to normal serum. Anionic phospholipid vesicles were coated with plasma from healthy controls, patients with APS, cancer, systemic lupus erythematosus (SLE), venous thromboembolism (VTE), or asymptomatic patients with positive antiphospholipid (aPL) antibodies, after which complement activation was triggered and levels of C5a (*left*) and sC5b-9 (*right*) were quantified. Only statistically significant differences are shown. $^{*}P < .05$, $^{***}P < .0005$, $^{****}P < .0001$ versus controls. $^{\#}P < .05$, $^{\#\#}P < .005$, $^{\#\#\#}P < .0005$, $^{\#\#\#\#}P < .0001$ versus APS. *(Adapted from Rand JH, Wu X-X, Wolgast LR, Lei V, Conway EM. A novel 2-stage approach that detects complement activation in patients with antiphospholipid antibody syndrome. Thromb Res. 2017;156:119–125.)*

(diphosphatidylglycerol), formed the basis for an immunoassay that prompted the identification of "anticardiolipin antibody syndrome," which was then renamed "antiphospholipid antibody syndrome." The other anomaly was the finding that some patients had a prolonged activated partial thromboplastin time (aPTT) due to a unique inhibitor of blood coagulation. The first patients identified with this anomaly had SLE, which led to the misnomer "LA". This brief history is helpful for appreciating that the current aPL tests, which were empirically derived from these two anomalies, are limited because they do not directly measure a disease mechanism. Nevertheless, these assays have become the mainstay markers of this disorder and have proven to be useful as surrogate reporters of thrombotic risk.

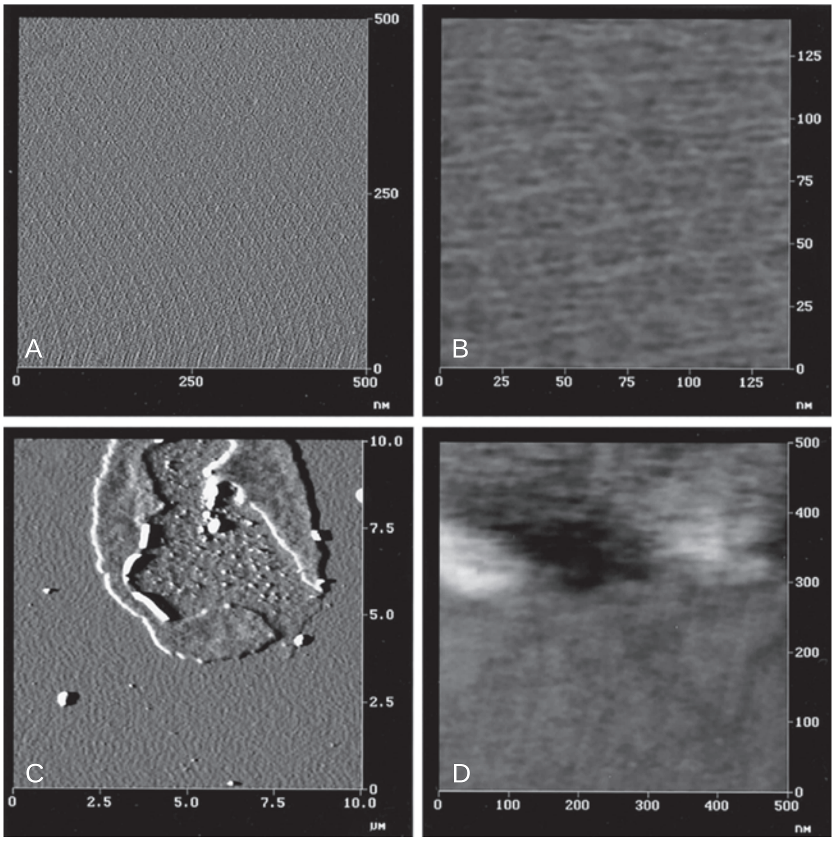

Figure 139.4 Sequential effects of β_2-glycoprotein I (β_2GPI) and antiphospholipid syndrome (APS) monoclonal antibodies on Annexin A5 crystal structure. Atomic force microscopy images from a dynamic imaging experiment showing the effect of APS monoclonal antibodies on a preformed annexin A5 crystalline lattice. The addition of β2GPI alone has no discernible effect on the lattice as observed using amplitude imaging (A) and at higher magnification with height imaging (B). After addition of APS monoclonal antibodies (anti-β2GPI IgG), circular deformities occur indicating disruption of the crystal lattice as seen in an amplitude image (C). A height image (D) within the circular deformities shows dark areas representing portions of the surface that have lost annexin A5 coverage, near light areas representing elevated structures, presumably antibody–antigen complexes. *(Reprinted from Rand JH, Taatjes DJ. Reimagining the antiphospholipid syndrome, an enigmatic thrombophilic disorder, through the looking glass of microscopic imaging. Histochem Cell Biol. 2018;150(5):529–543.)*

The current Sydney criteria for the diagnosis of APS identify LA, aCL, IgG and IgM, and anti-β2GPI IgG and IgM as the key diagnostic assays. To qualify for the diagnosis of APS, positive results must be obtained on two or more occasions at least 12 weeks apart (see Table 139.1).

"Criteria" Antiphospholipid Syndrome Assays

Lupus Anticoagulant Tests

LA tests are performed in a variety of configurations, all of which share the purpose of detecting antibody-mediated inhibition of phospholipid-dependent blood coagulation reactions.

An updated guidance on LA testing was published by the LA Subcommittee of the International Society on Thrombosis and Haemostasis Scientific and Standardization Committee (ISTH/SCC) in 2020.

LA tests include the dilute Russell viper venom time (dRVVT), modifications of the aPTT with LA-sensitive and LA-insensitive reagents, the kaolin clotting time (KCT), the dilute prothrombin time (dPT) which was previously known as the tissue thromboplastin inhibition time, the hexagonal phase array test, and the ecarin-taipan clotting time. The dRVVT and the silica clotting time, a form of the aPTT, are the most widely performed tests. Interlaboratory comparison studies demonstrate agreement on identification of plasmas containing strongly positive LA activity, but disagreement about samples with weaker activity (these are missed in approximately half the cases) and misdiagnosis of coagulation factor-deficient LA-negative plasmas as being LA-positive.

Despite the limitations, LA positivity is more sensitive and specific for the presence of aPL antibodies than aCL and anti-β2GPI assays. In a systemic review of 7000 patients and 25 studies, the presence of an LA was found to have a strong association with thrombosis, both in patients with and without SLE and regardless of site and type of thrombosis. Also, LA had a stronger association than aCL antibodies for thrombosis. Meanwhile, medium to high titer aCL antibodies were associated with cerebral stroke and myocardial infarction and not deep venous thrombosis. The mean odds ratios (ORs) for thrombosis were 11 for LA, 3 for high-titer aCL antibodies, and 1.6 for elevated levels of aCL antibodies. [LRW2] Furthermore, the Predictors of Pregnancy Outcome: Biomarkers in Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus (PROMISSE) study demonstrated that of the available aPL markers, a positive LA was the single strongest predictor of adverse pregnancy outcome in patients with APS. However, routine LA screening is unlikely to benefit the general population since the high relative risks reported in these studies should be seen in the context of the low baseline risks of thrombosis and adverse pregnancy outcomes in disease-free individuals. Nevertheless, LA testing and aPL assay testing may be beneficial to ascertain risk in patients with a high baseline thrombotic risk, such as patients with SLE or a previous thrombosis.

Patient Selection for Lupus Anticoagulant Testing

The recommendations for patient selection for LA testing were expanded in the 2020 ISTH/SSC guidance and are summarized in Table 139.4.

Prior to ordering testing for patients meeting the ISTH/SSC guidance, clinicians should consider that it is preferable for patients

TABLE 139.4 **Patient Selection for Lupus Anticoagulant Testing**

1. LA testing should be performed together with testing for anticardiolipin (aCL) and anti-β_2 glycoprotein I (aβ2GPI) to assess the risk profile in patients who are likely to have antiphospholipid syndrome (APS):
    - younger patients (<50 years) with unprovoked venous thromboembolism (VTE)
    - VTE at unusual sites
    - younger patients (<50 years) with ischemic stroke, transient ischemic attack, or other evidence of brain ischemia
    - arterial thrombosis in other sites in younger patients (<50 years)
    - microvascular thrombosis
    - recurrent VTE unexplained by subtherapeutic anticoagulation, patient nonadherence, or malignancy
    - pregnancy morbidity: fetal loss after 10 weeks, recurrent early (first trimester) miscarriages, prematurity (<34 weeks' gestation) associated with severe (pre)eclampsia, HELLP syndrome, placental insufficiency (fetal growth restriction), stillbirth
    - systemic lupus erythematosus: testing for lupus anticoagulant (LA) is part of the diagnostic criteria and contributes to risk assessment
2. LA testing could be considered in the following situations:
    - immune thrombocytopenia, particularly with presence of arthralgias or arthritis, hair loss, sun sensitivity, mouth ulcers, rash, or thromboembolism
    - livedo reticularis, particularly with presence of symptoms of other systemic autoimmune diseases or mild thrombocytopenia
    - younger patients (<50 years) with non-criteria clinical manifestations (i.e., those not included in the Sydney criteria) such as cognitive dysfunction and valvular heart disease with presence of evidence of other systemic autoimmune diseases
    - patients of younger age (<50 years) following provoked VTE when the provoking environmental factor is disproportionally mild
    - patients with unexplained prolonged aPTT as an incidental finding

not to be tested in the setting of an acute thrombotic event and that any such testing should be interpreted with caution because false positive and negative results can occur. Whenever possible, LA testing should not be performed in patients receiving anticoagulant treatment because false positives and negatives can occur. When there is a need to perform testing, it is best to suspend anticoagulant treatment when feasible. If patients are tested during treatment with low molecular weight heparin (LMWH), it is recommended that samples be taken, when possible, at least 12 hours after the last dose of LMWH and that the anti-Xa activity be checked concurrently. Direct oral anticoagulants (DOACs) are especially problematic in causing false positive LA tests and, whenever possible, should be held prior to testing.

Choosing LA assays.The ISTH/SCC has proposed specific criteria for standardizing the diagnosis of LA. When APS is suspected on clinical grounds, it is recommended that laboratories perform two different versions of LA tests. The dRVVT is widely used in clinical laboratories and is believed to be specific for detecting LA in patients at high risk for thrombosis who are not receiving anticoagulant therapy. aPTT tests performed with silica as an activator and low PL content were recommended as the second test of choice because of their sensitivity for LA, however, aPTT assays utilizing ellagic acid as the activator may also be used (see Chapter 127).

Dilute Russell Viper Venom Time. The dRVVT is considered one of the most sensitive LA tests. The assay uses Russell viper venom (RVV) in a system containing limiting quantities of diluted rabbit brain phospholipid. RVV activates factor X, leading to clotting. aPL antibodies which prolong the dRVVT by interfering with the assembly of the prothrombinase complex, an effect reversed by the addition of excess phospholipid (sometimes referred to as a "confirmatory test"). To ensure that prolongation of the clotting time is not the result of a factor deficiency, the procedure includes mixing of patient plasma with control plasma. Anticoagulant therapy with heparin, warfarin or DOACs can yield falsely abnormal test results.

Activated Partial Thromboplastin Time. The finding of a prolonged aPTT in an otherwise healthy individual without a history of bleeding is often attributable to a LA. aPTT reagents vary in their sensitivity to LA, so it is important to know the characteristics of the particular reagent that is being utilized. The LA needs to be differentiated from antibodies directed against specific coagulation factors (see Chapter 127) and from anticoagulant medications. In addition to utilizing specific assays to exclude these possibilities, the clinician can check whether the aPTT is normal if a LA-insensitive aPTT reagent is used. Mixing and incubating the test plasma with normal plasma may be helpful in differentiating LAs from coagulation factor inhibitors. aPTTs performed on mixtures of normal plasma and plasma containing a factor VIII inhibitor usually require incubation for 1 to 2 hours at 37°C to exhibit prolongation, whereas LA-containing plasmas typically prolong the aPTT immediately, without requiring incubation. The clinician should be aware that both types of anticoagulants (i.e., LA and specific coagulation factor inhibitors) may coexist and yield a confusing laboratory picture. LAs may also cause artifactual decreases in contact activation pathway coagulation factor levels because those assays are based on the aPTT; these patients are sometimes misdiagnosed as having multiple coagulation factor deficiencies. This problem can be identified by noting whether there is non-parallelism between dilutions of the plasma and the standard curve used for the assay, or by using an aPTT reagent that is insensitive to LA.

Anticardiolipin IgG and IgM Antibody Assays

The development of the quantitative aCL antibody radioimmunoassay and subsequent enzyme-linked immunosorbent assay (ELISA) was the single advance that led to the identification of APS as a new syndrome. Although aCL ELISAs are sensitive, they are not specific for APS, especially when present at low positive levels or in patients with certain infections. Patient with syphilis can have a false positive aCL antibody test. Alternatively, patients with aCL positive antibodies can have a false positive syphilis Venereal Disease Research Laboratory (VDRL) test since cardiolipin is used as an antigen target to detect non-specific antibodies released by spirochetes. Testing guidelines recommend using β2GPI-dependent cardiolipin targets to avoid detection of non-cofactor related aCL produced by infections or drugs.

aCL may be detected by ELISA or newer methods such as chemiluminescence analysis (CLIA) or multiline dot assay (MLDA). The cutoffs for medium to high aCL titers (i.e., 99th percentile) are greater than 40 IgG Phospholipid Units (GPL)/IgM Phospholipid Units (MPL) in ELISA and greater than 20 Chemiluminescent Units (CU) in CLIA.

High levels of aCL antibodies are associated with an increased risk of venous thromboembolism, myocardial infarction, stroke, and recurrent pregnancy loss. In a 10-year follow-up study, 50% of initially asymptomatic patients with persistently elevated aCL antibodies went on to develop APS. The presence of elevated titers of aCL antibodies 6 months after an episode of venous thromboembolism is a predictor of an increased risk of recurrence and of death.

It is very important for the clinician to recognize that **the majority of patients with elevated levels of aCL antibodies on routine screening do not have APS**. Many individuals have elevated antibody levels in response to infections; these antibodies have not been associated with thrombotic complications. In various studies, the prevalence of positive immunoassays in the asymptomatic "normal" population has range from 3% to nearly 20%. Therefore, it is important to repeat testing after 12 weeks to determine whether there is persistent positivity.

Anti-β2-Glycoprotein I IgG and IgM Antibody Assays

β2GPI is the major protein cofactor recognized by aPL antibodies. The protein is composed of five homologous domains and assumes a closed conformation in solution and an open conformation when bound to phospholipid membranes (see Fig. 139.2). Anti-β2GPI antibodies that bind to the circular closed form generally recognize epitopes between domains one and five, while in the open form, anti-β2GPI antibodies interact with the exposed domain one. Anti-β2GPI ELISAs are less sensitive but more specific for APS than aCL antibody assays. Although antibodies against β2GPI are usually found in conjunction with aCL and anti-phosphatidylserine antibodies, some patients with APS only have antibodies against β2GPI. Despite their higher specificity (98%), anti-β2GPI assays cannot be relied upon as a stand-alone test for APS because of their low sensitivity (40% to 50%) and concurrent testing for both antibodies, along with LA is advised. Antibodies against β2GPI can be detected by ELISA, CLIA, or MLDA. The determined cutoffs for medium to high titers (i.e., 99th percentile) are greater than 40 GPL/MPL in ELISA and greater than 20 CU in CLIA.

In a systematic literature review, 34 of 60 studies showed a significant association between anti-β2GPI antibodies and thrombosis. Anti-β2GPI antibodies were more often associated with venous than arterial thrombotic events and were independent risk factors for venous thrombosis.

Considerations and Limitations of Laboratory Immunoassays

Although a variety of assays are used, including more advanced and automated systems, there is no consensus on a "gold standard" for the detection of aCL and anti-β2GPI antibodies. Studies have shown poor agreement between commercially available immunoassays for detecting aCL and anti-β2GPI IgG/IgM antibodies. Therefore, it is recommended to use the same testing system for patient diagnosis and follow-up. In addition, guidelines recommend laboratories determine their own 99th percentile cutoffs for in-house assays using a population of at least 40 healthy volunteers.

The interpretation of immunoassays should also take into consideration the identified isotype. The aCL and anti-β2GPI IgG isotype have a stronger association with thrombosis than IgM. Although aCL and anti-β2GPI IgM isotypes have been associated with pregnancy morbidity and thrombosis in some reports, these associations have not been confirmed due to lack of paired IgG and IgM results. To not "miss" diagnosing APS patients, the guidelines advise continued measurement of IgG and IgM, with the presence of aCL and anti-β2GPI of the same isotype reinforcing the probability of APS.

Multipositivity for Antiphospholipid Tests and Other Scoring Systems for Clinical Risk

Strong positivity for more than one of the APS criteria assays (LA, aCL, and anti-β2GPI) has been correlated with increased risk for developing clinical events in several retrospective studies and in one prospective study. APS patients who are positive for all three tests (LA, aCL, and anti-β2GPI), referred to as "triple-positive" patients, have the highest risk of thrombosis. This risk is progressively lessened in double-positive (LA-negative) and single-positive patients.

In pregnant women with APS, triple APS assay positivity, with or without previous thromboembolism, is associated with a higher probability of adverse neonatal outcome than double or single aPL antibody-positivity and no thrombosis history. Multipositivity, but not single positivity, for aPL antibodies was associated with antenatal and postnatal deep vein thrombosis (DVT).

Both symptomatic and asymptomatic patients with persistent triple-positive laboratory results (LA-positive, aCL and anti-β2GPI of high titer, double-positive for LA, aCL and/or anti-β2GPI of high titer, or single positive for LA or persistently high aPL titers) should be considered high-risk for future manifestations of APS. Finally, single positivity for aCL IgG or IgM in low-medium titers or anti-β2GPI IgG or IgM in low-medium titers should be considered lower risk for APS but treatment may be warranted if such patients develop thrombosis or pregnancy complications or have other high-risk factors.

The global APS score (GAPSS) is a clinical scoring system that assigns points for the presence of six features—arterial hypertension (1 point), hyperlipidemia (3 points), LA (4 points), aCL antibodies (5 points), anti-β2GPI antibodies (4 points), and antiphosphatidylserine/prothrombin (aPS/PT) antibodies (3 points). GAPSS scores ≥ 10 have the best diagnostic accuracy. Higher GAPSS values are also associated with recurrent thrombotic events. A complementary version, the adjusted GAPSS (aGAPSS), which excludes aPS/PT, was also found to be higher in patients with recurrent thrombosis (arterial or venous) than in those without recurrence. Patients with recurrent arterial, but not venous, thrombosis had higher aGAPSS. A meta-analysis of both the GAPSS and aGAPSS scoring systems showed the highest scores in patients with arterial thrombosis and recurrence. Complement markers including platelet bound C4d (measured by flow cytometry) and low C3 have been included in some composite risk scores.

"Non-Critera" Antiphospholipid Syndrome Assays

Clinicians may consider testing selected patients with assays that are not included within the formal diagnostic criteria. An example would be a patient with SLE or another autoimmune disorder who has clinical manifestations that suggest APS but also has negative assays for aCL and aβ2GPI IgG and IgM along with negative LA tests.

IgA Antibodies Against Cardiolipin and β_2-Glycoprotein I

Although aPL antibodies of IgA isotype (either aCL or anti-β2GPI) were not included in the international consensus statement on the criteria for APS classification, testing for the IgA isotype (particularly IgA anti-β2GPI) was recommended in cases where APS is suspected but the IgG and IgM tests are negative. Anti-β2GPI IgA antibodies were reported to be associated with thrombosis. A recent retrospective case-control study of 56 patients with isolated anti-β2GPI IgA found that patients with this marker had significantly more thromboembolic events and higher polyclonal IgA levels than controls.

ANTIPHOSPHOLIPID SYNDROME TESTING PEARLS

- Laboratory testing for aPL antibodies should not be included in test panels for screening healthy individuals.
- Testing should be limited to patients with the thrombotic and/or pregnancy manifestations of the disorder or those with autoimmune diseases such as SLE.
- Weakly positive tests for aPL are unlikely to be clinically relevant.
- Transient aPL antibodies can result from infection (including HIV and COVID-19), liver disease, cancer, and medications such phenothiazines, quinine, procainamide, oral contraceptives, and TNF inhibitors.
- Asymptomatic triple-positive patients appear to be at high risk for thrombosis and should be considered for prophylactic therapy.

Anti-β2GPI IgA was associated with an increased risk of thromboembolic events in patients with SLE. The significance of aCL IgA for the development of thrombotic complications is still under investigation. In a study of 192 APS patients, 42% were positive for aCL IgA, while in 90 seronegative APS patients, 12% were positive for aCL IgA.

Antiphosphatidylserine/Prothrombin Assays

Prothrombin is considered the second major cofactor for aPL antibodies after β2GPI. Antibodies against phosphatidylserine are reported to correlate with APS more than aCL antibodies, particularly in patients with arterial thrombosis. Accordingly, this noncriteria assay is included in the GAPSS scoring systems. The data for individual antiprothrombin (aPT) and antiphosphatidylserine (aPS) assays have been mixed in terms of their utility for identifying patients with APS and their correlation with other APS criteria assays. Antibodies against the combined phosphatidylserine-prothrombin complex (aPS/PT) have been shown to be closely associated with APS and LA. The presence of aPS/PT antibodies was strongly correlated with the presence of LA, had a higher sensitivity and specificity than antiprothrombin antibodies alone for the diagnosis of APS, and exhibited comparable sensitivity and specificity to aCL for the diagnosis of APS. In a recent study that included 168 APS patients, 86% were positive for aPS/PT antibodies and 50% of the seronegative APS patients were positive. There was a significant association of aPS/PT IgG with thrombotic events and aPS/PT IgG and IgM with pregnancy loss. It has been proposed that the addition of aPS/PT IgG/IgM assays to current APS criteria could classify an additional 12% patients as having APS and an additional 43% patients as having obstetric APS. The apparent high diagnostic performance of this test may render it useful for identifying patients who are currently classified as APS negative, as an aid for risk assessment, and as an adjunct in situations where LA testing is unavailable.

Annexin A5 Resistance Assay and Anti-Annexin Assays

Annexin A5 (often referred to as annexin V) is a calcium-dependent protein that binds to anionic phospholipids on syncytiotrophoblast and vascular endothelium and forms a protective shield. This shield is disrupted by anti-β2GPI/β2GPI complexes, thereby exposing more anionic phospholipids and accelerating coagulation reactions. The annexin A5 resistance (A5R) assay was designed to measure disruption of the annexin A5 shield. The failure of annexin A5 to sufficiently prolong coagulation times because of interference by aPL antibodies is referred to as A5R. This assay has been correlated with an increased risk for thrombosis and pregnancy complications in patients with aPL. A study of 750 such patients demonstrated significantly lower A5R values in APS patients with a history of thrombosis than in aPL antibody-positive patients without a history of thrombosis, aPL antibody-negative patients with a thrombosis history, and healthy controls (Fig. 139.5). Lower A5R values also correlated with multipositivity for APS criteria assays and increased thrombotic risk. Clinicians should be aware that this assay falls into the category of laboratory developed tests (LDTs) and is not commercially available.

Anti-annexin A2 antibodies are significantly elevated in APS patients compared with healthy donors and patients with SLE without thrombosis.

Anti-Domain I of β_2-Glycoprotein I Assay

This immunoassay identifies IgG antibodies against a specific amino acid sequence, G40-R30, within domain I (D1) of β2GPI. Anti-D1 antibodies correlate better thrombosis and pregnancy loss than other aPL antibodies. Anti-D1 and LA positivity are associated with venous thrombosis in APS patients. A recent analysis of 198 samples from patients with a variety of autoimmune disorders revealed that the 52 patients with anti-β2GPI IgG antibodies could be divided into two groups: one whose antibodies recognized D1 alone and another

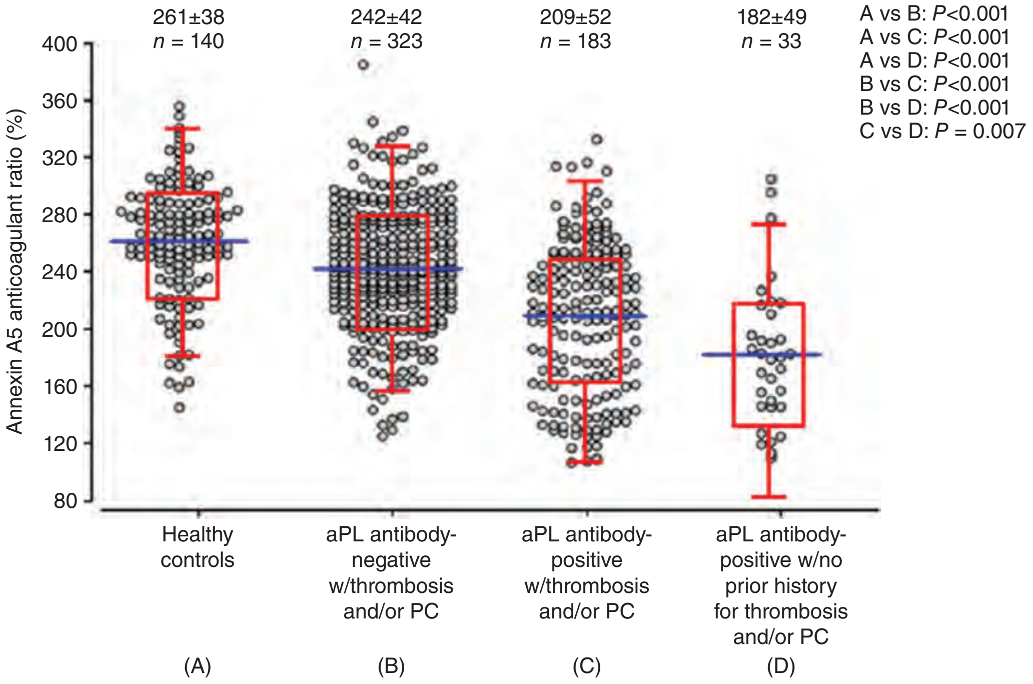

Figure 139.5 Antiphospholipid (aPL) antibody-positive patients have lower annexin A5 anticoagulant ratio (A5R) values and an increased risk of thrombosis and/or pregnancy complications. In patients with a history of thrombosis and/or pregnancy complications (PC), aPL antibody-positive patients had a significantly lower mean A5R value (mean ±SD, 209 ±52%; *n* = 183) than aPL antibody-negative patients (mean ± SD, 242 ± 42%; *n* = 323; *P* < .001) and disease-free patients (mean ± SD, 261 ±38%; *n* = 140; *P* < .001). Lower A5R values have been associated with an increased risk of thrombosis and/or pregnancy complications. In patients with no prior history of thrombosis and/or PC, aPL antibody-positive patients also had significantly lower A5R values (mean ± SD: 182 ± 49%; *n* = 33). Based on the findings in the prospective cohort, this group may be at increased risk of a future thrombosis and/or PC. *(From Wolgast LR, Arslan AA, Wu X-X, Beyda JN, Pengo V, Rand JH. J Thromb Haemost. 2017;15:1412–1421.)*

whose antibodies reacted with all domains; only the former group had positivity for LA and an increased risk of thrombosis.

Anti-D1 has a sensitivity of 85% and a specificity over 99% for APS, which may render it a valuable test for APS diagnosis. In a recent study, patients tested for anti-D1 IgG and aPS/PT IgG/IgM showed high positive predictive value for the diagnosis of APS. Positivity for anti-D1 was also associated with triple positivity.

Complement Testing

The modified Ham test, a functional indicator of complement activation, was reported to be positive in 88% of patients with CAPS, 69% of APS patients within a year of a thrombotic event, and 36% of APS patients overall, but only in 7% of patients with SLE. In 201 women with obstetric APS, 49% had decreased levels of complement proteins, either low C4 or C3 levels or a reduction in both. In pregnant APS patients, low C3 and/or C4 levels and evidence of complement activation (high plasma C5a and C5b-9 levels) were correlated with adverse pregnancy outcomes. Anti-C1q antibodies also may contribute to recurrent pregnancy loss and APS.

Genomic and Biomarker Testing in Antiphospholipid Syndrome

A recent study identified 16 genes that appear to contribute to thrombotic primary APS. These genes include platelet factor 4 variant 1 (PF4V1), selectin P (SELP) , TLR2 TLR4, serpin family member 1 (SERPINE1), apolipoprotein H (APOH, a synonym for β2GPI), integrin subunit alpha 2 (ITGA2) , platelet glycoprotein Ib alpha chain (GP1BA) , coagulation factor II thrombin receptor (F2R)), F2R like trypsin receptor 1 (F2RL1), TFPI, coagulation factor III tissue factor (F3), vascular endothelial growth factor A (VEGFA), fms-related tyrosine kinase1 (FLT1), and TNF-ALPHA.

Familial studies show a consistent genetic predisposition for APS with DR4 and DRw53 antigens. Population studies reveal an association between several HLA antigens and both primary APS and APS associated with SLE, although other studies suggest that these are distinct entities.

aPL antibodies modulate the expression of several prothrombotic genes in monocytes and endothelial cell lines. They induce the phosphorylation of MEK1/ERK proteins, p38 MAP kinase-dependent nuclear translocation, and activation of NFκB/Rel proteins, which upregulate the expression of tissue factor, IL-6, IL-8, and the inducible nitric oxide synthase (iNOS). Proteomic studies reveal that aPL antibodies alter the protein profile of APS monocytes, including dysregulated expression of annexin A1 (AnxA1), annexin A2 (AnxA2), ubiquitin-like protein Nedd8, Rho A protein, protein disulfide isomerase (PDI), and heat shock protein-60 (Hsp60). These proteins are associated with a hypercoagulable state, as well as with autoimmune-related responses.

APS patients have been reported to have polymorphisms in components of the hemostatic system that may promote thrombosis, including PAI-1, prothrombin, TFPI, TNFα, GP1b, GPIa/IIa, P-selectin, PSGL-1, β2GPI, and TLR4.

CLINICAL MANIFESTATIONS OF THE ANTIPHOSPHOLIPID SYNDROME

The clinical manifestations of APS can be categorized into “criteria manifestations” that are included in the formal definition of the disorder, and “non-criteria manifestations.” The criteria manifestations include thrombotic events, obstetric APS, and CAPS, while the non-criteria manifestations include other pathologic conditions that have been associated with aPL antibodies but have not yet been included in the classification of “definite APS” by the expert consensus groups.

Criteria Manifestations of Antiphospholipid Syndrome

Systemic Vascular Thrombosis

The most common manifestations of APS are deep vein thrombosis of the lower extremity, pulmonary embolism, and stroke/transient ischemic attack. These may occur spontaneously or in the presence of predisposing factors such as estrogen therapy, oral contraceptives, pregnancy, the postpartum state, surgery, or trauma. The usual age at the initial presentation with thrombosis is 35 to 45 years. Except for patients with SLE, men and women are equally susceptible to thrombotic manifestations. Not surprisingly, occasional patients with APS-associated venous thrombosis—but generally not with arterial thrombosis—have concurrent hereditary thrombophilic conditions such as heterozygosity for the factor V Leiden variant. Other sites of venous thrombosis include the thoracic veins (superior vena cava, subclavian or jugular veins), cerebral and/or retinal veins, and abdominal and/or pelvic veins. Sites of arterial thromboembolic events include myocardial infarction, nonatherosclerotic coronary artery occlusion, pulmonary hypertension attributed to thrombotic occlusion, and occlusions of abdominal, renal, and retinal arteries. In one study of patients with aPL antibodies and radiologic evidence of thrombosis, 59% had thrombosis limited to the venous circulation, 28% had only arterial thrombosis, and 13% had both types of events.

The most significant risk factor for recurrent thromboembolism in APS is a history of a prior thromboembolic event. The risk of recurrence after a first episode of venous thromboembolism in patients with aCL antibodies is about 30% at 4 years and is likely to be higher in those with a LA or with anti-β2GPI D1 antibodies.

Stroke and Transient Ischemic Attack

Ischemic stroke occurs relatively frequently in APS and can be an initial manifestation in approximately 25% of APS patients. APS should be suspected when young patients present with a transient ischemic attack or a stroke without other risk factors. Children presenting with an APS-associated stroke tend to have venous rather than arterial occlusion with 7% of children presenting with cerebral vein thrombosis in a multinational childhood registry. The CAPS registry reported that 56% of CAPS patients had cerebral manifestations and stroke was responsible for 19% of CAPS-related deaths.

Elevated levels of any of the three APS criteria assays (aCL, β2GPI, and LA) are associated with an increased risk for stroke. In women with LA positivity and other modifiable risk factors such as smoking or use of oral contraceptives, the risk of stroke is increased (from 43- to 201-fold with oral contraceptives and 87-fold with smoking). SLE and APS patients with valvular heart lesions are also at increased risk of cerebrovascular disease. An echocardiography should be considered for APS patients with stroke since a high proportion of have cardiac valvular abnormalities (see below).

Increased risk of recurrence has been demonstrated in multi-positive APS patients with an LA and either aCL or β2GPI antibodies. In addition to the immediate impact, recurrent stroke may lead to multi-infarct dementia that can mimic other causes of dementia.

Reproductive Manifestations

Pregnant women with APS tend to present with a history of recurrent (i.e., three or more) miscarriages. Studies have shown that up to 38% of pregnant women with recurrent fetal loss have elevated aPL antibodies. Pregnant women with elevated aPL antibodies have significantly more obstetric complications, including pre-eclampsia, placental abruption, miscarriage, prematurity, intrauterine fetal demise, intrauterine growth restriction, and oligohydramnios, than aPL antibody-negative pregnant women. In approximately half of the patients, the pregnancy loss occurs in the first trimester; other patients present with later loss, mostly in the second trimester, but some even later, including stillbirth. Pregnant women with APS are also more prone to develop deep vein thrombosis during pregnancy or the puerperium. CAPS occurs rarely in pregnant patients.

As mentioned earlier, routine aPL antibody screening of asymptomatic obstetrical patients is not warranted because of the high frequency of false positives with the current tests and the absence of any specified treatment for asymptomatic positives. Most studies have estimated the prevalence of aPL antibodies among general obstetric populations to be approximately 5% or less and most of these aPL antibody-positive patients are asymptomatic. A history of previous pregnancy loss, obstetrical complications, or thrombosis is a better predictor for future pregnancy loss than the laboratory abnormalities.

Studies have been mixed as to whether aPL antibodies cause infertility; it has been suggested that aPL antibodies may impair trophoblastic differentiation, proliferation, and migration, which can lead to implantation failure. However, the current consensus is that aPL antibodies do not contribute to early reproductive failure (i.e. infertility) and that patients with infertility do not need to be screened for aPL antibodies.

Non-Criteria Manifestations of Antiphospholipid Syndrome

Cardiovascular Manifestations

Approximately 65% of patients with APS have heart valve abnormalities detected by echocardiography. These include leaflet thickening, irregular nodules and/or non-bacterial vegetations (i.e., Libman-Sacks endocarditis), and severe valve dysfunction (regurgitation, stenosis) in the absence of a history of rheumatic fever or infective endocarditis. Valvular heart disease in APS patients can lead to heart failure, valve replacement and death. Emboli from valve vegetations may result in stroke. APS should be considered in patients without the more typical risk factors for coronary artery disease and in patients with evidence of thrombotic or embolic coronary occlusion who lack angiographic evidence of atherosclerotic disease.

Deposits of immunoglobulins, including aCL antibodies, and complement components are commonly found on the affected valves.

In women who used oral contraceptives or smoked, the presence of a LA increased the risk for myocardial infarction (5- to 22-fold with oral contraceptives and 34-fold with smoking). Antiprothrombin antibodies were reported to be a predictor of myocardial infarction in middle-aged men, particularly those with additional risk factors.

Neurologic Manifestations

In addition to stroke, other neurologic abnormalities associated with aPL antibodies include migraine, seizures, chorea, Guillain-Barré syndrome, transient global amnesia, dementia, diabetic peripheral neuropathy, orthostatic hypotension, acute sensorineural hearing loss, and transverse myelitis. Approximately 40% to 60% of multiple sclerosis patients are positive for at least one aPL antibody. The presence of aPL antibodies in multiple sclerosis patients may reflect disease progression or a disease flare.

Patients with psychotic disorders have an increased prevalence of LA and aCL antibodies, even in the absence of treatment with antipsychotic drugs, such as chlorpromazine, that can be associated with these antibodies. Approximately 25% to 32% of patients with acute psychosis have been reported to be aPL antibody positive. Patients with chronic schizophrenia have an increased frequency of aPL antibodies. Older patients with a history of cerebral ischemia and triple aPL antibody positivity are at greatest risk for neuropsychiatric disorders.

Cutaneous Manifestations

Cutaneous manifestations may be the first sign of APS. Livedo reticularis is relatively common, occurring in 24% of a series of 1000 aPL patients, and occasionally presents in a necrosing form. Noninflammatory vascular thrombosis is the most frequent histopathologic feature. Necrotizing vasculitis, livedoid vasculitis, superficial vein thrombosis, cutaneous ulceration and necrosis, erythematous macules, purpura, ecchymoses, painful skin nodules, subungual splinter hemorrhages, anetoderma (macular atrophy), discoid lupus erythematosus, and cutaneous T-cell lymphoma have all been reported.

Pulmonary Manifestations

Patients with APS may present with in situ thrombosis in pulmonary vessels and pulmonary hypertension. Studies have shown a high rate of aPL antibody positivity (15%) in patients with chronic thromboembolic pulmonary hypertension. Most patients with CAPS have dyspnea, and most of these individuals have ARDS.

Hepatic and Gastrointestinal Manifestations

The liver is the most commonly affected abdominal organ in APS. Occlusion of hepatic vessels supplying the biliary tree may present as acute acalculous cholecystitis with gallbladder necrosis.

aPL antibody levels are frequently elevated in patients with chronic liver disease. In one prospective study of patients with liver disease, approximately half of the patients with alcoholic liver disease and one third of the patients with chronic hepatitis C had elevated aPL antibody levels. The frequency was even higher in patients with more severe cirrhosis. Primary biliary cirrhosis has also been associated with aPL antibodies.

Gastrointestinal manifestations of APS include esophageal necrosis with perforation, intestinal ischemia and infarction, pancreatitis, colonic ulceration, and giant gastric ulcerations. APS has been reported in patients with mesenteric inflammatory veno-occlusive disease and with mesenteric and portal vein obstruction.

Renal and Adrenal Abnormalities

Renal involvement in APS presents with a variety of manifestations, including renal artery thrombosis or stenosis, renal vein thrombosis, allograft loss due to thrombosis after kidney transplantation, and injury to the renal microvasculature, also known as APS nephropathy. This nephropathy is characterized by fibrous intimal hyperplasia, focal cortical atrophy, and thrombotic microangiopathy. The most frequent clinical features are hypertension, microscopic hematuria, proteinuria (ranging from mild to nephritic levels), and renal insufficiency.

CLINICAL PEARLS

- APS is an acquired thrombophilic disorder associated with venous or arterial thrombosis and/or pregnancy complications attributable to placental insufficiency accompanied by l antiphospholipid antibodies in the blood.
- The syndrome is identified by persistent positivity of criteria laboratory tests including high titers of aCL and anti-β2GPI IgG or IgM antibodies detected by immunoassays and by positive LA.
- Rare patients have a CAPS in which there is disseminated thrombosis in large and small vessels, often after a triggering event such as infection or surgery, and often with multiorgan ischemia and infarction.
- Selected patients may be suspected of having APS without necessarily meeting the strict investigational criteria.

With respect to endocrine manifestations, in one series hypothyroidism was found in 22% of APS patients and thyroid antibodies in 18%. Adrenal insufficiency has been reported as the most significant endocrine manifestation of APS and adrenal crisis as a complication of adrenal insufficiency has been reported in SLE and APS patients. Acute adrenal failure secondary to bilateral infarction of the adrenal glands has been reported as a first manifestation of primary APS. In a recent study of 105 cases of SLE and APS patients with adrenal insufficiency, the mortality rate was 4%.

Retinal Abnormalities

As many as 80% of APS patients have ocular involvement. In absence of known risk factors, APS should be suspected in patients with recurrent ocular thrombosis and in younger patients with central retinal artery or vein occlusion. An ophthalmologic assessment is recommended for all patients with APS. The diagnosis of APS retinopathy should be suspected in patients with diffuse retinal vaso-occlusion, particularly when characterized by involvement of arteries and veins, neovascularization at presentation, and symptoms of systemic rheumatologic disease. Elevated aPL antibody levels were present in 5% to 33% of patients with retinal vein occlusion. Cilioretinal artery occlusion, optic neuropathy, and severe vaso-occlusive retinopathy have been described with APS.

Hematological Abnormalities

Approximately 20% to 53% of patients with APS have varying degrees of thrombocytopenia. The decrease in platelet count is generally mild or moderate, and is rarely significant enough to cause bleeding complications or affect anticoagulant therapy. Thrombocytopenia in patients with elevated aPL antibodies has been associated with arterial thrombosis.

Patients with aPL antibodies can develop antibodies against glycoproteins on platelets (GPIIb/IIIa, GPIb/IX, GPIa/IIa, and GPIV) and are at risk for immune thrombocytopenic purpura (ITP). ITP patients who are triple positive for aPL antibodies have also been shown to have lower platelet counts and are at risk for thrombosis with concurrent steroid therapy (see Chapter 129). In a prospective cohort study, the 5-year thrombosis-free survival rates for aPL antibody-positive and aPL antibody-negative ITP patients were 39% and 98%, respectively, suggesting that thrombocytopenia itself is not protective against thrombosis.

By themselves, aPL antibodies are not associated with defective hemostasis. Therefore, patients with APS who exhibit a bleeding tendency should be evaluated for a concurrent acquired coagulopathy. In APS patients with normal platelet counts, the differential diagnosis for a bleeding tendency should include hypoprothrombinemia, acquired thrombocytopathy, acquired factor VIII inhibitor, and acquired von Willebrand syndrome (see Chapters 126 and 127).

Catastrophic Antiphospholipid Syndrome

Rare patients present with CAPS, which is characterized by severe widespread vascular occlusion and a high mortality. The formal diagnosis of CAPS requires evidence of involvement of at least three organs, systems and/or tissues, development of manifestations simultaneously or within 1-week, histopathological evidence of small vessel occlusion, and presence of aPL antibodies (Table 139.2).

In contrast to the diagnostic criteria for APS, the diagnostic criteria for CAPS accept histological evidence of vasculitis together with thrombosis. Patients with CAPS may present with severe multiorgan ischemia/infarction usually with concurrent microvascular thrombosis, extensive venous thromboembolism, respiratory failure, stroke, abnormal liver enzymes, renal impairment, adrenal insufficiency, and cutaneous infarction. The respiratory failure is usually due to acute respiratory distress syndrome (ARDS) and diffuse alveolar hemorrhage. There may be laboratory evidence of disseminated intravascular coagulation (see Chapter 137).

According to the CAPS Registry at the time of writing, most CAPS patients are female (69%) and in their late 30 s (mean age of 38 years), but patients can present at any age (range 0 to 85 years). In 46% of CAPS cases, the catastrophic event was their first manifestation of APS. Precipitating factors for CAPS include infections (present in 49% of the cases), surgical procedures (17%), malignancies (16%), anticoagulation withdrawal or low international normalized ratio (8%), pregnancy complications (8%), drugs (5%), and active SLE(3%); 60% of patients had primary APS, 30% had SLE, 4% had SLE-like disease, and 6% had other autoimmune diseases.

The most frequently affected organs were the kidneys (73% of episodes), followed by the lungs (60%), brain (56%), heart (50%), and skin (47%) (Fig. 139.6). Other organs affected included peripheral vessels, intestine, spleen, adrenal glands, pancreas, retina, and bone marrow.

Thrombocytopenia was detected in 67% of cases and one third of patients had evidence of hemolysis and 11% had DIC. About 70% of CAPS patients are positive for at least one aPL antibody. The mortality rate for patients in the CAPS Registry was 35% and the only identified predictive factor for adverse outcome was underlying SLE. Fortunately, relapse is rare in survivors.

Coronavirus Disease–Associated Antiphospholipid Syndrome

There have been several reports of patients infected with severe acute respiratory syndrome corona virus 2 (SARS-CoV-2) and ensuing COVID-19 who have developed antiphospholipid antibodies. This is intriguing because vascular thrombosis is a frequent complication in these patients. In one series from France, 50 out of 58 critically ill COVID-19 patients tested positive for LA. However, these results are difficult to evaluate because testing was performed in the acute setting where false positives are common and where elevated levels of C-reactive protein (CRP) can mimic LA. In most studies, tests were done at a single time point and levels were above the usual reference ranges but below those considered clinically significant. Therefore, the relevance of these findings remain uncertain.

Pediatric Antiphospholipid Syndrome

APS is a significant cause of thrombosis in the pediatric population. In a European registry, children with primary APS tended to be younger and to have a higher frequency of arterial thrombosis than those with secondary APS. Patients with secondary APS were more likely to have venous thrombotic events associated with hematologic and skin manifestations. Compared with adult APS, pediatric primary APS patients are more likely to develop other autoimmune diseases, present with cerebral thrombotic events (i.e., cerebral vein thrombosis or ischemic stroke) and develop more non-criteria manifestations such as Evans syndrome, Raynaud phenomenon, and chorea. Furthermore, the rate of recurrent thrombosis is higher in pediatric APS than in adult APS. CAPS has been reported in children but is rare. Infection induced aPL antibodies are the most common form in pediatric patients.

aPL antibodies have been found in up to 30% of offspring of mothers with APS. However, thrombosis is rare in newborns delivered from mothers with APS, and only a few cases have been reported, mostly associated with other prothrombotic factors. Other complications in neonates born to APS mothers include prematurity, neurodevelopment abnormalities and learning disabilities.

In a recent European prospective study, 17% of neonates born to APS mothers were premature; however, no specific complications were found during the 5-year follow-up.

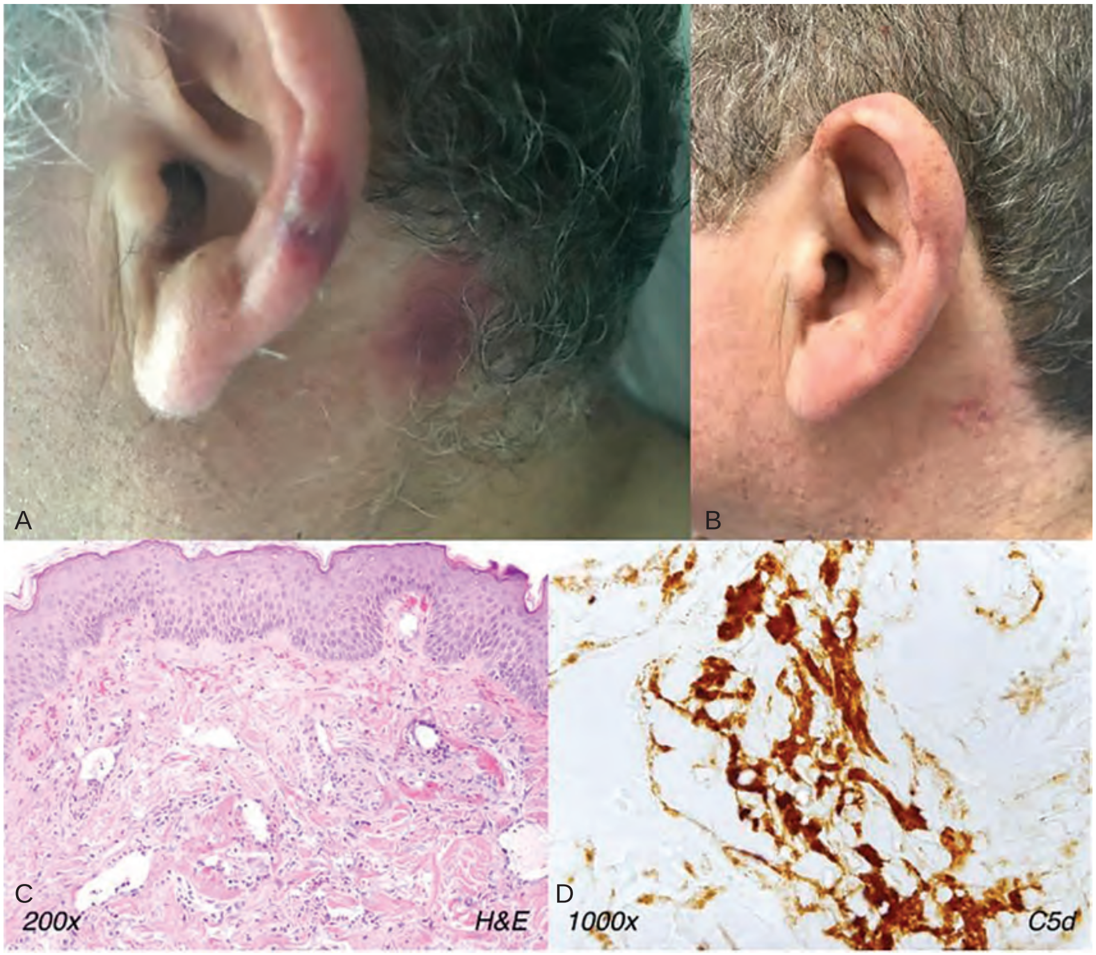

Figure 139.6 Catastrophic antiphospholipid syndrome (CAPS) manifesting as ear cartilage thrombosis successfully treated with eculizumab. (A) Ear cartilage thrombosis. (B) Resolution after treatment with complement inhibitor. (C) Ear cartilage biopsy (H&E staining) showing pale pink thrombi. (D) Immunohistochemistry staining with C5b-9 showing vessel deposition. *(From Nauseef JT, Lim HI, DeSancho MT. Successful outcome with eculizumab treatment in a patient with antiphospholipid syndrome presenting with an unusual thrombotic storm. J Thromb Thrombolysis. 2021;52(2):597–600.)*

The Single Hub and Access point for pediatric Rheumatology in Europe (SHARE) initiative was launched to develop diagnostic criteria and management regimens for pediatric APS.

TREATMENT OF ANTIPHOSPHOLIPID SYNDROME

There is general agreement that patients with recurrent or spontaneous thrombosis require long-term anticoagulant therapy with warfarin and that patients with recurrent spontaneous pregnancy losses require antithrombotic therapy with heparin and aspirin for most of the gestational period and with warfarin or LMWH for the puerperium (see Chapter 149). There are differences of opinion regarding the approach to treatment of patients with a single thrombotic event, a history of a remote thrombotic events (i.e., greater than 5 years previously), or patients with thrombotic events provoked by major transient risk factors such as surgery, pregnancy, or estrogens. Recently, the European League Against Rheumatism (EULAR) summarized treatment recommendations for patients with definite APS (Table 139.5).

There is controversy regarding the use of DOACs in APS. A prospective, randomized study that compared warfarin with rivaroxaban in patients with triple positive APS patients and a history of thrombosis reported more recurrent thrombotic events and more major bleeding events with rivaroxaban. A recent metanalysis confirmed these findings. It remains unclear whether these findings are only applicable to multipositive APS patients and to rivaroxaban. Nonetheless, until more data are available, it would be prudent to avoid DOACs in APS patients. The 2019 EULAR recommendations include avoiding rivaroxaban in patients with triple positivity or arterial events, but states that DOACs may be considered in patients with difficulty achieving a target international normalized ratio (INR) of 2 to 3 despite warfarin compliance or who have contraindications to warfarin. However, switching treatment from warfarin to a DOAC due to low compliance should be avoided.

Thrombosis

For the acute management of thrombotic APS, unfractionated heparin (UFH) or LMWH should be overlapped with a vitamin K antagonist such as warfarin (see Chapter 143). The parenteral anticoagulant can be stopped when the INR is therapeutic. The dose of warfarin should be adjusted to achieve an INR between 2.0 and 3.0. A recent review on warfarin for treatment of venous and arterial thrombosis in APS patients, showed no benefit of higher-intensity warfarin. It is also recommended that other cardiovascular risk factors should be addressed to minimize the risk of recurrence, including dyslipidemia, smoking, obesity, arterial hypertension, and diabetes.

Anticoagulation for thrombotic APS, even in patients with a single thrombotic event, should generally be continued indefinitely. Although many studies are underway on patients with low-risk aPL profiles, there have been no definitive studies reporting safe termination of anticoagulation in thrombotic APS patients.

TABLE 139.5 Recommendations for Treatment of Antiphospholipid Syndrome in Adults

APS Category	Clinical Manifestation/ Indication	Treatment	Duration
Definite APS with venous thrombosis	First unprovoked venous thrombosis	VKA with target INR 2–3 is recommended	Long term
	Provoked venous thrombosis	VKA with target INR 2–3 is recommended	Same duration as non-APS patients, however longer term if patient is triple aPL antibody positive
	Recurrent venous thrombosis, despite VKA treatment INR 2–3	Consider one of the following: • Addition of low-dose aspirin • Increase VKA INR to 3–4 • Change to low molecular weight heparin	Long term
Definite APS with arterial thrombosis	First arterial thrombosis	VKA with target INR 2–3 or INR 3–4 is recommended, considering bleeding and recurrence riskVKA with target INR 2–3 plus low-dose aspirin may also be considered	Long term
	Recurrent arterial thrombosis	Consider one of the following: • Increase VKA INR to 3–4 • Addition of low-dose aspirin • Change to low molecular weight heparin	Long term
Pregnant women with obstetric APS only (no prior thrombotic events) with or without SLE	History of ≥ 3 recurrent spontaneous miscarriages <10th week gestation	Combination treatment with low-dose aspirin and heparin at prophylactic doses	Duration of pregnancy, continue prophylactic dose of heparin for 6 weeks after delivery
	History of fetal loss ≥ 10 week of gestation	Combination treatment with low-dose aspirin and heparin at prophylactic doses	Duration of pregnancy, continue prophylactic dose of heparin for 6 weeks after delivery
	History of delivery <34 weeks gestation due to eclampsia or severe pre-eclampsia, or due to placental insufficiency	Treatment with low-dose aspirin alone or combination treatment with low-dose aspirin and heparin at prophylactic doses, if high-risk profile or other risk factors	Duration of pregnancy, if on heparin, continue prophylactic dose of heparin for 6 weeks after delivery
	Recurrent pregnancy complications despite combination treatment with LDA and heparin at prophylactic doses	Consider one of the following: • Increase heparin dose to therapeutic dose • Addition of hydroxychloroquine • Low-dose prednisone in the first trimester • IVIG may be considered in select cases	Duration of pregnancy, if on heparin, continue prophylactic dose of heparin for 6 weeks after delivery
Pregnant women with non-criteria obstetric APS	History of two recurrent spontaneous miscarriages <10th week gestation	Treatment with low-dose aspirin alone or combination treatment with low-dose aspirin and heparin at prophylactic doses if high-risk profile or other risk factors	Duration of pregnancy, if on heparin, continue prophylactic dose of heparin for 6 weeks after delivery
	History of delivery ≥34 weeks gestation due to eclampsia or severe pre-eclampsia	Treatment with low-dose aspirin alone or combination treatment with low-dose aspirin and heparin at prophylactic doses if high-risk profile or other risk factors	Duration of pregnancy, if on heparin, continue prophylactic dose of heparin for 6 weeks after delivery
Pregnant women with a history of thrombotic APS	History of arterial or venous thrombosis	Combination treatment with low-dose aspirin and heparin at therapeutic doses if high-risk profile or other risk factors	Duration of pregnancy, switch from VKA to heparin as soon as pregnancy is confirmed (ideally before 6th week gestation)
Catastrophic antiphospholipid syndrome prevention	For all aPL antibody–positive individuals and thrombotic APS patients	Prompt treatment of infections Avoid interruption in anticoagulation medication Minimize low INR levels	Long term
Catastrophic antiphospholipid syndrome	First-line treatment	Triple combination therapy with glucocorticoids, heparin and plasma exchange, or IVIG. Treat all triggering factors.	

Note: Direct oral anticoagulants (DOACs) should not be used in patients with triple aPL antibody positivity and arterial events, except in extraordinary circumstances where clinical judgement may prevail.

TREATMENT PEARLS AND HIGH-RISK aPL ANTIBODY PROFILE IN ASYMPTOMATIC PATIENTS

Treatment Pearls

- Long-term anticoagulant therapy with warfarin is recommended for APS patients with thrombosis.
- DOACs are **not** recommended.
- Aspirin and heparin are recommended for pregnant APS patients and for VTE prophylaxis postpartum.
- CAPS is associated with high mortality; in addition to anticoagulants, patients with CAPS often require plasmapheresis and immunosuppressive agents; some patients may benefit from complement inhibitors.
- Asymptomatic patients with high-risk aPL antibody profiles should be considered for prophylactic therapy with low-dose aspirin.

High-Risk aPL Antibody Profile in Asymptomatic Patients

The presence (on two or more occasions at least 12 weeks apart) of:

- LA-positive (measured according to ISTH guidelines)
- Double positive (any combination of LA, aCL, or anti-β2GPI antibodies)
- Triple positive (LA, aCL, and anti-β2GPI antibodies)
- Persistently high titers of aCL and/or anti-β2GPI antibodies

Stroke

In APS patients with stroke, high-intensity warfarin or concomitant use of aspirin or other antiplatelet drugs has not been shown to be of benefit over usual intensity warfarin alone.

Pregnancy Complications

The current approach to treating pregnant women with APS and recurrent pregnancy loss or other aPL antibody associated complications of pregnancy includes daily low-dose aspirin (75 to 81 mg/day) and prophylactic doses of either UFH or LMWH although LMWH is preferred (see Chapters 149). Heparin is withheld when labor begins or 24 hours prior to a cesarean section. Anticoagulation with either LMWH or warfarin (although most patients and physicians prefer LMWH for convenience, despite the need for injection) is then resumed for 6 weeks due to the increased risk of venous thromboembolism (VTE) in this period. In obstetric APS patients who are planning to become pregnant, low-dose aspirin should be started prior to conception and heparin (LMWH or UFH) should be added as soon as pregnancy is confirmed. Women with a history of thrombotic APS, should be switched from warfarin to a combination treatment of low-dose aspirin and heparin at therapeutic dosage during pregnancy.

Anticoagulant Monitoring Considerations

For patients treated acutely with intravenous UFH, care must be taken to determine whether the patient has a preexisting LA that can interfere with aPTT monitoring of heparin. This problem can be circumvented by using an LA-insensitive aPTT reagent or by measuring anti-Xa levels. An alternative approach would be to treat with weight-based dose of LMWH.

In some patients with APS, an LA can artifactually elevate the prothrombin time and INR. A multicenter study reported that all but one of the commercial thromboplastins in use at nine centers provided acceptable INR values for APS patients with LA. New thromboplastins should be checked for their responsiveness to LA prior to their use for monitoring warfarin therapy in patients with APS. Chromogenic factor X (CFX) assays can be used as an alternative to the INR for APS patients, especially for patients with a prolonged baseline prothrombin time prior to initiating warfarin therapy, those with a persistently positive LA, and those with recurrent VTE. Therapeutic CFX values range from 20% to 40%; thus, a CFX of 40% would approximate an INR of 2.0, and a CFX of 20% would approximate an INR of 3.0.

Catastrophic Antiphospholipid Syndrome

Patients with CAPS require aggressive treatment because of the high mortality. Treatment for CAPS is directed toward the thrombotic events and suppression of the cytokine cascade. Conventional anticoagulant therapy is usually insufficient and treatment modalities may include anticoagulation with heparin, immunosuppressive therapy with high-dose steroids, intravenous immunoglobulin (IVIG) cyclophosphamide, azathioprine, or rituximab. Plasmapheresis may be a helpful adjunct in some patients. Triple therapy, including anticoagulation, steroids, and either IVIG, plasma exchange, or both is recommended. The increased application of this triple therapy strategy has resulted in a significant reduction in mortality rate to 30% in CAPS.

In addition, concurrent treatment of precipitating factors is also recommended (e.g., infection or malignancy). For refractory CAPS, either rituximab (B cell depletion) or eculizumab (complement inhibition) may be considered.

Asymptomatic Antiphospholipid Antibody-Positive Patients

Asymptomatic patients with no previous thrombosis but a high-risk aPL antibody profile should be considered for long term prophylaxis with low-dose aspirin, especially if there are other thrombotic risk factors (see boxes on Treatment Pearls). Furthermore, aPL antibody carriers should be considered for thromboprophylaxis with usual doses of LMWH in high-risk situations, such as surgery, prolonged immobilization, and the puerperium. In addition to low-dose aspirin, aPL-antibody carriers with SLE should be considered for treatment with hydroxychloroquine as primary prophylaxis. (See boxes on Treatment Pearls and High-Risk aPL Antibody Profile in Asymptomatic Patients.)

A meta-analysis of seven observational studies of 460 asymptomatic aPL carriers reported that low-dose aspirin reduced the risk of first thrombosis half compared with nonuse. It is also recommended that thrombosis risk factors such as hypertension and dyslipidemia should be treated and patients should be counseled on the increased risk of thrombosis with oral contraceptives, pregnancy, estrogen replacement, surgery, or immobilization. Treatment recommendations for asymptomatic patients with low- and high-risk aPL antibody profiles are summarized in Table 139.6.

Other Treatments for Antiphospholipid Syndrome

Hydroxychloroquine

Hydroxychloroquine (HCQ), a synthetic antimalarial drug with anti-inflammatory properties, is a standard of care for the treatment of SLE. HCQ has also been associated with a reduction in the risk of thrombosis in APS and SLE. The potential effectiveness of this treatment is supported by the results of an animal model of aPL antibody thrombosis, and the evidence that HCQ disrupts aPL IgG-β2GPI complexes and reverses the inhibitory effect of aPL antibodies on annexin A5 on phospholipid bilayers and on human placental syncytiotrophoblasts. In a longitudinal cohort study that included 272 patients with APS and 152 taking HCQ (17 of 272 were on warfarin, 203 were on prednisolone, 112 on azathioprine, 38 on aspirin) there were fewer thrombotic complications in those taking HCQ (OR 0.17, 95% CI 0.07 to 0.44; $P < .0001$). In asymptomatic aPL antibody-positive patients with SLE, primary prophylaxis with aspirin and HCQ appeared to reduce the frequency of thrombotic events. A 2017 study showed that long term use of HCQ significantly reduced aPL antibody levels and the rate of recurrence. These studies suggest that

TABLE 139.6 Recommendations for Primary Prevention of Antiphospholipid-Positive Asymptomatic Adults

Clinical History	aPL-Antibody Profile Risk	Treatment
Asymptomatic	High risk*	Low-dose aspirin 75–100 mg/day recommended
SLE and no history of thrombosis or PC	High risk[a]	Low-dose aspirin 75–100 mg/day recommended with hydroxychloroquine treatment
	Low risk[b]	Low-dose aspirin 75–100 mg/day recommended with hydroxychloroquine treatment
Non-pregnant women with a history of obstetric APS only (with or without SLE)	Low[b] and high risk[a]	Low-dose aspirin 75–100 mg/day after adequate risk/benefit evaluation
Pregnant women with no history of thrombosis or PC (with or without SLE)	High risk[a]	Low-dose aspirin 75–100 mg/day should be considered

[a] High-risk aPL Antibody Profile: The presence (in 2 or more occasions at least 12 weeks apart) of lupus anticoagulant (measured according to ISTH guidelines), or of double (any combination of lupus anticoagulant, aCL antibodies or anti-β2GPI antibodies), triple (all three subtypes) aPL positivity, or the presence of persistently high aPL titers.

[b] Low-risk aPL Antibody Profile: Isolated aCL or anti-β2GPI antibodies at low-medium titers, particularly if transiently positive.

aPL, Antiphospholipid; *APS*, antiphospholipid syndrome; *PC*, pregnancy complication; *SLE*, systemic lupus erythematosus.

Adapted and Modified from Tektonidou MG, Andreoli L, Limper M et al. *Ann Rheum Dis* 2019;78:1296–1304.

HCQ is a useful adjunct to anticoagulant therapy. An ongoing study (HIBISCUS: Hydroxychloroquine for the secondary prevention of thrombotic and obstetrical events in primary antiphospholipid syndrome) is exploring the benefits of HCQ. EULAR guidelines state that HCQ could be used in women with refractory obstetric APS not responding to standard therapy.

Rituximab

Rituximab is an anti-CD20 chimeric monoclonal antibody approved for the treatment of rheumatoid arthritis. It has been shown to be effective in treating non-criteria manifestations refractory to conventional therapy. The task force recommends using Rituximab in difficult to treat APS patients with hematological and microangiopathic manifestations.

Eculizumab

Eculizumab is an anti-C5 monoclonal antibody that inhibits terminal complement activation. The drug was reported to be effective in selected patients with refractory CAPS and evidence of microangiopathic hemolytic anemia (see Fig. 139.6). A study of eculizumab in CAPS patients with end stage renal disease is underway (clinicaltrials.gov identifier NCT01029587).

CHAPTER 140

VENOUS THROMBOEMBOLISM

Noel C. Chan and Jeffrey I. Weitz

Venous thromboembolism (VTE) encompasses deep vein thrombosis (DVT) and pulmonary embolism (PE). DVT commonly affects the deep veins of the legs, and infrequently involves veins at other anatomical sites (such as upper extremity, splanchnic, or cerebral veins). Thrombotic occlusion of the deep veins impairs drainage of blood, thereby resulting in pain and swelling distal to the obstruction. Embolization of thrombus from deep veins in the leg to the pulmonary arteries is the leading cause of PE. About two-thirds of patients with symptomatic VTE present with DVT, whereas the remainder present with PE,[1] and about 1 in 20 patients with DVT and 1 in 10 with PE die within 30 days.[2] In patients who survive, long-term complications, such as post-thrombotic syndrome (PTS) and chronic thromboembolic pulmonary hypertension (CTEPH), are important causes of morbidity in up to 50% of patients with DVT and 4% of those with PE, respectively.[3] Thrombosis can also affect superficial veins. Although the condition is self-limiting when superficial veins in the arms are involved as a complication of intravenous catheters or drug delivery, thrombi in the superficial veins of the lower extremities, particularly those in the thigh close to the saphenofemoral junction, can propagate into the deep veins, thereby resulting in DVT and PE.

EPIDEMIOLOGY

VTE affects 1 to 2 in 1000 individuals annually and is the third most common cause of vascular death after myocardial infarction and stroke.[1,4] In the United States, about 900,000 people are diagnosed with VTE each year, with more than half related to hospitalization or institutionalization.[5] Consequently, VTE is considered the number one cause of preventable death in hospitalized patients.[6]

The incidence of VTE increases with age, from 1 case per 10,000 persons per year in individuals younger than 40 years of age to 5 to 10 cases per 1000 persons per year in those 80 years of age or older.[4] Although men and women are affected equally overall, the incidence is higher in women of childbearing age than in men of similar age; for those 45 years of age or older, the incidence of VTE is higher in men than in women.[4] The incidence of VTE is higher in Whites and African Americans and is lower in Asians, Asian Americans, and Native Americans.[1,4] The incidence of VTE is twofold higher in high-income countries than in low-income countries even after adjustments for baseline characteristics and risk factors.[7]

PATHOGENESIS OF VENOUS THROMBOEMBOLISM

Except in pregnancy (see Chapter 141), DVT usually starts in the deep veins of the calf where it forms in the valve pockets. Although most calf DVT spontaneously resolves, there is propagation into more proximal veins in about 20% of the cases.[3,8] These more proximal clots have the potential to break off and embolize to the lungs, resulting in PE. Thus, PE can be detected in about 40% of patients with proximal DVT and at least 50% of patients with PE have evidence of DVT.

DVT in pregnancy usually involves the iliofemoral vein, spares the distal veins, and affects the left leg in greater than 80% of cases (see Chapter 141).[9] Localization to the left iliofemoral veins likely reflects a May-Thurner-like syndrome, as the enlarging uterus exaggerates the compression of the left iliac vein where it is crossed by the right iliac artery.

The pathogenesis of VTE involves an interplay among hypercoagulability of the blood, sluggish blood flow, and damage or activation of the vessel wall, which are the components of the so-called Virchow triad.[10] Hypercoagulability of the blood triggers a systemic increase in thrombin generation, whereas stasis and damage or activation of the vessel wall explain why DVT usually occurs in the deep veins of the leg.[11]

Hypercoagulability

Many hereditary and acquired disorders are associated with hypercoagulability. Hereditary disorders that are potent risk factors for VTE include deficiencies of natural anticoagulants such as antithrombin, protein C, and protein S (discussed in Chapters 125 and 138).[12] With reduced levels of these endogenous anticoagulants, there is increased thrombin generation and the potential for clot formation. Moderate genetic risk factors for VTE include factor (F) V Leiden and the prothrombin gene mutation. FV Leiden, an FV variant that is resistant to inactivation by activated protein C, is found in about 5% of individuals of European descent.[13] The prothrombin gene mutation, which is found in about 3% of those of European descent, is a single nucleotide polymorphism in the 3′ untranslated region that increases prothrombin synthesis.[14] Delayed inactivation of FVa Leiden and elevated prothrombin levels lead to increased thrombin generation. Although these inherited thrombophilic disorders increase the risk of the first episode of VTE, their impact on the risk of recurrence is unclear. Consequently, routine thrombophilia testing is not recommended in patients with VTE because such tests rarely influence long-term management (see Chapter 138).[15]

Up to 50% patients with the first episode of VTE have no identifiable major risk factors and are described as having unprovoked VTE. The remainder develops VTE secondary to risk factors and these episodes are considered provoked. Acquired risk factors for VTE can be divided into those that are transient or persistent and major or minor.[16] Examples of major transient risk factors are surgery, trauma and hospitalization for COVID-19, whereas minor transient risk factors include immobilization, long-distance travel, pregnancy, and estrogen therapy. Common examples of major persistent risk factors are cancer and antiphospholipid syndrome, whereas minor persistent risk factors include advanced age, obesity, renal impairment, and chronic inflammatory disorders such as inflammatory bowel disease and rheumatoid arthritis. Patients with both hereditary and acquired risk factors are at particularly high risk of VTE because risks tend to be multiplicative rather than additive. Local factors explain why DVT usually starts in the calf.

Stasis, Hypoxia, and Endothelial Dysfunction

Most venous thrombi originate in the valve pockets of the calf veins where there is stasis and hypoxia.[17,18] Consistent with slow blood flow, contrast dye lingers in the valve pockets after venography.[17] Hypoxia occurs because the valve leaflets are avascular and the oxygen tension in the valve pockets rapidly decreases when blood flow stops because of immobility.[18] Endothelial cells lining the valve pockets express antithrombotic proteins such as thrombomodulin and endothelial protein C receptor on their surface (see Chapter 125).[19] Expression is downregulated by local hypoxia or inflammation and by reduced expression of the oscillatory shear-dependent transcription factors that endow perivalvular venous endothelial cells with an antithrombotic phenotype (see Chapters 121 and 122).[20] In addition, stasis and hypoxia induce a pro-inflammatory and prothrombotic endothelial phenotype by the upregulation of adhesion molecules such as P- and E-selectin, intercellular adhesion molecule 1 (ICAM-1), and von Willebrand factor. Therefore, stasis and hypoxia in the valve pockets of the veins in the lower extremities promote a hypercoagulable microenvironment, which explains why DVT starts in this site. In contrast, upper extremity DVT is often triggered by central venous catheters or by extrinsic compression of the arm veins (e.g., Paget-Schroetter syndrome).[21] Indwelling catheters or extrinsic compression retard blood flow, whereas delivery of chemotherapy, or antibiotics via the catheters, induces local activation of the endothelium. Regardless of whether DVT occurs in the upper or lower extremities, however, the initiators of coagulation are likely to be similar.

Initiators of Coagulation in Venous Thromboembolism

Tissue factor initiates coagulation in patients with VTE, but the source of the tissue factor remains elusive.[22] Overt damage to the vessel wall is rarely seen with DVT. However, hypoxia and inflammatory cytokines upregulate tissue factor expression by endothelial cells and circulating monocytes and induce endothelial cell expression of adhesion molecules such as P-selectin. The importance of endothelial cell tissue factor is uncertain, but P-selectin tethers tissue, factor-bearing monocytes, and microparticles onto their surface via interaction with P-selectin glycoprotein ligand.[23] By preventing such binding, P-selectin inhibitors attenuate venous thrombosis in animal models. Statins and proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors attenuate tissue factor expression by monocytes, which may explain why they reduce the risk of recurrent VTE.[24–26] Therefore, adhesion of tissue factor expressing leukocytes and microparticles to the activated endothelium appears to be an important driver of DVT.

In addition to tissue factor, emerging data suggest that the contact system also plays a part in the initiation of coagulation in VTE.[27–29] Neutrophil extracellular traps (NETs) extruded from activated neutrophils trapped within venous thrombi provide a scaffold for platelet adhesion and activate FXII, thereby initiating coagulation via the intrinsic pathway (see Chapters 121 and 125).[30] Likewise, inorganic polyphosphate released from activated platelets enhances FXII activation.[31] Thrombin feedback activation of FXI, a reaction enhanced by polyphosphate, amplifies coagulation via the intrinsic pathway. With increasing evidence that the contact system is involved in the initiation of VTE, FXI has emerged as a target for new anticoagulants that have the potential to be safer than those that inhibit FXa or thrombin (see Chapter 143).[32]

There is mounting evidence that platelets play a part in the pathogenesis of VTE.[33] Venous thrombi consist of a central core that lies adjacent to the vessel wall and is rich in fibrin and trapped red blood cells and an overlying shell composed of platelet-rich layers. There is evidence from mouse models that platelets are important in the initiation and propagation of venous thrombosis. Thus, P-selectin-dependent recruitment of platelets and leukocytes is essential for thrombus formation after incomplete ligation of the inferior vena cava because inhibition or depletion of platelets or neutrophils suppressed thrombus formation in this model.[34] Likewise, platelet depletion abrogated spontaneous venous thrombosis induced by concomitant knockdown of antithrombin and protein C. In addition, antiplatelet agents such as aspirin or clopidogrel attenuated thrombosis in a murine venous stasis model.[35,36] Findings in mice may be translatable to humans because patients with acute VTE have evidence of systemic platelet activation and increased levels of platelet-derived soluble P-selectin.[37] Therefore, platelets likely contribute to VTE, which explains why aspirin is effective for its prevention, albeit less so than anticoagulants.[38]

Stabilization, Embolization, and Resolution of Venous Thrombi

In patients with DVT, the risk of PE appears to be dependent on the size and the stability of the thrombus. The importance of thrombus size is highlighted by the fact that calf DVT rarely causes PE, whereas up to 50% of patients with proximal DVT have associated PE. Clot stability also influences the risk of PE. Thrombin activates FXIII, which stabilizes the clot and renders it more resistant to lysis by crosslinking the fibrin polymers and by facilitating retention of red blood cells in the thrombus.[39,40] Enhanced thrombin generation and subsequent FXIII activation in patients with FV Leiden could explain the epidemiological evidence that DVT is more common than PE in such patients. This concept is supported by the results of studies in mice.[41] Thus, treatment with dabigatran after ferric chloride-induced femoral vein thrombosis enhanced PE by suppressing thrombin-mediated FXIII activation. Conversely, FXIII supplementation reduced the risk of PE without promoting thrombus growth.

Thrombus resolution depends on fibrinolysis, which occurs when plasminogen is converted to plasmin. Degradation of thrombi by plasmin likely explains why most calf DVT resolve spontaneously. Migration of leukocytes into the thrombus promotes fibrinolysis and contributes to early thrombus resolution by releasing clot digesting enzymes.[42] Impaired fibrinolysis has been linked to recurrent VTE and up to 50% of patients with proximal DVT have ultrasound evidence of residual vein occlusion 1 year after their index event. Reduced blood flow contributes to PTS, which is the major long-term complication of DVT.

CLINICAL MANIFESTATIONS OF VENOUS THROMBOEMBOLISM

Deep Vein Thrombosis

DVT typically causes swelling, pain, and erythema of the affected extremity. DVT in the proximal veins of the lower extremity is more likely to be symptomatic than DVT confined to the calf veins. Extensive thrombosis involving the iliac and femoral veins can cause phlegmasia cerulea dolens, an uncommon limb-threatening syndrome characterized by severe leg pain, swelling, venous gangrene, and arterial ischemia with loss of distal pulses.

The differential diagnosis of patients with suspected DVT includes musculoskeletal disorders (muscle or tendon strains or tears), lymphatic obstruction, venous insufficiency, a ruptured popliteal (Baker) cyst, cellulitis, sciatica, muscle hematoma, and post-thrombotic syndrome.

Pulmonary Embolism

The most common symptoms and signs of PE include dyspnea on exertion, chest pain which is often pleuritic in nature, tachypnea, and cough. Many patients with PE have concomitant symptoms and signs of DVT. Less common symptoms and signs include fever, hemoptysis, cyanosis, hypotension, and shock. Other non-specific symptoms include palpitations, anxiety, and lightheadedness.

Patients with severe PE often have dyspnea at rest and hypotension, and they may present with syncope because of hypoxemia and low cardiac output. Central and peripheral cyanosis can occur, and the jugular veins may be distended if right heart failure develops. The second heart sound can be widely split, and the pulmonic component may be loud because of delayed emptying of the right ventricle.

A right ventricular heave may be present with severe PE because of acute pulmonary hypertension.

When patients present with chest symptoms suggestive of PE, the differential diagnosis includes pulmonary disorders, such as pneumonia, an exacerbation of chronic obstructive lung disease or asthma, pleurisy secondary to connective tissue disease, cardiac disorders such as heart failure, acute coronary syndrome, or pericarditis; and musculoskeletal disorders such as rib fracture.

DIAGNOSIS OF VENOUS THROMBOEMBOLISM

In patients with suspected VTE, rapid and accurate diagnosis is essential because failure to institute anticoagulant therapy in those with VTE can result in thrombus progression and PE, which can be fatal, whereas unnecessary anticoagulation in those without VTE can cause bleeding. Clinical diagnosis of DVT or PE is unreliable because no individual symptom or sign is sufficiently predictive for confirming or excluding the diagnosis. Therefore, non-invasive imaging tests are often needed.

Compression ultrasound is used for the diagnosis of DVT and CT pulmonary angiography (CTPA) or, less frequently, ventilation-perfusion (V/Q) lung scanning is used for the diagnosis of PE. The challenge with the reliance on imaging tests for ruling out VTE is that most patients with suspected VTE do not have it. Of those with suspected DVT and PE, the diagnosis is confirmed in only about 20% and 5%, respectively.[43–45] Therefore, relying on imaging in all patients with suspected VTE is problematic because of the cost to healthcare systems, the unnecessary exposure to radiation for many patients with suspected PE, and the potential for overdiagnosis of events of uncertain clinical significance, such as calf DVT and subsegmental PE. Instead, a sequential diagnostic approach that starts with the determination of the pretest probability of DVT or PE using validated risk assessment models enhances reproducibility and testing efficiency because it guides the need for imaging, thereby minimizing unnecessary testing.

Although clinical risk assessment tools categorize patients according to their pretest probability of VTE with reasonable accuracy, they should not be used as a standalone to exclude or confirm VTE diagnosis. Instead, risk assessment models should be combined with D-dimer testing, which if negative, excludes the diagnosis of VTE in patients with a “VTE-unlikely” pretest probability. If the D-dimer test is positive or if VTE is likely, the diagnosis of DVT or PE requires confirmation with compression ultrasonography or lung imaging (CTPA or V/Q scan), respectively.

Diagnostic Tests

D-Dimer

D-dimer is a plasmin-derived breakdown product of cross-linked fibrin and is a biomarker that reflects coagulation activation and fibrinolysis (see Chapters 121 and 125).[46] D-dimer levels are elevated in most patients with VTE. D-dimer assays vary in their sensitivity and specificity. Enzyme-linked immunosorbent and advanced turbidimetric D-dimer assays have sensitivities greater than 95%. With highly sensitive assays, the combination of a negative D-dimer test and a ‘VTE-unlikely’ pretest probability effectively rules out DVT or PE, thereby obviating the need for imaging. However, the test is nonspecific because D-dimer levels are increased in a variety of conditions, including malignancy, inflammatory disorders, and infections. Therefore, patients with a positive D-dimer test require imaging to confirm a diagnosis of VTE. Consequently, the D-dimer test is most useful as a tool to rule out suspected VTE.

Compression Ultrasonography

Compression ultrasonography with or without Doppler imaging is the most widely used non-invasive test for the diagnosis of DVT.[47] Noncompressibility of the proximal leg veins on ultrasonography is diagnostic of DVT in symptomatic patients and is an indication for treatment. Compared with venography, venous compression ultrasonography has a sensitivity and specificity for detection of proximal DVT (femoral or popliteal veins) of about 95%; the sensitivity and specificity for detecting calf DVT are lower.[48] Consequently, some centers examine only the veins above the trifurcation in the calf, whereas others examine both the proximal and calf veins. A normal whole leg ultrasound effectively excludes the diagnosis of DVT because the risk of missing DVT is less than 2% at 3 months. If only the proximal veins are examined, the ultrasound should be repeated in 1 week to exclude extension of possible calf DVT into the proximal veins.

Venography

Although ascending contrast venography remains the gold standard for diagnosis of DVT, the test is rarely performed because of its expense, discomfort to the patient, and potential for complications. A constant intraluminal filling defect is diagnostic and DVT can be excluded in patients with a normal, adequately performed venogram. Minor side effects of venography include local pain, nausea; serious adverse reactions, such as anaphylaxis, are rare.

Computed Tomography Pulmonary Angiography

Multidetector CTPA has largely replaced V/Q lung scanning for diagnosing PE because of its wide availability, the rapidity of its results, and a sensitivity and specificity sufficient for its use as a standalone test. In contrast to V/Q scanning, CTPA not only permits direct visualization of thrombi in the pulmonary arteries of patients with PE but also provides an alternative diagnosis in many of those without PE. In a meta-analysis of 16 studies that included 4392 participants, the pooled estimates for the sensitivity and specificity of CTPA for PE were 94% and 98%, respectively.[49] A CTPA showing thrombus in segmental or more proximal pulmonary arteries provides evidence of PE, whereas a negative CTPA excludes the diagnosis. Compared with V/Q scanning, CTPA detects more isolated subsegmental thrombi in about 1% to 5% of patients, but it is unclear whether isolated subsegmental defects are benign or associated with outcomes like those of more proximal thrombi. A normal D-dimer level and/or a normal bilateral venous compression ultrasound examination may help to exclude VTE in this setting.

Ventilation/Perfusion Lung Scan

This two-part test consists of a ventilation phase and a perfusion phase. The ventilation phase involves inhalation of an aerosol form of radioactive isotopes of xenon or technetium to assess air delivery to the various parts of the lung. The perfusion phase involves intravenous injection of technetium-labeled macroaggregates of albumin, which enables assessment of blood flow within the lungs once the aggregates lodge in the pulmonary microcirculation. Images for both parts of the test are acquired using a gamma counter. Areas of the lung affected by PE do not light up on the perfusion scan because the macroaggregates of albumin fail to reach sites where the pulmonary arteries are occluded. Areas with abnormal perfusion because of PE will ventilate normally, yielding a ventilation-perfusion mismatch. A normal V/Q lung scan excludes the diagnosis of PE, but only 25% of patients with suspected PE have a normal scan.[49] One or more segmental or larger perfusion defects that ventilate normally characterize a high probability lung scan, which establishes the diagnosis of PE. However, even with single-photon emission CT technology, only about 10% of patients with suspected PE have a high-probability scan. The remaining 65% of lung scans exhibit smaller areas of mismatch or matched defects, and fall within the non-high probability category. Because up to 40% of patients with non-high probability scans have PE, such patients often require additional investigations to exclude the diagnosis.

Although CTPA has largely replaced V/Q lung scanning for the diagnosis of PE, the lung scan is the diagnostic test of choice for patients with renal impairment or a history of allergy to contrast media, and for women younger than 40 years of age to reduce radiation exposure to the breasts. For the diagnosis of PE in pregnancy, lung scanning produces less maternal and fetal radiation exposure and is sometimes preferred over CTPA (see Chapter 141).

Pulmonary Angiography

Although direct pulmonary angiography is the reference standard for establishing the presence or absence of PE, it is an invasive test associated with a mortality rate of 0.2%, particularly in patients with hemodynamic compromise or respiratory failure. Because of the widespread availability of CTPA and V/Q scanning, pulmonary angiography is rarely undertaken.

Diagnostic Strategies for Suspected Deep Venous Thrombosis

Diagnostic algorithms for the noninvasive diagnosis of suspected DVT are presented in Fig. 140.1. The diagnosis of DVT requires an integrated approach because the clinical symptoms and signs are not specific, and clinical risk assessment models or D-dimer testing used in isolation are not sufficiently predictive to confirm or exclude the diagnosis. When assessing outpatients with suspected DVT, clinical prediction rules assign a pretest probability score (DVT likely or unlikely) based on the clinical manifestations and the presence or absence of risk factors. The Wells clinical prediction rule for DVT assigns a risk category based on the following factors: active cancer (or cancer treated within the previous 6 months), calf swelling (≥3 cm compared with the asymptomatic leg), swelling of superficial veins (non-varicose), unilateral pitting edema, tenderness along the course of the deep veins, recent immobilization (≥3 days), or major surgery (within 12 weeks), and absence of an alternative diagnosis.[50]

Acute DVT can be excluded in patients with a DVT-unlikely pretest probability and a negative D-dimer result. Patients with a positive D-dimer result or a DVT-likely pretest probability should proceed to objective testing. If compression ultrasonography cannot be promptly performed, patients can be empirically anticoagulated pending diagnostic testing on a subsequent day. A positive ultrasound result in a patient with a DVT-likely pretest probability confirms the diagnosis of DVT. Serial ultrasonography should be considered if the clinical suspicion of DVT remains high despite a negative initial leg ultrasound and no alternative diagnosis is identified.

Among inpatients with suspected DVT, imaging is required because the performance of clinical prediction models such as the Wells score is lower in hospitalized patients than in outpatients and upfront D-dimer testing is associated with a high rate of false positives because of comorbidities.

Diagnostic Strategy for Suspected Pulmonary Embolism

A diagnostic algorithm for evaluation of patients with suspected PE is shown in Fig. 140.1. After a history and physical examination, electrocardiogram (ECG), and chest X-ray, the pretest probability of PE should be assessed using a validated clinical prediction model. The Wells clinical prediction rule assigns a pretest probability based on the presence of the following: clinical signs of DVT, recent immobilization or surgery, heart rate above 100 beats/min, previous history of VTE, hemoptysis, active malignancy, and absence of an alternative diagnosis.[51]

A PE-unlikely pretest probability combined with a negative D-dimer test excludes PE. Patients with a positive D-dimer test or a high pretest probability require imaging. A negative CTPA or a normal V/Q scan rules out PE. An intraluminal filling defect in a segmental or more proximal pulmonary artery on the CTPA, or one or more segmental (or larger) perfusion defects with normal ventilation on the V/Q scan, establishes a diagnosis of PE. The diagnosis of PE cannot be excluded if perfusion defects correspond with abnormalities on the chest X-ray. CTPA is the preferred diagnostic test when there are chest X-ray abnormalities, but if this cannot be done, bilateral leg compression ultrasonography may be helpful to rule out DVT.

EVALUATION FOR UNDERLYING MALIGNANCY

Cancer is a risk factor for VTE. A comprehensive history should be taken, and physical examination performed in patients with

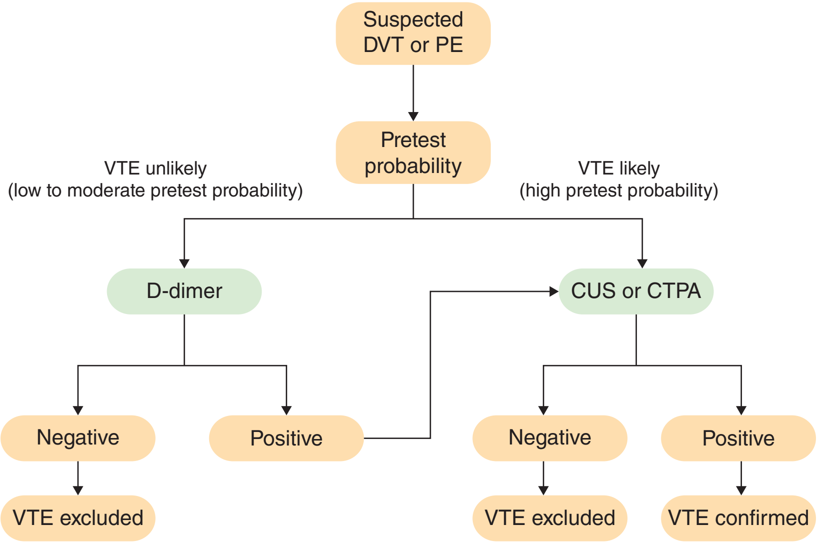

Figure 140.1 DIAGNOSTIC APPROACH IN PATIENTS WITH SUSPECTED DEEP VEIN THROMBOSIS (DVT) OR PULMONARY EMBOLISM (PE). The first step is an assessment of the pretest probability using a validated DVT or PE clinical prediction model. Patients categorized as VTE unlikely (low or moderate pretest probability) should undergo D-dimer testing. A negative D-dimer excludes the diagnosis, whereas those with a positive D-dimer test result or those categorized as VTE likely (high pretest probability) should undergo diagnostic imaging with compression ultrasound (CUS) or computed tomography pulmonary angiography (CTPA) to rule out or confirm DVT and PE, respectively.

documented VTE, along with routine tests such as blood counts, tests of liver function, urinalysis, and stool for occult blood.[52] Age- and sex-specific cancer screening tests (e.g., colonoscopy and mammography) should be performed over the next few months. If these tests are negative, the likelihood of finding occult cancer within a year of diagnosis of VTE is less than 5%. Therefore, routine abdominal and pelvic CT scanning or positron emission tomography is not recommended because such testing is expensive and does not increase the rate of cancer diagnosis or improve outcomes.

TREATMENT OF VENOUS THROMBOEMBOLISM

Anticoagulant therapy is the mainstay for the treatment of acute VTE to prevent thrombosis progression and fatal PE, and to minimize the risk of long-term complications. Unless the risk of bleeding is high, anticoagulation therapy should be started immediately in patients with a likely pretest probability of PE or DVT even while awaiting confirmatory imaging tests. Once the diagnosis is established, patients with contraindications to anticoagulant therapy may require the insertion of an inferior vena cava filter.

Most patients with acute DVT or with low-risk PE can receive out-of-hospital treatment because such treatment is as safe as inpatient treatment.[53,54] In patients with PE, risk stratification using prediction rules such as the Pulmonary Embolism Severity Index (PESI) can help to identify the 50% of those who can safely be treated as outpatients.[55] In non-low-risk patients with PE without evidence of hemodynamic instability, further risk stratification is recommended. The presence of right ventricular (RV) dysfunction as identified by imaging (echocardiogram or CTPA) or by biochemical assays (cardiac biomarkers such as troponin or B-type natriuretic peptide) predicts higher early mortality risk.[54,56] These higher risk patients should be observed in the hospital to ensure that they remain hemodynamically stable. Patients with evidence of both RV dysfunction on imaging and elevated cardiac biomarkers require close monitoring for hemodynamic decompensation and consideration for reperfusion therapy.

The risk of recurrent VTE is highest in the first few weeks after diagnosis and progressively decreases thereafter. Consequently, VTE treatment has been divided into three stages: initial therapy for the first 1 to 3 weeks, the goals of which are to prevent thrombus extension and fatal pulmonary embolism; therapy for the subsequent 3 months, which is often termed long-term therapy and is given to treat the VTE and to reduce the risk of complications, such as PTS and chronic thromboembolic pulmonary hypertension; and extended therapy beyond 3 months, which is administered when the risk of recurrent VTE without anticoagulant therapy exceeds the risk of major bleeding with continued therapy.

Severe Pulmonary Embolism

Patients with acute PE associated with hemodynamic compromise, defined as systolic blood pressure below 90 mm Hg for more than 15 minutes, or with cardiopulmonary arrest should be considered for pharmacologic, mechanical, or surgical reperfusion therapy in addition to anticoagulation therapy.[54,56] Pharmacologic reperfusion therapy involves the systemic administration of a fibrinolytic agent such as activase (tissue plasminogen activator) or tenecteplase (see Chapter 143). Up to 13% of patients given systemic fibrinolytic therapy experience a major bleed, and the rate of intracranial or fatal bleeding can reach 1.8%. Consequently, systemic fibrinolytic therapy is only justified in patients with severe pulmonary embolism without contraindications. The risk of bleeding is likely to be lower with catheter-directed or pharmacomechanical thrombolysis than with systemic fibrinolysis because lower doses of fibrinolytic agents are used with these techniques. A surgical pulmonary embolectomy is an option for patients with severe PE secondary to large proximal emboli who are at high risk for bleeding with systemic fibrinolytic therapy or who have failed such treatment.

Extensive Iliofemoral Deep Vein Thrombosis

Patients with iliofemoral DVT who present with phlegmasia or with severe leg pain and swelling may be candidates for catheter-directed or pharmacomechanical thrombolysis. Randomized clinical trials comparing these procedures with anticoagulation therapy alone have yielded mixed results.[57,58] The interventions produce a more rapid resolution of the pain and swelling but are associated with an increased risk for bleeding and have a variable effect on the risk of PTS. Therefore, catheter-directed or pharmacomechanical thrombolysis should be reserved for patients with limb-threatening DVT or severe leg pain and swelling who are at low risk of bleeding.

Anticoagulant Therapy for Acute Venous Thromboembolism

Guidelines give preference to direct oral anticoagulants (DOACs) over warfarin for the treatment of most patients with VTE (Table 140.1)[54]; special populations are discussed below. The DOACs include dabigatran, which inhibits thrombin, and apixaban, edoxaban, and rivaroxaban, which inhibit FXa (see Chapter 143). Apixaban and

TABLE 140.1 **Anticoagulant Dosing Regimens for Treatment of Venous Thromboembolism**

Anticoagulant Regimens	Venous Thromboembolism Treatment Stage		
	Initial Therapy	Long-Term Therapy	Extended Therapy
Unfractionated heparin	80 IU/kg iv bolus, then 18 IU/kg/h, with dose adjustment aiming for a hospital-specific aPTT target range	N/A	N/A
Enoxaparin	1 mg/kg twice daily or 1.5 mg/kg once daily		
Dalteparin	100 IU/kg twice daily or 200 IU/kg once daily	150 IU/kg once daily (for cancer-associated VTE)	
Tinzaparin	175 IU/kg once daily		
Warfarin	Dose adjusted to a target INR of 2.0–3.0		
Apixaban	10 mg twice daily for 7 days, followed by 5 mg twice daily	5 mg twice daily	2.5 mg twice daily
Dabigatran	After an initial 5-day course of LMWH: 150 mg twice daily Consider 110 mg twice daily if: age >75 years or creatinine clearance 30–49 mL/min		
Edoxaban	After an initial 5-day course of LMWH: 60 mg once daily 30 mg once daily if creatinine clearance 15–50 mL/min, body weight ≤60 kg or concomitant use of potent P-glycoprotein inhibitor		
Rivaroxaban	15 mg twice daily for 21 days followed by 20 mg daily		10 mg once daily

rivaroxaban are the agents most frequently used for acute VTE treatment because unlike dabigatran or edoxaban, they do not require an initial 5-day course of low-molecular-weight heparin (LMWH) prior to their initiation.

The risk of recurrence is higher in the first few weeks after the diagnosis of VTE than it is later in the course of the disease. Consequently, the initial doses of apixaban and rivaroxaban are higher than subsequent doses (see Table 140.1). Thus, apixaban is given at a starting dose of 10 mg twice daily for 7 days followed by 5 mg twice daily thereafter, whereas rivaroxaban is started at a dose of 15 mg twice daily for 21 days, followed by 20 mg once daily thereafter. If dabigatran or edoxaban is chosen, a minimum 5-day course of treatment with a parenteral anticoagulant is needed prior to their initiation at doses of 150 mg twice daily and 60 mg once daily, respectively. The dose of edoxaban is reduced to 30 mg once daily if the creatinine clearance is between 15 and 50 mL/min, the body weight is 60 kg or less, or there is concomitant use of potent P-glycoprotein inhibitors such as verapamil or dronedarone.

Warfarin is an alternative to DOACs for VTE treatment in patients taking medications such as phenytoin, carbamazepine, or ritonavir, those with antiphospholipid syndrome (see Chapter 139) or end-stage kidney disease, or for patients with body weights over 150 kg because of limited information on the efficacy of DOACs in such individuals. If warfarin is used, treatment starts with its administration together with a rapid-acting parenteral anticoagulant such as unfractionated heparin, LMWH, or fondaparinux. The drugs are overlapped for at least 5 days and the parenteral anticoagulant is stopped when the international normalized ratio (INR) is 2.0 or more for two consecutive days.

Unfractionated heparin is the parenteral agent of choice for patients with a creatinine clearance less than 30 mL/min because LMWH and fondaparinux are cleared by the kidneys. Heparin should be administered by continuous intravenous infusion and dosed using a weight-based nomogram. The dose of heparin is adjusted based on the results of the activated partial thromboplastin time (aPTT). The aPTT is determined 6 hours after starting heparin or after changing the infusion rate; once daily aPTT determination is sufficient once a therapeutic value is achieved (see Table 140.1). Rapid achievement and maintenance of a therapeutic aPTT are important to reduce the risk for recurrent VTE.

Up to 25% of patients with acute VTE have resistance to unfractionated heparin, which is defined as a requirement for higher-than-expected doses to achieve a therapeutic aPTT. If available, anti-factor Xa level monitoring is recommended in such patients. In addition to coagulation monitoring, the platelet count should be measured at least two or three times per week because of the risk for heparin-induced thrombocytopenia (see Chapter 131).

LMWH is administered in weight-based doses using prefilled syringes. Dosage regimens differ with various LMWH formulations, but once-daily administration is as effective and safe as twice-daily administration (see Table 140.1). LMWH does not require coagulation monitoring, but the determination of anti-factor Xa levels can be considered for patients with a creatinine clearance less than 30 mL/min, those with morbid obesity, and pregnant women in the second and third trimester who may require adjustment as their weight changes. Anti-factor Xa levels are usually determined on blood samples drawn 4 hours after subcutaneous injection; therapeutic ranges of 0.6 to 1.0 IU/mL for twice-daily dosing and 1.0 to 2.0 IU/mL for once-daily dosing have been proposed.

Fondaparinux is a synthetic analog of the pentasaccharide sequence required for the binding of heparin to antithrombin. The drug is given subcutaneously once daily in a weight-adjusted manner: 5 mg for a body weight below 50 kg; 7.5 mg for body weights of 50 to 100 kg, and 10 mg for body weights greater than 100 kg.

Long-Term Anticoagulant Therapy

All VTE patients require anticoagulant therapy for at least 3 months, at which point the decision to stop or extend treatment is made based on the balance between the risk of recurrence if treatment is stopped and the risk of bleeding if it is not.[54] Patient preference also needs consideration.

A 3-month course of treatment is sufficient for patients whose VTE was provoked by major transient and reversible risk factors, such as surgery or trauma, provided that these risk factors have resolved. The risk of recurrence after stopping anticoagulation treatment in such patients is about 1% at 1 year and 5% at 5 years. Women who develop VTE with estrogen therapy also can be treated for 3 months if hormonal treatment is withdrawn.

Patients with unprovoked VTE or persistent major risk factors, such as active cancer, are at higher risk for recurrence if anticoagulant therapy is stopped (at least 10% at 1 year and 30% at 5 years) and, therefore, require extended treatment unless they are at high risk for bleeding.

In patients with unprovoked VTE, an elevated D-dimer level 1 month after stopping anticoagulant therapy identifies those at higher risk for recurrence.[59] Even with a normal D-dimer level, however, men have a 1-year risk of recurrence of about 9%, which is too high to justify stopping anticoagulation therapy. In women with unprovoked VTE, the risk of recurrence in those with a normal D-dimer level 1 month after stopping anticoagulant therapy is about 5% at 1 year; only women with unprovoked VTE who are less than 65 years of age, not obese, have no evidence of PTS and have a normal D-dimer level should consider stopping anticoagulation therapy.

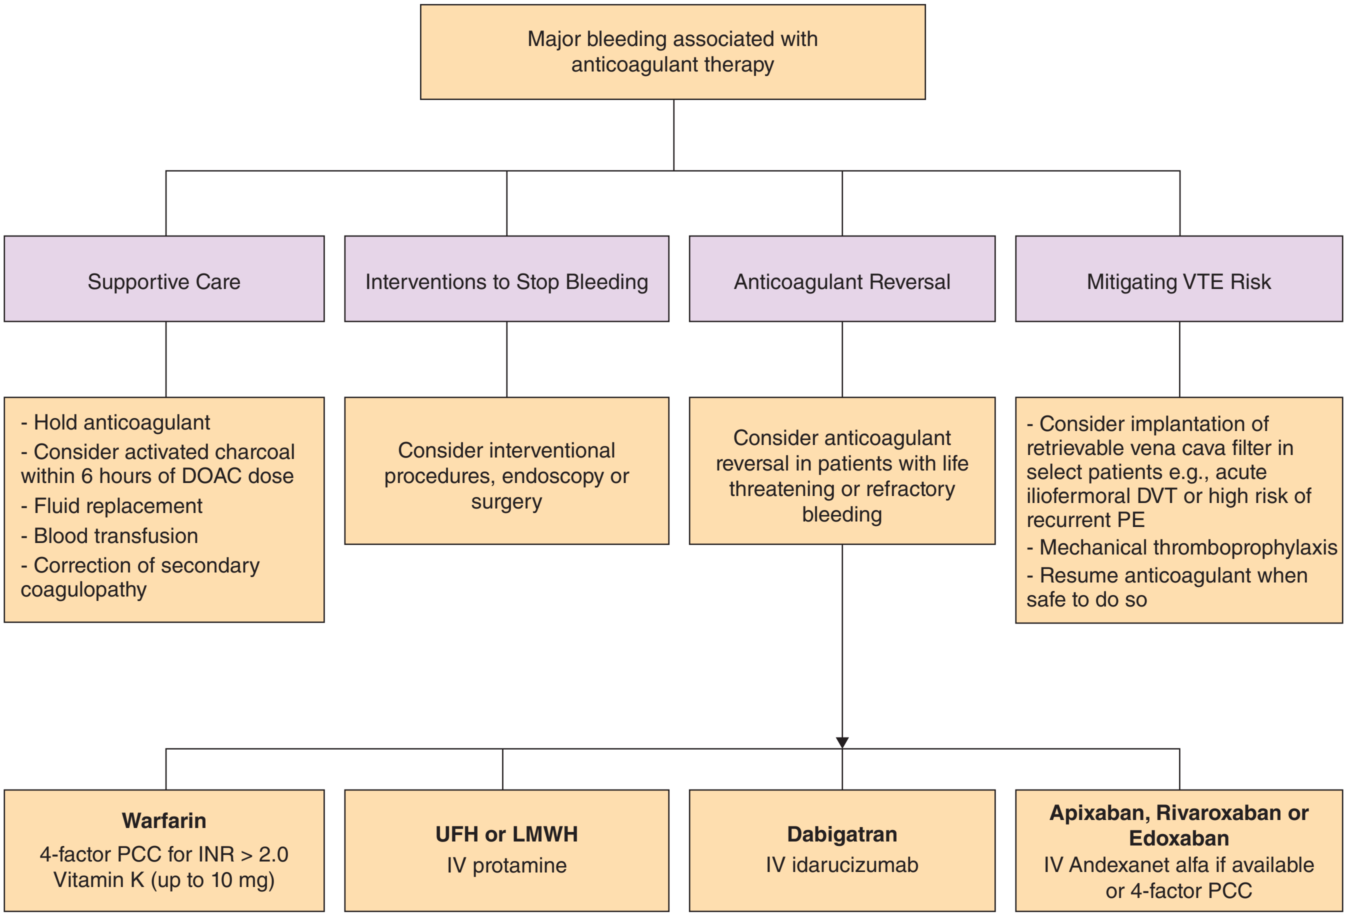
For extended anticoagulation therapy beyond 6 months, the doses of apixaban and rivaroxaban can be reduced to 2.5 mg twice daily and 10 mg once daily. If warfarin is used, the dose still needs to be adjusted to achieve a target INR of 2 to 3; adjustment to a lower target INR of 1.5 to 2 was associated with a higher rate of recurrence.

Side Effects of Anticoagulant Therapy

Bleeding is the most common side effect of anticoagulant therapy. Major bleeding, which includes intracranial, gastrointestinal, or retroperitoneal bleeding and leads to hospitalization, transfusion, and death, occurs 1% to 3% per year of patients treated with warfarin. The risk of major bleeding is lower with DOACs than with warfarin. With both warfarin and DOACs, the risk for major bleeding increases with older age, the presence of comorbid conditions (e.g., hypertension, renal impairment, previous gastrointestinal bleeding, or cancer), and the use of concomitant drugs, particularly antiplatelet agents.

An approach to the management of major bleeding is detailed in Fig. 140.2. If serious bleeding occurs with heparin or LMWH, protamine sulphate completely reverses the anticoagulant effect of heparin and partially reverses that of LMWH (see Chapter 143). For serious bleeding with warfarin, vitamin K should be given by slow intravenous infusion along with four-factor prothrombin complex concentrate to replenish the missing vitamin K-dependent clotting factors. Dabigatran is rapidly reversed with idarucizumab, a monoclonal antibody fragment that binds dabigatran with high affinity.[60] Andexanet alfa, a recombinant variant of factor Xa, reverses the anticoagulant effects of apixaban, rivaroxaban, and edoxaban as well as heparin and LMWH.[61] If andexanet alfa is not available, four-factor prothrombin complex concentrate is often given based on data from cohort studies suggesting that it is effective. Ciraparantag, a small synthetic molecule that binds DOACs and heparin, is undergoing evaluation for DOAC reversal.[62]

Heparin-induced thrombocytopenia is a life- and limb-threatening complication of heparin that occurs less frequently with LMWH and almost never with fondaparinux (see Chapter 131). Heparin and LMWH are associated with a reversible elevation in the levels of transaminases. Skin necrosis (see Chapters 137 and 142) and blue toes (see Chapter 142) are rare complications with warfarin.



Major bleeding associated with anticoagulant therapy
Supportive Care
Interventions to Stop Bleeding
Anticoagulant Reversal
Mitigating VTE Risk
- Hold anticoagulant
- Consider activated charcoal within 6 hours of DOAC dose
- Fluid replacement
- Blood transfusion
- Correction of secondary coagulopathy
Consider interventional procedures, endoscopy or surgery
Consider anticoagulant reversal in patients with life threatening or refractory bleeding
- Consider implantation of retrievable vena cava filter in select patients e.g., acute iliofermoral DVT or high risk of recurrent PE
- Mechanical thromboprophylaxis
- Resume anticoagulant when safe to do so
Warfarin
4-factor PCC for INR > 2.0
Vitamin K (up to 10 mg)
UFH or LMWH
IV protamine
Dabigatran
IV idarucizumab
Apixaban, Rivaroxaban or Edoxaban
IV Andexanet alfa if available or 4-factor PCC

Figure 140.2 MANAGEMENT OF BLEEDING IN PATIENTS TAKING ANTICOAGULANTS. *DOAC*, Direct oral anticoagulant; *FEIBA*, factor eight inhibitor bypass agent; *LMWH*, low-molecular-weight heparin; *PCC*, prothrombin concentrate complex; *UFH*, unfractionated heparin.

VENOUS THROMBOEMBOLISM MANAGEMENT IN SPECIFIC POPULATIONS

Cancer-Associated Venous Thromboembolism

Cancer and its treatment increase the risk for VTE, and VTE is the second most common cause of death after tumor progression in cancer patients. Reduced mobility, venous compression by tumor central venous catheters, expression of tissue factor and other procoagulants by cancer cells, and chronic inflammation contribute to the increased risk of VTE in cancer patients. Therefore, the index of suspicion should be high in cancer patients who present with symptoms and signs suggestive of DVT or PE. Imaging for the staging of cancer may reveal incidental PE or DVT, which also requires treatment.

In patients with cancer-associated VTE, LMWH reduces the risk of recurrence more effectively than warfarin without significantly increasing the risk of bleeding. However, LMWH is more expensive than warfarin, and adherence is limited because of the need for daily subcutaneous injections. DOACs are more effective than LMWH for the treatment of cancer-associated VTE but are associated with more bleeding in patients with gastroesophageal cancer, unresected colorectal cancer, or urothelial cancers. Thrombocytopenia (platelet count below 50,000/μL) and metastatic disease to the brain, particularly with melanoma or renal cell cancer, also increase the risk for bleeding.

LMWH may be a better choice than DOACs for VTE treatment in patients at risk of bleeding. A prophylactic dose of LMWH can be used if the platelet count is between 30,000 and 50,000/μL, and the full dose is used once the count rises above 50,000/μL. If there is no bleeding after several weeks of treatment with LMWH, switching to a DOAC can be considered.

Patients with cancer-associated VTE require continued anticoagulation treatment if they have active cancer or are receiving ongoing cancer treatment.[63] The lower dose regimens of apixaban and rivaroxaban used for secondary prevention have not been evaluated in patients with active cancer. Until more data are available, therefore, the full dose regimens should be used.

Venous Thromboembolism in Pregnancy

Warfarin and DOACs are contraindicated in pregnancy. The approach to the prevention, diagnosis, and treatment of VTE in pregnancy is detailed in Chapter 141.

Antiphospholipid Syndrome

Antiphospholipid syndrome is associated with a hypercoagulable state and an increased risk of venous and arterial thrombosis (see Chapter 138 and 139). In patients with VTE in the setting of triple-positive antiphospholipid syndrome, defined by the presence of a lupus anticoagulant and increased levels of anticardiolipin and anti-β2-glycoprotein I antibodies, randomized trials revealed a higher risk of recurrence with DOACs than with warfarin.[64,65] Therefore, warfarin should be used for treatment in these patients (see Chapter 139). Patients with antiphospholipid syndrome have a high risk of recurrence if anticoagulation therapy is stopped. Therefore, indefinite anticoagulation is recommended.

Diagnosis and Treatment of Recurrent Venous Thromboembolism

The diagnosis of recurrent VTE is challenging.[45] A history of DVT increases the pretest probability of recurrence and reduces the diagnostic specificity of ultrasonography because, with proximal DVT, residual ultrasound abnormalities are found in up to 50% of patients 1 year after the index event. Consequently, compression ultrasonography in such patients is useful only if the comparison with a previous examination shows the involvement of a new venous segment. An elevated D-dimer level also suggests recurrence.

For patients with suspected recurrent PE, a normal D-dimer level helps to exclude the diagnosis. If the D-dimer test is positive, imaging with CTPA should be undertaken. CTPA is preferred over V/Q scanning for diagnosis of recurrence because filling defects detected by CTPA usually resolves with anticoagulation treatment, whereas perfusion defects detected by V/Q scanning are often persistent.

When assessing patients with suspected recurrent VTE who are on anticoagulant therapy, the adequacy of such treatment is an important consideration (e.g., nonadherence, subtherapeutic INR values, interruptions for procedures or surgery). Recurrent thrombosis despite adequate therapeutic anticoagulation occurs most commonly in patients with cancer, antiphospholipid syndrome (see Chapters 138 and 139), or heparin-induced thrombocytopenia (see Chapter 131).

Strategies for managing patients with recurrent VTE despite anticoagulation include LMWH, higher-intensity warfarin, or higher doses of DOACs. The anticoagulant dose can be increased to full dose in patients who were receiving lower dose regimens of LMWH, apixaban, or rivaroxaban for secondary prophylaxis. If recurrent VTE occurs despite full-dose LMWH, the drug can be given twice daily instead of once daily, and the dose can be increased by 25%; the anti-factor Xa level should be quantified to ensure that a therapeutic level is achieved. LMWH also is an option for the treatment of breakthrough VTE in patients who were taking full doses of DOACs; such patients can be considered for a switch back to DOACs after at least a month of successful treatment with LMWH. Patients with breakthrough thrombosis despite warfarin can be switched to a DOAC, or the dose of warfarin can be increased to obtain a higher target INR (e.g., 2.5 to 3.5).

Vena Cava Filters

Inferior vena cava filters, which are inserted percutaneously, are useful for patients at high risk for PE who have contraindications for anticoagulation therapy, such as recent surgery or major bleeding, or for those with a recent diagnosis of VTE who require major surgery (see Fig. 140.2). Retrievable filters should be used in these cases, and the devices should be removed as soon as anticoagulant therapy can safely be administered.

Long-Term Complications

Post-Thrombotic Syndrome

The initial pain and swelling in patients with DVT are caused by venous obstruction and inflammation. Acute obstruction usually resolves with anticoagulation therapy once recanalization occurs, and collateral venous channels develop. Venous hypertension develops if there is residual venous obstruction and incompetence of the venous valves. Venous hypertension, the hallmark of PTS, develops in up to 50% of patients with proximal DVT, usually 6 months to 2 years after the event.[66] The syndrome is characterized by dependent pain and swelling that is worse at the end of the day and is relieved with leg elevation.

Compression stockings do not prevent PTS. Therefore, their use can be delayed until the acute inflammatory process and outflow obstruction have subsided. Lifestyle alterations such as frequent leg elevation, avoidance of prolonged standing or sitting, and occasional use of analgesics will relieve symptoms in many patients. If symptoms are severe, a lightweight stocking can be helpful until the edema improves. A stocking that applies 30 to 40 mm Hg of pressure at the ankle can be prescribed if symptoms persist or worsen despite these measures.

Venous ulcers, the most severe complication of PTS, typically occur in the perimalleolar area. The best management is prevention by application of graduated compression stockings if skin changes develop in association with leg swelling. Treatment of ulcers consists of an emollient and regular leg wrapping. After the ulcer heals, graduated compression stockings should be prescribed. Surgical closure or removal of incompetent saphenous veins does not accelerate ulcer healing time compared with dressings alone but reduces the risk of recurrence.

Chronic Thromboembolic Pulmonary Hypertension

A rare complication of PE, CTEPH develops in 0.5% to 5% of patients over the course of months or years when emboli in major pulmonary arteries are replaced by fibrous tissue that becomes incorporated into the vessel walls, thereby narrowing or obstructing them.[67] Chronic obstruction of the pulmonary vascular bed increases pulmonary arterial resistance and can lead to right heart failure. Although patients may be asymptomatic at first, they experience increasing dyspnea on exertion and hypoxemia as the disease progresses. CTEPH should be suspected in patients with pulmonary hypertension, and the diagnosis is established with a combination of echocardiography, V/Q scanning, and CTPA.

Patients with CTEPH require lifelong anticoagulation therapy. Definitive treatment involves surgical thromboendarterectomy to remove the occluding material from the pulmonary arteries. For patients too sick for surgery, balloon pulmonary angioplasty may be considered. Medical therapy focuses on the treatment of right heart failure and the use of prostacyclin analogs or soluble guanylate cyclase stimulators.

PSYCHOSOCIAL CONSIDERATIONS

Long-term studies suggest that up to 50% of patients with PE report functional limitations and reduced quality of life for many years after their index event. The term post-PE syndrome has been used to describe patients with dyspnea, exercise limitation, and impaired quality of life that persists for more than 3 months despite anticoagulation therapy. The syndrome encompasses patients with CTEPH, chronic thromboembolic disease (CTED), and dyspnea with functional limitations but without evidence of pulmonary vascular disease.[68]

CTEPH is defined by the presence of a mean pulmonary artery pressure of 25 mm Hg or greater, mismatched perfusion defects on the V/Q scan, and specific findings on CTPA or magnetic resonance angiography. Patients with CTED have exercise limitations and imaging findings like those with CTEPH but do not meet the criteria for pulmonary hypertension. The incidence of CTED is unknown, but it likely affects less than 5% of patients with PE. Post-PE syndrome, persistent dyspnea with functional limitation, is common and its pathophysiology is poorly understood. CTEPH can be excluded with a normal V/Q scan and echocardiogram and other causes of dyspnea should be explored. A cardiopulmonary rehabilitation program or self-monitored exercise program may be beneficial. With ongoing symptoms, stopping anticoagulation therapy is problematic because patients may present with suspected recurrent PE and require repeated imaging tests. More work on this entity is needed.

PREVENTION OF VENOUS THROMBOEMBOLISM

More than half of the VTE events that occur each year in the United States are related to recent hospitalization or institutionalization, and up to 75% of all fatal PEs are associated with recent hospitalization. Therefore, VTE is the number one cause of preventable death in hospitalized patients. Consequently, the risk of VTE should be assessed in all hospitalized patients and if indicated, appropriate thromboprophylaxis should be administered.[69,70]

Despite the plethora of large, randomized trials demonstrating the efficacy and safety of mechanical and pharmacologic measures for reducing the risk of VTE in hospitalized patients, prophylaxis remains underused. Factors that increase the risk for DVT include surgery (particularly major orthopedic surgery and neurosurgery), major trauma, prolonged bed rest or immobilization, previous history of VTE, cancer, heart failure, paralysis or paresis, morbid obesity, advanced age, admission for COVID-19 or other forms of pneumonia, and elevated D-dimer levels.

Unfractionated heparin or LMWH is the mainstay of in-hospital thromboprophylaxis. Mechanical prophylaxis (anti-embolic stockings and intermittent pneumatic compression) should be used as an adjunct to pharmacologic prophylaxis or as standalone prophylaxis in patients at high risk for bleeding. Thromboprophylaxis should be continued until hospital discharge and extended for 30-days after discharge in patients undergoing hip or knee arthroplasty, surgery for hip fracture, or major pelvic or abdominal surgery for cancer. Selected medically ill patients may also benefit from extended thromboprophylaxis including those with elevated D-dimer levels or severe COVID-19 infection. Low-dose rivaroxaban (10 mg once daily) can be used in place of LMWH in such patients to simplify out-of-hospital thromboprophylaxis.

CHAPTER 141

PREVENTION AND TREATMENT OF VENOUS THROMBOEMBOLISM IN PREGNANCY

Leslie Skeith and Shannon M. Bates

Pregnant persons and those who are postpartum are at increased risk of venous thromboembolism (VTE). Although pregnancy-related VTE can affect any part of the venous circulation, as in the non-pregnant population, it most commonly manifests as deep vein thrombosis (DVT) or pulmonary embolism (PE). Management of pregnancy-related VTE is complicated as the diagnosis, prevention, and treatment of pregnancy-related VTE must consider fetal, as well as maternal, well-being. Moreover, there are limited high-quality data to help clinicians manage this patient population.

EPIDEMIOLOGY

VTE is a cause of significant maternal morbidity and mortality globally. The incidence of pregnancy-related VTE has been estimated at 1.2 per 1000 deliveries (95% confidence interval [CI], 0.6 to 1.8).[1] Although this absolute risk is low, VTE is responsible for 3.2% of all maternal deaths.[2] In higher-income countries, where death from obstetrical hemorrhage is less common, that figure is 13.8%.[2]

In a meta-analysis of 20 studies, the pooled incidence of VTE was similar in each of the antepartum and postpartum periods at 0.6 per 1000 pregnant persons.[1] Given the shorter length of the postpartum period, the daily risk is substantially higher after delivery (15- to 35-fold increase in relative risk) than during pregnancy (5- to 10-fold relative risk increase).[3] The daily VTE risk is highest in the first three to six weeks after delivery, although a small absolute risk increase may be seen up to 12 weeks after delivery.[1,4]

Risk Factors

The most important risk factor for pregnancy-associated VTE is a prior history of venous thrombosis, which increases the risk of VTE antepartum to 4.2% (95% CI, 0.3% to 6.0%) and postpartum to 6.5% (95% CI, 4.3% to 9.7%).[5,6] The risk of antepartum recurrence has been reported to vary according to provoking factors present at the initial event, with estimated risks of 6.4% (95% CI, 3.9% to 10.4%), 3.6% (95% CI, 1.4% to 8.9%), and 1.1% (95% CI, 0.2% to 5.8%) in those with a history of hormonal-associated, unprovoked, and provoked (nonhormonal temporary risk factor) events, respectively.[5,6]

Inherited thrombophilias are also important risk factors, especially when accompanied by a family history of VTE (Table 141.1).[5] While there have been many studies evaluating the association between hereditary thrombophilias and pregnancy-related VTE, the impact of acquired thrombophilias has been less well investigated in this setting. The most common acquired thrombophilia is antiphospholipid syndrome (see Chapter 139). There are few data on the risk of pregnancy-associated VTE in those with antiphospholipid antibody positivity and no prior thrombosis history; however, in those with obstetrical antiphospholipid syndrome, it has been estimated at 0% (95% CI, 0% to 1.2%) antepartum and 1.1% (95% CI, 0.2%% to 6.2%) postpartum.[7]

Many clinical risk factors have been shown to increase the risk of pregnancy-associated VTE[5]; however, most, including cesarean delivery, have only a small effect with absolute risks far less than 1% in each of the antepartum and postpartum periods.[5,8] How combinations of independent risk factors might affect overall VTE risk has not been well studied, although one might reasonably expect that combinations of factors might result in more significant risks. Factors with estimated antepartum or postpartum VTE risks greater than 1% are listed in Table 141.2.

PATHOPHYSIOLOGY

The pathophysiology of pregnancy-associated VTE can be related to Virchow's triad.[6] Changes in hemostasis include alterations in levels of coagulation factors and natural inhibitors of coagulation that favor thrombosis (increased levels of factor VIII and factor X, von Willebrand factor, and fibrinogen, as well as decreased protein S levels) and a reduction in fibrinolytic activity (increased activity of plasminogen activator inhibitors-1 and -2 and decreased tissue plasminogen activator activity). VTE risk is also heightened by decreased lower extremity venous flow resulting from hormonally mediated increases in lower limb venous distensibility and capacity, as well as by compression of the pelvic veins by the gravid uterus and of the left iliac vein by the right iliac artery. Damage to the endothelium may occur from venous distension and at the time of delivery.

CLINICAL MANIFESTATIONS

The clinical manifestations of pregnancy-associated VTE can be similar to those in the non-pregnant population and include lower extremity pain, tenderness, and swelling for DVT and chest pain, dyspnea, tachypnea, tachycardia, palpitations, hemoptysis, pre-syncope/syncope, and apprehension for PE. Symptoms or signs of lower extremity DVT occur in less than 25% of pregnant persons with proven PE.

Differences in VTE presentation during pregnancy include a predilection for left leg DVT (greater than 80% of cases during pregnancy) and for isolated iliac and/or femoral vein thrombosis.[9] These latter events usually present with back, flank, or buttock pain and swelling and discoloration of the entire leg.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for DVT includes venous insufficiency, superficial vein thrombosis, cellulitis, hematoma, ruptured Baker's cyst, congestive heart failure, and tumor. The differential diagnosis for PE is extensive and includes pneumonia, pleurisy, congestive heart failure, pneumothorax, musculoskeletal pain, and myocardial infarction. Of course, symptoms like those of VTE are common even in uncomplicated pregnancies and are not usually due to DVT or PE. It is, therefore, important to ask about sudden changes or worsening in symptoms and to be vigilant for associated features of VTE out of keeping with normal pregnancy.

Studies in which pregnant women with symptoms suggestive of DVT or PE underwent appropriate testing report a prevalence of VTE of less than 10%. However, healthcare providers must have a high index of suspicion for VTE when a pregnant woman presents

TABLE 141.1 **Asymptomatic Hereditary Thrombophilia and Risk of Pregnancy-Associated Venous Thromboembolism**

Thrombophilia	Antepartum Risk	Postpartum Risk
Positive Family VTE History [Absolute risk (95% CI)[a]]		
Antithrombin deficiency	2.70% (95% CI, 0%–8.53%)	4.83% (95% CI, 0%–15.65%)
Protein C deficiency	1.63% (95% CI, 0%–5.02%)	1.06 (95% CI, 0%–4.09%)
Protein S deficiency	0% (95% CI, 0%–1.46%)	1.76% (95% CI, 0%–5.99%)
Factor V Leiden, heterozygous	0.50% (95% CI, 0.06%–1.21)	0.62% (95% CI, 0%–1.90%)
Factor V Leiden, homozygous	6.88% (95% CI, 1.04%–15.83%)	5.87% (95% CI, 0.57%–14.44%)
Prothrombin mutation, heterozygous	0 (95% CI, 0%–0.73%)	0.95% (95% CI, 0%–3.26%)
Prothrombin mutation, homozygous	No data, likely at least as high as in those with no family history	No data, likely at least as high as in those with no family history
Combined thrombophilia	0 (95% CI, 0%–2.35%), although risk likely at least as high as in those with no family history	1.06% (95% CI, 0%–5.30%)
Negative Family VTE History [Risk Ratio (95% CI); Estimated absolute risk[b]]		
Antithrombin deficiency	OR: 6.09 (95% CI, 1.58–23.43) Absolute risk: 0.36%	OR: 6.09 (95% CI, 1.58–23.43) Absolute risk: 0.36%
Protein C deficiency	OR: 4.8 (95% CI, 2.2–10.6) Absolute risk: 0.3%	OR: 4.8 (95% CI, 2.2–10.6) Absolute risk: 0.3%
Protein S deficiency	OR 3.2 (95% CI, 1.5–6.9) Absolute risk: 0.2%	OR 3.2 (95% CI, 1.5–6.9) Absolute risk: 0.2%
Factor V Leiden, heterozygous	OR: 4.6 (95% CI, 2.6–7.9) Absolute risk: 0.28%	OR: 4.6 (95% CI, 2.6–7.9) Absolute risk: 0.28%
Factor V Leiden, homozygous	OR: 34.4 (95% CI, 9.9–120.1) Absolute risk: 2.06%	OR: 34.4 (95% CI, 9.9–120.1) Absolute risk: 2.06%
Prothrombin mutation, heterozygous	OR: 5.43 (95% CI, 3.66–8.03) Absolute risk: 0.32%	OR: 5.43 (95% CI, 3.66–8.03) Absolute risk: 0.32%
Prothrombin mutation, homozygous	OR: 26.4 (95% CI, 1.2–559.3) Absolute risk: 1.6%	OR: 26.4 (95% CI, 1.2–559.3) Absolute risk: 1.6%
Combined thrombophilia (for factor V Leiden and prothrombin gene mutation, compound heterozygosity)	OR: 47 (95% CI, 26–84) Absolute risk: 2.82%	OR: 47 (95% CI, 26–84) Absolute risk: 2.82%

[a] Risks from family cohort studies, estimates of absolute risk (95% CI).

[b] Risks from case control studies, absolute risk estimated by OR × baseline VTE risk of 0.6/1000 pregnancies.

CI, Confidence interval; *OR*, odds ratio.

Data from Bates SM, Rajasekhar A, Middeldorp S, et al. American Society of Hematology 2018 guidelines for management of venous thromboembolism: venous thromboembolism in the context of pregnancy. *Blood Adv.* 2018;2(22):6–8.

with these symptoms since missing a diagnosis exposes the patient to the risk of fatal PE.

LABORATORY MANIFESTATIONS

While D-dimer levels are instrumental in guiding the investigation of suspected VTE in the nonpregnant population, there is less of a role for D-dimer measurements in the pregnant population. The majority of pregnant patients have an elevated D-dimer, especially as pregnancy progresses. However, D-dimer values are significantly higher in pregnant patients who have confirmed DVT, compared with pregnant patients without DVT.[10] While higher D-dimer cutpoints or trimester specific D-dimer levels have been proposed to improve the utility of D-dimer values during pregnancy, these strategies have not been validated. D-dimer levels should not be used in isolation to evaluate a pregnant woman with suspected DVT or PE. A systematic meta-analysis that investigated the safety of D-dimer to rule out VTE in pregnant persons reported a high sensitivity and negative predictive value for the assay[11]; the authors suggested that their results suggest that D-dimer can safely rule out VTE during pregnancy when the disease prevalence is consistent with a low/intermediate or unlikely pre-test probability. However, the number of studies (three prospective, one retrospective) and subjects with VTE ($n = 69$) were small and only two of the included studies were prospective management studies. Recent advances in the use of D-dimer in combination with clinical prediction rules in pregnant patients are described below.

Diagnosing Suspected Deep Vein Thrombosis in Pregnancy

Imaging with a compression Doppler ultrasound of the leg is the recommended first test to evaluate suspected DVT in pregnancy. Because the majority of DVTs in pregnancy start in the pelvic veins and progress distally, ultrasonography should include evaluation of the iliac veins. If there is high clinical suspicion for isolated iliac vein thrombus after an initial negative leg ultrasound, then magnetic resonance imaging (MRI) of the pelvic veins should be considered where available.[5] In a large database study, there was no increased risk of pregnancy loss, congenital anomaly, neoplasm or hearing loss

TABLE 141.2 Clinical Risk Factors for Pregnancy-Associated Venous Thromboembolism With Estimated Risks of Greater Than 1%

Clinical Risk Factor	Adjusted Odds Ratio (95% CI) from Case Control Studies and Estimated Absolute Risk (%)[a]	Absolute Risk % (95% CI)
Antepartum		
Prior venous thromboembolism		4.2% (95% CI, 0.3%–6.0%)
• Hormonal–related		6.4% (95% CI, 3.9%–10.4%)
• Unprovoked		3.6% (95% CI, 1.4%–8.9%)
• Non-hormonal provoking factor		1.1% (95% CI, 0.2%–5.8%)
Immobility[b] with prepregnancy BMI $\geq$25 kg/m^2	OR: 62.3 (95% CI: 11.5–337.0) Estimated absolute risk: 3.8%	
Dermatomyositis	OR: 24.07 (95% CI: 5.93–97.70) Estimated absolute risk: 1.9%	
Severe ovarian hyperstimulation syndrome or ovarian hyperstimulation syndrome requiring hospitalization		1.6%–6.6%
Myeloid leukemia	OR: 20.75 (95% CI: 6.61–65.12) Estimated absolute risk: 1.3%	
Postpartum		
Prior venous thromboembolism		6.5% (95% CI, 4.3–9.7%)
Immobility[b] with prepregnancy BMI $\geq$25 kg/m^2	OR: 40.1 (95% CI: 8.0–201.5) Estimated absolute risk: 2.4%	
Infection[c] following vaginal delivery	OR: 20.2 (95% CI: 6.4–63.5) Estimated absolute risk: 1.2%	

[a] Absolute risk estimated by OR × baseline VTE risk of 0.6/1000 pregnancies.
[b] Immobility classified as strict bedrest for $\geq$1 week in the antepartum period.
[c] Infection defined as clinical signs/symptoms with fever and elevated white blood cell count.
BMI, Body mass index; *CI*, confidence interval; *OR*, odds ratio.
Data from Bates SM, Rajasekhar A, Middeldorp S, et al. American Society of Hematology 2018 guidelines for management of venous thromboembolism: venous thromboembolism in the context of pregnancy. *Blood Adv.* 2018;2(22):6–8; and Bates SM, Middeldorp S, Rodger M, et al. Guidance for the treatment and prevention of obstetric-associated venous thromboembolism. *J Thromb Thrombolysis.* 2016;41(1):92–128.

in children with first trimester MRI exposure.[12] However, non-gadolinium techniques should be used and gadolinium avoided when possible due to reported side effects of pregnancy loss, rheumatological, inflammatory, or infiltrative skin disorders and the rare complication of nephrogenic systemic fibrosis.[12] If the initial ultrasound is negative, then a repeat clinical assessment and serial leg ultrasounds with iliac imaging three to seven days later is recommended to ensure no progressive DVT is missed.[5] If isolated iliac vein thrombosis is suspected and MRI is not available, a repeat ultrasound can be performed sooner, and consideration should be given to empiric anticoagulation until a negative follow-up test is obtained. A strategy of a single whole leg ultrasound (including the calf veins) with imaging of the iliac veins is used in some centers, but the upper bound of the 95% CI around the risk estimate for missed VTE (1.4%; 95% CI, 0.3% to 4.9%) was greater than that generally accepted.[5] In a systematic review of eight studies that evaluated the utility of serial ultrasonography after a single negative proximal or whole leg ultrasound with iliac vein imaging in pregnant patients with suspected DVT, the false negative frequency for a single ultrasound was 1.3% (95% CI, 0.4% to 2.6%), and a follow-up DVT was diagnosed on fewer than 1% of serial tests.[13] There were insufficient data to compare a whole leg versus proximal ultrasound strategy. Given the relatively small sample size, high upper bound 95% CI, and the lack of a confirmatory patient management study showing the safety of a single proximal ultrasound with iliac vein imaging, a serial ultrasound approach that includes imaging of the iliac veins is still recommended in most cases. However, this information can be used to counsel patients in shared decision making regarding the need to return for follow-up tests.

Diagnosing Suspected Pulmonary Embolism in Pregnancy

A clinical prediction rule to evaluate suspected DVT in pregnancy called the LEFt rule (Left leg, Edema of calf circumference of 2 centimeters or over, and a First Trimester presentation)[9] has been developed. Research is ongoing to prospectively validate the use of the LEFt rule in combination with D-dimer (LEaD: clinicaltrials.gov ID NCT02507180) in pregnant persons with suspected DVT.

Until recently, there were no validated clinical prediction rules to evaluate suspected PE in the pregnant population and, consequently, advanced chest imaging was the recommended first test in all patients. Ventilation/perfusion (V/Q) lung scanning and computed tomography pulmonary angiography (CTPA) have similar diagnostic accuracy for PE and frequency of nondiagnostic test results in pregnancy.[5] While the fetal radiation dose is typically higher with V/Q scanning than with CTPA, levels with both are below the threshold of radiation exposure of 50 mGy (5 cGy). Above this level, there is up to a twofold increase in the risk of childhood malignancy; only in higher doses (100 to 200 mGy) are major malformations seen.[5,8] V/Q scanning is often the preferred test, if available locally, because there is less radiation exposure to the breast tissue and a theoretically lower breast cancer risk over time, compared to that with CTPA scanning.[5,8] Newer generation CT scanners and different CTPA scan protocols may minimize the amount of radiation exposure, and some scintigraphy protocols include perfusion only, lower radioisotope dose, or no accompanying chest radiograph. However, how these protocols affect diagnostic accuracy of PE is less well known and they may lead to a higher proportion of non-diagnostic scans. Some diagnostic algorithms and guidelines suggest completing bilateral compression doppler leg ultrasounds prior to any chest imaging, however, the yield for detecting asymptomatic DVT is very low, and imaging may still miss thrombosis of the pelvic veins.

Two recent large prospective studies have demonstrated the safe use of clinical prediction rules in combination with D-dimer testing in the pregnant population. In the first, women with none of the YEARS criteria (clinical signs of DVT, hemoptysis, or PE as the most likely diagnosis) and D-dimer < 1000 ng/mL or one or more YEARS criteria and D-dimer < 500 ng/mL had chest imaging withheld.[14] Patients with clinical signs of DVT first underwent compression ultrasonography of the symptomatic leg, and if DVT was present then treatment was initiated, and no chest imaging performed. Among the 195 patients that avoided CT chest imaging, symptomatic VTE was diagnosed during three months of follow-up in 0.51% (95% CI, 0.09% to 2.9%). Furthermore, among the 494 patients in whom DVT was not diagnosed at baseline, CTPA was avoided in close to 40% of patients.[14] In the second study, CTPA was safely avoided in 12% of the study patients with a low or intermediate clinical pretest probability of PE using the revised Geneva score and D-dimer less than 500 ng/mL (frequency of symptomatic VTE after three months of follow-up was 0% [95% CI, 0% to 8.0%]).[15]

There are limitations to these clinical prediction rules that require further study. Clinical gestalt is still required with the YEARS algorithm for the "PE as the most likely diagnosis" criterion. The revised Geneva score also applies imperfectly to pregnant persons as it includes an item for "age greater than 65 years." Nevertheless, data from these prospective studies suggest that D-dimer results in combination with clinical pretest probability can safely exclude PE in a significant proportion in pregnant patients without the need for radiologic imaging.

If a clinical prediction score is used for suspected PE in pregnancy, we recommend use of the YEARS algorithm (including lower extremity ultrasounds in those with leg symptoms) to avoid advanced chest imaging in the largest proportion of patients. Of the two strategies described in the text, the YEARS algorithm had the most robust estimate for VTE frequency after three months of follow-up and it has also been retrospectively validated using data from the other study described in the text that used the revised Geneva score in combination with D-dimer.

PROGNOSIS

The case fatality rate of pregnancy-related VTE has been estimated at 0.68% (95% CI, 0.41% to 0.96%), while that for PE is 2.00% (95% CI, 1.44 to 2.56).[1] Patients who develop iliofemoral thrombosis, which is more common in pregnancy, are more likely to develop post-thrombotic syndrome, a condition that can be associated with chronic swelling, discomfort, discoloration and, less commonly, leg ulceration. In a large case control study, 42% of women with pregnancy-associated DVT had some degree of post-thrombotic syndrome with strong predictors that included proximal DVT in the postpartum period, advanced age, and smoking.[16] Patients rarely develop chronic thromboembolic pulmonary hypertension (CTEPH) and, more commonly, have a continued reduction in exercise capacity after PE (post-PE syndrome), although data on both in the pregnant population are lacking. PE can have significant psychosocial effects, including anxiety, post-traumatic or a panic-like syndrome. Younger patients typically report a greater impact than older patients,[17] and it would be reasonable to hypothesize that this would be even greater during stressful periods like pregnancy and postpartum.

THERAPY

Anticoagulant Use During Pregnancy

While unfractionated heparin (UFH) and low molecular weight heparin (LMWH) do not cross the placenta and are safe for the fetus, LMWH is preferred because of its improved bioavailability, longer drug half-life, more predictable dose response, and improved safety profile (see Chapter 143).[5] Side effects of LMWH include antepartum bleeding (~1.4%), early postpartum bleeding (~1.9%), adverse skin reactions, wound hematomas, and rarely heparin-induced thrombocytopenia (HIT; see Chapter 131).[18] Longer-term use of therapeutic-dose LMWH may lead to reduced bone mineral density, but this has not been found with prophylactic doses of LMWH.[5,8] Because of the rare but serious risk of epidural hematoma and associated hemiplegia, it is recommended that neuraxial anesthesia be delayed at least 24 hours after the last dose of therapeutic LMWH and 12 hours after the last dose of prophylactic LMWH.[5,8]

In the setting of previous or active HIT, use of danaparoid is recommended if it is available because it does not cross the placenta and is safe for the fetus (see Chapter 131). As fondaparinux does cross the placenta in small amounts and safety data are primarily limited to case series with exposure later in pregnancy, its use should be avoided (especially early in pregnancy) unless there is no safe alternative. Switching to a different LMWH formulation improves skin reactions in many cases.

Vitamin K antagonists (VKAs) like warfarin carry a known risk of congenital anomalies, fetal hemorrhage, and pregnancy loss and so should be avoided in pregnancy for VTE indications, as safe and effective alternatives like LMWH are available.[8] Warfarin embryopathy typically occurs with exposure between 6 and 12 weeks' gestation and includes nasal hypoplasia, stippled epiphyses and, less commonly, limb hypoplasia. Other congenital anomalies including central nervous system malformations have been reported with VKA use during pregnancy.[8]

Direct oral anticoagulants (DOACs) cross the placenta and animal exposure studies indicate a risk of reproductive toxicity, including implantation loss, congenital malformations, altered ossification, and hemorrhage. To date, limited clinical data (predominantly with rivaroxaban) do not show a specific pattern of fetal anomalies, with rates of congenital anomalies similar to those seen in the general pregnant population; however, more research is still needed.[19] Based on guidance from the International Society on Thrombosis and Haemostasis (ISTH), exposure to a DOAC in pregnancy does not warrant elective termination of pregnancy but pregnant persons with DOAC exposure should be switched to LMWH as soon as possible.[20]

Patients receiving long-term VKA or DOAC therapy should be counselled about associated fetal risks with exposure and the need to seek medical attention as soon as possible with a positive pregnancy test. A pregnancy-specific anticoagulant management plan should be developed prior to any planned pregnancy.[6] Options include conversion to LMWH before conception is attempted (which may result in extended LMWH exposure) and performance of frequent pregnancy tests with substitution of LMWH as soon as possible once pregnancy is achieved. Given the paucity of data regarding the risk of embryopathy with DOAC therapy, ISTH guidance recommends a transition to LMWH or VKA prior to conception.[20]

Anticoagulant Therapy

In a patient with a new confirmed DVT or PE diagnosed in pregnancy, initial weight-based therapeutic dose LMWH is recommended. A systematic review involving the nonpregnant population and limited data in pregnancy suggest no difference in bleeding or efficacy with once or twice daily dosing regimens and guidance documents suggest that either approach is acceptable.[5,8] The recent American Society of Hematology (ASH) guidelines have suggested against the routine use of anti-Xa level monitoring given resource and cost implications, lack of test reliability, lack of clinical outcome data, and absence of validated anti-Xa level therapeutic ranges in pregnancy.[5]

There is wide practice variation with respect to LMWH dosing and the role of anti-Xa level monitoring in pregnancy. Consideration may be given to using peak anti-Xa levels to direct dosing in selected cases such as those with antithrombin deficiency and early in therapy in those with extensive VTE, recurrent VTE while on therapeutic dose anticoagulation, or extreme over or under body weight although clinical outcome data are lacking. There is a limited role for checking trough anti-Xa levels, but this can be considered in renal insufficiency to exclude drug accumulation.

Interventional Management of Venous Thromboembolism in Pregnancy

Evidence for the use of systemic or catheter directed thrombolysis in this patient population is limited to case reports and case series. Because of concerns about both maternal bleeding and fetal complications, pregnancy is often considered a relative contraindication to thrombolysis; however, patients should not be denied potentially life-saving therapy just because they are pregnant. Systemic thrombolysis in pregnancy should be reserved for patients with life-threatening hemodynamic instability or limb-threatening compromise.[5] There are limited data on the use of catheter-directed thrombolysis in pregnancy because of the associated radiation risks. Extrapolation from randomized controlled data in the non-pregnant population highlights an important bleeding risk. Given high risks of major obstetrical bleeding with use thrombolytic therapy following delivery, if available, thrombectomy may be preferred over systemic thrombolysis during the immediate postpartum period.

Inferior vena cava (IVC) filter placement is technically more challenging during pregnancy because of anatomic changes, including dilation of the IVC, and concerns about fetal radiation exposure during fluoroscopy. Filter thrombosis and IVC penetration may be more common in pregnancy and there are important long-term implications with failure of filter retrieval. Consequently, IVC filter placement should be avoided when possible and filter placement is generally reserved for those patients in whom anticoagulant therapy cannot be safely given or must be withheld (e.g., for delivery) within two to four weeks of newly diagnosed VTE.

Prevention of Venous Thromboembolism

In pregnant persons with prior VTE, a detailed history of their event and discussion about the role of thromboprophylaxis is needed. In those with a prior unprovoked or hormone-associated VTE, the risk of recurrent VTE is sufficiently high that LMWH prophylaxis is recommended during pregnancy and for 6 weeks postpartum (Tables 141.2 and 141.3).[5–7] In someone with a previous event associated with a major provoking risk factor (e.g., hospitalization, major surgery), the risk of recurrence appears lower and prophylaxis is recommended only in the postpartum period with clinical vigilance during pregnancy. Where the provoking event may have been more modest (e.g., long haul flight or minor illness) or there are additional risk factors

VTE, Venous thromboembolism.
Recommendations from Bates SM, Rajasekhar A, Middeldorp S, et al. American Society of Hematology 2018 guidelines for management of venous thromboembolism: venous thromboembolism in the context of pregnancy. *Blood Adv.* 2018;2(22):6–8; based on a VTE risk threshold antepartum of 2% and postpartum of 1%.

(e.g., known thrombophilia), a discussion about the potential risks and benefits of thromboprophylaxis during pregnancy and the postpartum period is needed, with a focus on patient values and preferences.

For patients with inherited thrombophilia but no personal history of VTE, clinical practice guideline recommendations vary based on limited data and different VTE risk thresholds chosen for thromboprophylaxis.[5] Prophylaxis recommendations are typically based on thrombophilia severity and family VTE history. Antepartum prophylaxis is typically reserved for those with more severe thrombophilias, with clinical vigilance typically recommended for patients with mild thrombophilias (e.g., heterozygosity for the factor V Leiden or prothrombin gene mutation). Prophylaxis is more commonly provided during the postpartum period as the daily VTE risk is higher and the burden of prophylaxis is lower given the shorter time frame. The ASH guidelines prophylaxis recommendations are summarized in Table 141.3.[5]

The optimal LMWH dose for prevention of VTE in pregnancy is unknown, with standard prophylactic and intermediate dosing regimens commonly used both antepartum and postpartum. A randomized controlled trial comparing a prophylactic versus an intermediate LMWH dose strategy will provide guidance (Highlow study NTR3894). In patients with severe thrombophilias such as marked antithrombin deficiency, therapeutic doses of LMWH are often used for prophylaxis, even in the absence of a VTE history.

Management of Anticoagulant Therapy at Delivery and Postpartum

An individualized, multidisciplinary approach with shared decision making is important when making decisions about delivery plans and anesthetic options. Risks of bleeding around the time of delivery and of recurrent VTE with anticoagulant interruption, as well as the importance placed by both patients and healthcare providers on avoiding induction of labor and preserving access to regional anesthesia, must be considered. In North America, induction of labor with planned interruption of LMWH is commonly used to increase access to neuraxial anesthesia and decrease the risk of bleeding during delivery, especially for those on therapeutic-dose LMWH. This strategy was recommended in the ASH guidelines for those receiving therapeutic LMWH.[5] Those guidelines suggested against scheduled delivery with discontinuation of anticoagulants in women receiving prophylactic LMWH, given the shorter time interval required before safe insertion of an epidural catheter. Other strategies include holding LMWH and allowing spontaneous delivery or stopping LMWH ahead of the expected delivery date (which may be associated with an increased risk of recurrent VTE). Some centers substitute prophylactic UFH for prophylactic LMWH close to term to increase the likelihood of access to regional anesthesia with spontaneous labor. A switch to twice daily LMWH or intravenous UFH prior to induction to limit the time off therapeutic anticoagulation may be used in women with more recently diagnosed VTE (e.g., within one month of delivery). Postpartum, anticoagulation resumption should be done cautiously as initiating therapeutic anticoagulation too quickly may lead to bleeding complications.

Anticoagulants and Breastfeeding

VKAs, UFH, LMWH, danaparoid, and fondaparinux are considered safe to use while breastfeeding.[5] VKAs and UFH do not cross into breast milk. A small amount of LMWH is detected in breast milk but is considered safe due to a very low oral drug bioavailability. No or very low levels of danaparoid are detected in breast milk and there are no published data on the excretion of fondaparinux into breast milk; however, both agents have low oral availability and so significant absorption by breastfeeding infants is unlikely.[8] Low to moderate levels of rivaroxaban and apixaban have been detected in breast milk and their use should be avoided in breastfeeding women.[5,21]

COVID-19 AND PREGNANCY

Venous Thromboembolism Risk in Pregnant Persons With COVID-19

There is an increased risk of venous and arterial thrombosis in pregnant patients with COVID-19 infection, compared to those without COVID-19.[22,23] The risk of a thrombotic event in pregnant women with COVID-19 appears to be less than 1% (~0.2% to 0.3%),[22–25] but data are still evolving. Additional factors may increase this thrombotic risk further, including traditional risk factors for pregnancy-associated VTE and severity of COVID-19 illness. There is less information known about the risk of thrombosis in the postpartum period for pregnant patients with COVID-19.[25] A proportion of COVID-19-affected pregnancies have evidence of coagulopathy with laboratory abnormalities including thrombocytopenia, prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT), elevated D-dimer and hyper-fibrinogenemia that reflects an immunothrombotic state.[24,26] How coagulopathy is associated with thrombosis in pregnancies with COVID-19 remains an active area of study.

Prevention of Venous Thromboembolism in Pregnant Individuals With COVID-19

To date, there are no high-quality pregnancy-specific data to guide the role of thromboprophylaxis in pregnant patients with COVID-19.[26] Large randomized controlled trials that studied the role of prophylactic, intermediate, or therapeutic-dose LMWH for the prevention of VTE and other outcomes in the setting of COVID-19 infection have systemically excluded pregnant patients.[26] As a result, currently decisions need to be made by extrapolating data from these randomized trials and from non-COVID-19 pregnancy cohort and case-control studies that include other pregnancy-associated VTE risk factors. Recent trials of non-pregnant patients have found that therapeutic LMWH may be beneficial in moderately ill hospitalized patients, but not in severely ill patients.[27] Careful consideration and multidisciplinary decision-making should be used when deciding on anticoagulant dosing around delivery and the immediate postpartum period, as drawbacks of therapeutic LMWH include risk of bleeding and reduced access to neuraxial anesthesia.

FUTURE DIRECTIONS

Areas of active research include validating and optimizing diagnostic algorithms for suspected DVT and PE in pregnancy; evaluating strategies for prevention of postpartum VTE; optimizing VTE anticoagulant management during pregnancy and the postpartum periods, as well as around the time of delivery; evaluating how the impact of COVID-19 is similar to and differs from that in the non-pregnant population; and studying how best to incorporate patient values and preferences in shared decision making around anticoagulation in pregnancy.

CHAPTER 142

ATHEROTHROMBOSIS

Daisy Sahoo, Moua Yang, and Roy L. Silverstein

Morbidity and mortality from atherosclerosis, the pathologic process underlying acute myocardial infarction, sudden death, stroke, and limb loss, represent an enormous burden on society and health care systems (see Chapters 144–146). Even though death rates from heart attack and stroke have dropped precipitously over the past 48 years (68% and 77%, respectively),[1] cardiovascular disease (CVD) is still the number one cause of death in the United States, accounting for more than 30% of all deaths—approximately 2200 per day (or one every 40 seconds). Unfortunately, as the developing world adopts a more “Western” lifestyle marked by a high-fat, calorie-rich diet and limited physical activity, these statistics are becoming the norm worldwide. The annual financial burden of cardiovascular disease in the United States in 2015 was estimated by the American Heart Association (AHA) to be $351 billion, including $138 billion due to lost productivity. These costs are predicted to double over the ensuing 15 years, as analyses of population survey data predict a 30% increase in the number of people with CVD during this time. Importantly, improved treatments for acute complications of atherosclerosis also come with the burden of increased chronic complications (e.g., heart failure).

The increasing prevalence of other metabolic disorders such as the dual world-wide epidemics of type II diabetes and obesity[2] increase risk of adverse thrombotic events and are associated with increased mortality from CVD, both directly and indirectly. Furthermore, the global SARS-CoV-2 pandemic that began in early 2020 has produced a large population of individuals with post-infection complications, so-called “long-COVID-19.” Some of these complications are cardiovascular in nature, but the long-term impact on CVD prevalence remains unknown at this time. Thus, concerns have been raised that reduction in mortality due to cardiovascular disease will eventually stop or even reverse direction.

Much of our knowledge of the epidemiology of cardiovascular disease comes from large-scale, long-term population studies, the most important being the Framingham Heart Study sponsored by the National Heart, Lung, and Blood Institute (NHLBI). This ongoing prospective study began in 1948 with a cohort of ≈5200 men and women between the ages of 30 and 62 in Framingham, Massachusetts, and has since added two subsequent generations and several other cohorts. Through this study and others elsewhere in the United States and Europe, major risk factors for cardiovascular disease have been identified, including cigarette smoking, low-density lipoprotein (LDL) cholesterol, family history, systolic blood pressure, male sex, waist circumference, menopause, physical inactivity, body mass index, high-sensitivity C-reactive protein (hsCRP), and coronary artery calcification scores. High-density lipoprotein (HDL) was identified as a protective factor. Based on these data, risk scores have been developed to guide physicians and patients, and public health campaigns developed targeting hypertension, elevated cholesterol, and lifestyle modifications. These have clearly contributed to the reductions in cardiovascular mortality, although they cannot account for the entire decrement. Cardiovascular risk can also be altered by dietary modifications. For example, Mediterranean diets and foods rich in fish oils like the omega-3 fatty acids eicosapentaenoic acid and docosahexaenoic acid have been shown to reduce cardiovascular mortality and improve cardiovascular outcomes. Furthermore, racial and ethnic disparities are well described in cardiovascular risk, with Blacks having higher rates than all other groups.

PATHOBIOLOGY

Atherosclerosis is caused by the progressive formation of arterial plaques, which are characterized by accumulation of lipids, in particular cholesterol and its derivatives, and inflammatory cells in the tunica intima of large- and medium-sized arteries (Fig. 142.1). Although occlusion of blood flow by plaque encroachment into the lumen can cause ischemia of downstream tissues, most of the severe clinical events associated with atherosclerosis derive from acute or subacute thrombosis at a site of an unstable, inflamed, or ruptured plaque or at a site of recent mechanical or pharmacologic intervention, a process termed atherothrombosis. The past 45 years have seen a remarkable increase in our understanding of the basic pathophysiologic mechanisms that govern plaque formation, plaque progression and acute arterial thrombosis.[3] Translation of this knowledge into diagnostic, preventive, and therapeutic strategies has been impressive, but there is still much unmet need for improvement. This chapter will summarize the current prevailing models of atherogenesis and atherothrombosis, highlighting some key knowledge gaps and potential new therapeutic targets.

CENTRAL ROLE OF LIPOPROTEINS IN ATHEROGENESIS

Epidemiologic and clinical trial data, along with numerous animal model studies, show unequivocally that elevated levels of plasma lipids, especially LDL cholesterol, are essential for plaque development. Atherosclerotic lesions can be induced in “athero-resistant” animals, including mice and rabbits, by manipulating their diets and/or genomes to cause hypercholesterolemia. The development of mouse genetic models nearly 30 years ago has led to mechanistic insights into the underlying pathobiology of plaque formation. In humans, raising LDL cholesterol levels increases the risk for atherosclerosis proportionally, while lowering levels either by lifestyle change or

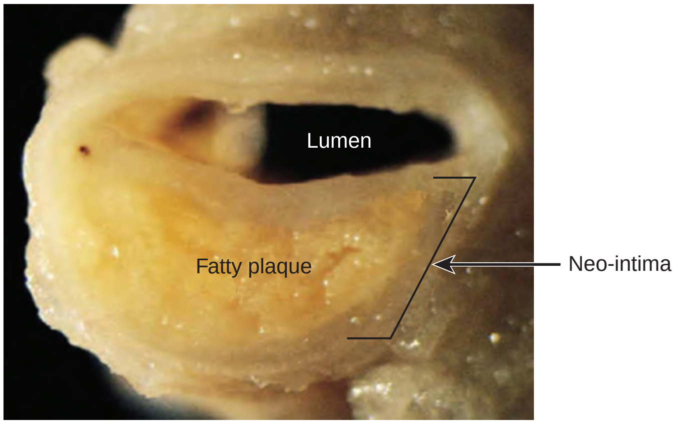

Figure 142.1 ATHEROMATOUS PLAQUE. Cross-sectional view of a human artery taken from an autopsy, showing accumulation of yellow-colored fatty materials in neointima.

pharmacologic intervention reduces risk. In general, lowering LDL cholesterol levels by 10% reduces risk for cardiovascular events by 25% and cardiovascular death by 10%.

Normally, cholesterol levels are tightly controlled in response to diet and cellular needs by a complex transcriptional pathway mediated by sterol response element-binding protein 2 (SREBP2). At low levels of cellular cholesterol, SREBP2 is activated and binds to specific DNA sequences in target genes known as *sterol response elements* to activate their transcription. The two key target genes are *HMGCR* and *LDLR*, which encode 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase (the rate-limiting enzyme in cholesterol biosynthesis) and the LDL receptor and their activation increases cholesterol production and cellular LDL uptake, respectively. At high levels of cellular cholesterol, SREBP2 is inactive, cholesterol biosynthesis is turned off, and LDL receptor expression is downregulated. As shown in Fig. 142.2, statin drugs decrease cellular cholesterol biosynthesis by inhibiting HMGCoA reductase and thereby inducing an increase in LDL receptor expression and driving down plasma LDL cholesterol levels.

Multiple randomized clinical trials have demonstrated efficacy of statin class drugs in reducing risk for cardiovascular events in high-risk individuals. Initial studies focused on secondary prevention in patients with a history of a previous atherosclerotic event, but later trials demonstrated efficacy as part of a primary prevention strategy in subjects with LDL cholesterol greater than 190 mg/dL or in subjects with "normal" LDL cholesterol (70 to 190 mg/dL) in the setting of a high-risk score. These studies, along with those showing benefit of lowering LDL cholesterol to levels well below "normal" (e.g., to 70 mg/dL in high-risk individuals),[4] are consistent with the concept that "normal" levels of LDL cholesterol, as defined by population means in the Western world, are not reflective of a true normal biology.

Genetic studies of rare individuals with extremely low LDL cholesterol levels identified a null mutation in a gene known as *PCSK9* that encodes a serine protease involved in downregulating LDL receptor expression. Individuals with this mutation seem to be otherwise normal, despite nearly absent LDL, suggesting that targeting this enzyme could represent an effective strategy for cholesterol-lowering therapeutics. Indeed, humanized monoclonal antibodies inhibiting PCSK9 function were quickly tested through clinical trials (OSLER and ODYSSEY) and approved by the FDA in 2015 as second line therapy for hypercholesterolemia.[5] The trials showed that these agents are well-tolerated and lower LDL cholesterol by approximately 60%, decrease cardiovascular events by half, and long-term efficacy and safety were demonstrated in at least one study. Emerging information on expression patterns of PCSK9 and regulation of other cellular receptors by this enzyme points to potential for off-target effects, and, thus, the need for long term follow-up of individuals on this therapeutic modality.

Niemann-Pick C1-like1 protein is expressed on the surface of enterocytes and hepatocytes and facilitates cholesterol absorption. Ezetimibe, a well-tolerated FDA-approved drug, inhibits this protein and lowers LDL cholesterol by approximately 20%. Early enthusiasm for this drug waned when studies failed to show improved cardiovascular outcomes, raising doubts about the relationship between biochemical endpoints and clinical efficacy, but a more recent trial of Ezetimibe in combination with a statin showed a 10% reduction in cardiovascular events at 7 years associated with a mean decrease in LDL cholesterol of 16 mg/dL compared with statin alone.[6] The most recent clinical guidelines published by AHA and the American College of Cardiology (2018) recommend considering non-statin drugs, including Ezetimibe and PCSK9 inhibitors, in higher risk individuals whose LDL cholesterol levels remain above 70 mg/dL after maximizing statin therapy.

Peripheral cells have the capacity to eliminate excess cholesterol through a process known as *reverse cholesterol transport (RCT)*. In this pathway, summarized in Fig. 142.3, post-lysosomal trafficking of intracellular cholesterol to the plasma membrane, mediated in part by the actions of acyl-CoA cholesterol acyltransferase (ACAT) and Niemann-Pick type C (NPC) protein, allows the cell surface adenosine triphosphate (ATP)–binding cassette (ABC) proteins ABCA1 and ABCG1 to transport excess cholesterol to apolipoprotein A (apoA)-containing lipoproteins, either nascent HDL (via ABCA1) or mature

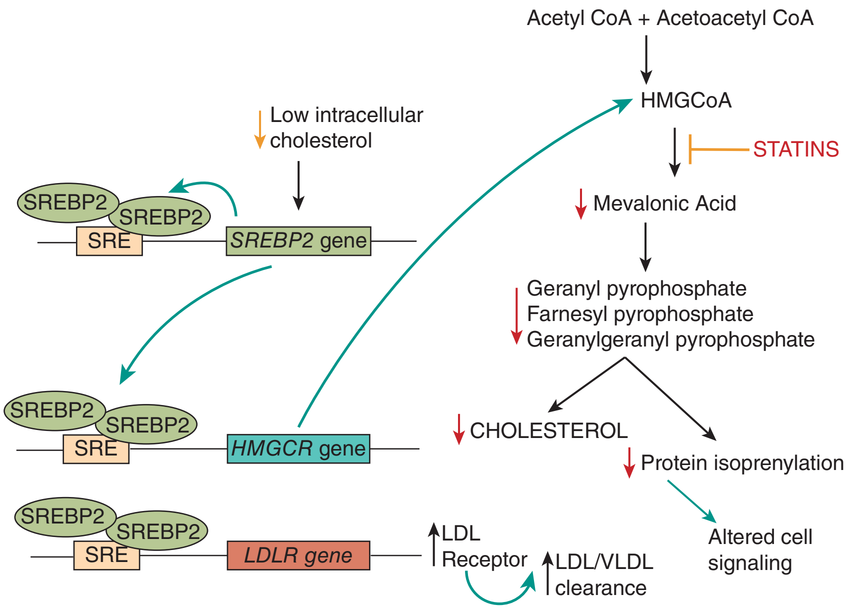

Figure 142.2 STATINS TARGET CHOLESTEROL AND ISOPRENYLATION PATHWAYS. The statin class of drugs inhibits the intracellular enzyme 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase. This enzyme converts HMGCoA to mevalonic acid, which is a precursor in the biosynthesis of the isoprenoids geranyl and farnesyl pyrophosphates, which in turn are precursors of cholesterol, as well as intermediates in isoprenyl modification of proteins, including small-molecular-weight G proteins. Since HMGCoA reductase is the rate-limiting step in these pathways, its inhibition by statins leads to decreases in cholesterol biosynthesis, hepatic VLDL production, and protein isoprenylation *(red arrows)*. Low levels of intracellular cholesterol activate the sterol response element-binding protein 2 (*SREBP2*) gene, which encodes the SREBP2 transcription factor *(green ovals)* that binds to sterol response elements (SRE) in multiple genes, including those encoding HMGCoA reductase (*HMGCR*) and the low-density lipoprotein (LDL) receptor (*LDLR*). The ensuing increased expression of LDL receptor results in increased clearance of apoB-containing lipoproteins (LDL and very low-density lipoprotein [VLDL]) from plasma, further lowering plasma cholesterol levels.

HDL (via ABCG1). HDL then "delivers" the cholesterol back to the liver, where it is selectively taken up by hepatocytes through a protein known as scavenger receptor B1 (SRB1) and ultimately secreted into bile and excreted in feces. The role of HDL in RCT probably accounts for its association with lowered risk for cardiovascular disease, but HDL particles also contain anti-inflammatory and antioxidant proteins that may further contribute to lowering atherosclerosis risk.

Pharmacologic and lifestyle approaches to enhance RCT have received significant attention as potential anti-atherosclerosis strategies. HDL levels can be raised by physical exercise, as well as by moderate alcohol ingestion, and these are both associated with lower cardiovascular risk. The only FDA-approved pharmacologic agent capable of raising HDL is niacin, but high doses are required, and these are often poorly tolerated because of side effects such as facial flushing. A combination of high-dose niacin with a prostaglandin D_2 receptor antagonist to block facial flushing and an extended-release form of niacin have been developed, but although both raise HDL levels, neither decreased cardiovascular risk.

The circulating plasma enzyme, cholesteryl ester transfer protein (CETP), functions to transfer cholesteryl esters from HDL to very low-density lipoprotein (VLDL) and LDL (see Fig. 142.3) in exchange for triglycerides. Inhibiting CETP raises HDL levels (and lowers LDL) significantly in humans, but multiple large phase III randomized clinical trials with pharmacologic CETP inhibitors failed to show efficacy despite raising HDL levels and at least one agent was associated with excess mortality.

Failure of CETP inhibitors and niacin led to doubts about the value of targeting HDL for anti-atherosclerosis therapy. An emerging concept, however, is that HDL particles are sensitive to oxidative modification in the pro-atherogenic milieu, and that these modifications can render HDL particles incompetent to function in RCT.[7] Simply raising HDL in this milieu, therefore, might not impact RCT. In this regard, novel assays to assess HDL function—so-called cholesterol efflux capacity—have been developed[8] and show potential as biomarkers for RCT in future drug development efforts. One such potential new target is microRNA-33a (miR-33a) which is encoded by a DNA sequence embedded in the SREBP2 gene and was found to repress several key genes involved in cholesterol homeostasis (see Fig. 142.3), including *ABCA1* and *ABCG1*, as well as genes involved in fatty acid oxidation and glucose metabolism.[9] Blocking miR-33a in mice increased HDL levels and inhibited atherosclerosis, suggesting that this could be a good target for therapeutic development. Other strategies under development to enhance RCT include direct infusion of cholesterol acceptors from ABCA1 or G1, including recombinant apoA or small apoA mimetic amphipathic peptides.

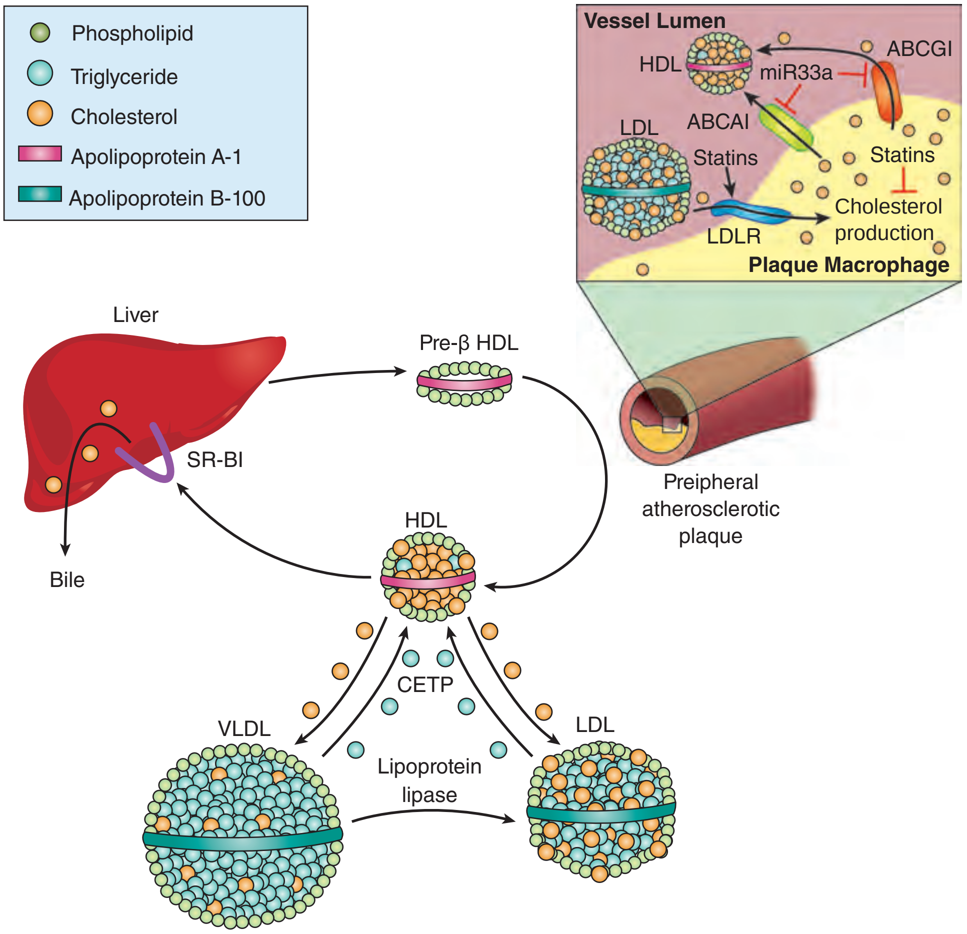

Figure 142.3 REVERSE CHOLESTEROL TRANSPORT. Cells in the periphery, including macrophage foam cells *(inset)*, have the capacity to unload intracellular cholesterol via two members of the adenosine triphosphate–binding cassette (ABC) transporter family: ABCA1 and ABCG1. The former transfers cholesterol to apoA and/or nascent high-density lipoprotein (HDL) particles, whereas the latter transfers cholesterol to mature HDL. HDL interacts with scavenger receptor B1 (SRB1) on liver cells, and through a process known as *selective cholesterol uptake*, the cholesterol within the HDL is internalized, where it can ultimately be reused or excreted via bile. The cholesterol in HDL can exchange with triglycerides in low-density lipoprotein (LDL) and very low-density lipoprotein (VLDL) particles through the action of an enzyme, cholesterol ester transfer protein (CETP). Inhibitors of CETP thus raise plasma HDL levels and lower LDL levels. LDL and VLDL are normally cleared by cells in the periphery via internalization by LDL receptors. Statin drugs (inset), by inhibiting HMGCoA reductase, lower intracellular cholesterol levels and raise LDL receptor levels, thus lowering plasma LDL. A microRNA (miR33a) encoded within the SREBP gene blocks expression of ABCA1 and ABCG1. *(Courtesy of Hayley Powers, MCW.)*

Multiple epidemiologic and genetic studies have shown positive associations between circulating triglyceride levels and coronary artery disease risk (see Chapter 145). Genetic variants in the gene encoding lipoprotein lipase, a key regulator of triglyceride metabolism, have also been associated with circulating triglyceride levels and with coronary artery disease risk, as have genetic variants in the *APOC3* and *APOA5* genes, which encode apolipoproteins in triglyceride-rich lipoproteins that critically regulate lipoprotein lipase in a reciprocal manner. Common variants in the *ANGPTL3* gene, another regulator of lipoprotein lipase activity, have also been identified.[10] Therapeutic interventions targeting the lipoprotein lipase pathway, including APOC3 antisense oligonucleotides or monoclonal antibody therapy against ANGPTL3 are under development.

FOAM CELL FORMATION AND THE FATTY STREAK

Atherosclerotic plaque develops in a geographically discontinuous manner very slowly and continuously evolves over many decades.[3] Autopsy studies of motor vehicle accident victims showed early "pre-atherosclerotic" lesions present in the aorta of otherwise healthy young children. These small superficial lesions consist predominantly of lipid-laden macrophages, so-called *foam cells*, and are termed *fatty streaks*. These are considered precursors of atherosclerotic plaque.

The initial event in formation of the fatty streak and atherosclerotic plaque is most likely transudation of apolipoprotein B–containing lipoproteins across the endothelial cell monolayer into the arterial wall (Fig. 142.4). A transcytosis mechanism mediated by scavenger receptors (SRs) expressed on the luminal cell surface of endothelial cells may also play a role.[11] These lipoproteins are predominantly LDL although remnant lipoproteins derived from chylomicrons produced by the intestinal epithelium are also found. The primary sites of lipoprotein entry are at arterial branch points or curvatures, explaining the discontinuous nature of atherosclerotic lesions. These locations are where normal laminar blood flow (and T-cell activity) is disturbed. Normal laminar flow activates a specific genetic "protection" program in endothelial cells that enhances barrier function and promotes an anti-inflammatory, antioxidant, and antiatherogenic phenotype. Loss of these shear-dependent signals disrupts the normal endothelial architecture and increases permeability, allowing unregulated entry of lipoproteins into the tunica intima. Within the intima, the lipoproteins become "trapped" by specific interactions with normal components of the vessel wall, such as glycosaminoglycans, and undergo structural modifications, including aggregation, oxidation, and in the setting of hyperglycemia, glycation.

Just as data show an unequivocal role for LDL cholesterol in atherogenesis, equally compelling studies in humans and animal models show that mononuclear phagocytes are necessary for plaque formation and progression, and that atherosclerosis is associated with a chronic inflammatory state in the vessel wall and in the systemic circulation.[12] Targeted genetic mutations that block monocyte development from hematopoietic precursors or that prevent monocyte trafficking into tissues dramatically protect mice from experimental atherosclerosis. The earliest and most prominent cell types in human and mouse atherosclerotic lesions are monocytes and macrophages. Initial monocyte entry into the arterial intima is in response to poorly understood cues related to endothelial cell dysfunction. Environmental and genetic influences, such as hypertension, angiotensin II production, cigarette smoke, diabetes, metabolic syndrome, and chronic periodontal infection may contribute to generalized endothelial dysfunction, but it is likely that the modified lipoproteins, particularly oxidized LDL (oxLDL) trapped in the vessel wall, play a major initiating role.[13] OxLDL activates an endothelial cell receptor known as LOX1 to induce expression of monocyte adhesion molecules and this response is amplified in the presence of angiotensin II. Other components of the "dysfunctional" endothelial cell phenotype include von Willebrand

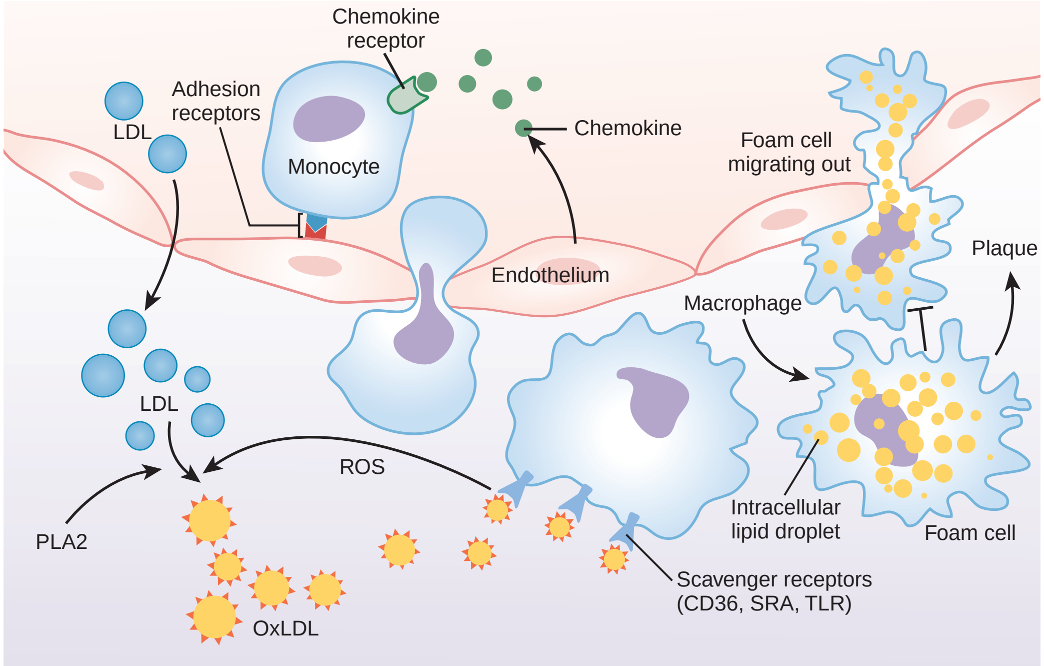

Figure 142.4 FOAM CELL FORMATION IS AN EARLY EVENT IN ATHEROGENESIS. Low-density lipoprotein (LDL) particles, which are transudated through a dysfunctional endothelium at arterial branch points or areas of disrupted shear, enter the intima and become trapped within the extracellular matrix. In the presence of inflammation, the LDL particles become oxidized or otherwise modified and contribute to endothelial dysfunction by interacting with receptors on endothelial cells, such as LOX1. Monocytes, in response to chemokines secreted by activated endothelial cells and/or inflammatory leukocytes and platelets, adhere to the endothelium via selectin family adhesion receptors, as well as β2 integrins and their counter receptors (ICAM and VCAM). The monocytes then diapedese into the intima, where they differentiate into inflammatory macrophages that generate oxidant stress within the vessel wall and release proinflammatory mediators. Scavenger receptors, in particular CD36, expressed on macrophages recognize and internalize oxidized LDL (oxLDL), leading to a feed-forward loop of increased LDL oxidation and increased scavenger receptor expression, resulting ultimately in the formation of cholesterol-laden foam cells. These accumulate in the intima, in part because of signals induced by oxLDL that inhibit migration, forming plaque. *ROS*, Reactive oxygen species.

factor release from Weibel-Palade bodies and altered homeostasis of nitric oxide and eicosanoid pathways (see Chapter 122).

Monocyte recruitment to the vessel wall (see Fig. 142.4) begins with their capture and rolling along the activated endothelium mediated by specific interaction of selectin family adhesion molecules (L-selectin on circulating monocytes and P-selectin on activated endothelial cells) with their counter receptors, including PSGL1. Subsequent signals induced by endothelial-derived chemokines, including CCL5/RANTES, CCL2/MCP1, IL-8, and CXCL1, lead to further recruitment of monocytes and facilitate firm adhesion of the rolling monocytes to the vessel wall. The latter is mediated by interaction of ICAM1 and VCAM on the activated endothelial surface with specific integrin family counter receptors on monocytes, β2 integrins for ICAM1 and α4β1 for VCAM. The adherent monocytes then go through diapedesis via disrupted endothelial junctions and enter the intima. Recent studies have suggested that a particular subset of circulating "inflammatory" monocytes, defined by high expression of the Ly6C antigen (in mice) or CD14 (in humans), are the predominant source of entering cells. The normal vasculature also contains a small number of resident macrophages, as well as "patrolling" monocytes.[14] The latter are distinct from the $Ly6C^+/CD14^{hi}$ cells and exhibit a less inflammatory phenotype.

The fate of monocytes within the intima is probably determined in part by lineage commitment programs carried by the entering monocytes and in part by local environmental cues. Most, however, seem to polarize toward the so-called M1 inflammatory macrophage phenotype. Investigators have, however, detected dendritic cell-like phenotypes (expressing CD11c), M2-like cells that express arginase and eNOS and are highly phagocytic and anti-inflammatory, and proangiogenic VEGF-expressing macrophage phenotypes within plaque. In addition to monocytes, lymphocytes,[15] particularly T cells, also enter the intima, where they contribute to plaque formation by secreting cytokines and other mediators. Of these infiltrating lymphocytes, interferon-γ producing Th1 cells and interleukin-17 producing Th17 cells have been shown to promote atherosclerosis, while the Treg cell subset is protective.

Reactive oxygen species (ROS) generated by the inflammatory milieu within the atherogenic vessel wall modify the trapped LDL by oxidizing both protein and lipid moieties (see Fig. 142.4), creating what are called collectively oxLDL and affecting the 2,3-diphosphoglycerate (2,3-DPG, also known as 2,3-bisphosphoglycerate or 2,3-BPG) levels.[13] Modified LDL lose their affinity for the LDL receptor but gain affinity for a genetically unrelated family of receptors known as SRs, including SRA1 and CD36, which are present at high levels on the macrophage surface. These receptors are part of the innate immune system, and their recognition of specific structures within oxLDL presumably relates to their mimicry of similar structures found on pathogenic organisms. CD36, for example,[16] also recognizes mycobacterial and *Staphylococcus* cell wall components, certain fungal structures, and falciparum malaria–infected erythrocytes. TLR family members, including TLR2, TLR4, and TLR6, can also recognize modified LDL and can partner with CD36 in these functions. Unlike the LDL receptor, which is downregulated in the setting of excess intracellular cholesterol, SR expression is not regulated in that manner, and, in fact, is increased by the presence of oxLDL. This, in part, results from internalization of oxidized fatty acids that serve as ligands for the PPAR family of transcription factors, particularly PPARγ, which is a major positive regulator of CD36 expression.[17] Thus, over many months and years, the continued entry and oxidation of LDL in the intima coupled with upregulated expression of SRs lead to massive intracellular accumulation of cholesterol and formation of lipid-laden foam cells.

OxLDL-SR interactions initiate a cascade of events in macrophages, including internalization of the bound oxLDL, activation of proinflammatory pathways, and activation of transcriptional pathways. The CD36-oxLDL interaction, in addition to promoting ROS formation, also decreases expression of endogenous antioxidant pathways and inhibits macrophage migration. Furthermore, recognition of oxLDL by CD36 initiates metabolic repurposing from mitochondrial respiration to a glycolytic-like state. Although not mirroring the Warburg effect in cancer cells, CD36-mediated metabolic repurposing results in mitochondrial dysfunction, ROS production, and phenotypic polarization toward a proinflammatory state. These events result in a feed forward loop that increases leukocyte recruitment into the vessel wall, inhibits macrophage migration out of the vessel wall, and increases oxLDL formation. The net effect is formation and accumulation of lipid-laden foam cells and proinflammatory immune cells, which together form plaque (see Fig. 142.4).

Although abundant data from animal models and correlative human studies support the oxidative stress hypothesis, considerable controversy remains because interventional trials of antioxidant therapy in humans have generally failed to prevent the complications of atherosclerosis.[18] These trials, however, are difficult to interpret because of lack of convincing evidence that the tested "antioxidant" therapies target the relevant vascular or circulating oxidant pathways. These oxidant systems include NADPH oxidase, xanthine oxidase, myeloperoxidase (MPO), uncoupled nitric oxide synthase, and dysfunctional mitochondrial electron transport chain. MPO is of particular interest because it generates a highly specific oxidized phospholipid ligand for CD36 from LDL and because circulating MPO levels correlate with risk for atherosclerosis and acute cardiovascular events.

Another potential problem with the antioxidant clinical trials is that the choice of antioxidants may have been flawed. Most used vitamin E formulations containing mainly α-tocopherol. Recent studies showed that tocopherols, in addition to having activity as antioxidants, have important cell-signaling functions mediated by specific cellular receptors. Therapy with formulations containing primarily α-tocopherol may downregulate endogenous γ-tocopherol levels, leading to imbalance in natural tocopherol signaling pathways. Furthermore, tocopherols are lipid-based structures that are themselves subject to oxidation, producing lipid peroxides that can promote further oxidative stress. Nevertheless, it is also possible that pathways of cholesterol uptake unrelated to LDL oxidation and SR expression, such as by micro- and macropinocytosis of "native" LDL or aggregated LDL, play a significant role in foam cell formation.

Important unresolved issues in the pathogenesis of early atherosclerotic lesions include understanding why macrophages do not exit the vessel wall and travel to regional nodes after ingesting modified LDL, as they would after ingesting exogenous pathogens, and why cholesterol efflux cannot keep up with LDL uptake to maintain homeostasis. OxLDL inhibition of macrophage migration (see Fig. 142.4) may explain the former, suggesting that blocking oxLDL-mediated signaling pathways might have therapeutic potential by facilitating macrophage exit from developing plaque. Indeed, in experimental animals, transplantation of atherosclerotic aortae from hypercholesterolemic animals into normal recipients induces migration of lipid-laden macrophages out of the vessel wall and plaque regression. The second issue might relate to differential gene regulation of SRs compared with cholesterol efflux transporters, and/or to intracellular cholesterol trafficking that might make it inaccessible to efflux transporters. In addition, as noted previously, HDL particles, like LDL, are sensitive to oxidative modification which may render them dysfunctional in RCT and, thus, lose their atheroprotective properties.[7]

An intriguing recent development in understanding the cellular composition of plaque comes from lineage marker studies which show that a surprisingly large percentage of foam cells expressing macrophage markers are derived from a smooth muscle cell lineage.[19] These studies suggest that local cues in plaque might interact with intimal or adventitial smooth muscle cells to redirect their genetic programs toward a macrophage-like phenotype. It is possible that such cells do not possess the full migratory capacity of macrophages, and this could contribute to the trapping of foam cell in plaque.

LESION EVOLUTION: REMODELING AND THE VULNERABLE PLAQUE

In humans, plaque develops and evolves very slowly over many decades, explaining in part why animal models in which advanced lesions develop rapidly over weeks and months may not accurately reflect the human condition. Accumulation of foam cells is only one component of the atherogenic process. Early on, signals from macrophages (Fig. 142.5) and the injured endothelium, primarily platelet-derived growth factor (PDGF), stimulate adventitial smooth muscle cells to migrate into the intima and to proliferate.[3] These cells contribute to the mass of the lesions, secrete collagen and other factors that change the nature of the intimal extracellular matrix, and may even contribute to the burden of foam cells. Lymphocytes infiltrating from the circulation and mast cells from the adventitia also contribute to the inflammatory milieu and matrix remodeling. Platelet antigens are also readily detectable in plaque, suggesting that platelets enter the intima, where they may contribute to matrix remodeling and the inflammatory state by secreting PDGF, transforming growth factor-β, and other growth factors, along with platelet factor 4, which is a potent chemokine, also known as *CXCL4*, for monocytes. Animal studies suggest that platelets may facilitate monocyte recruitment, serving as a bridge between the endothelium and circulating monocytes (see Fig. 142.5).[20] Sophisticated single-cell imaging studies in mice showed that monocytes continue to traffic through the "shoulders" of even advanced stage lesions.

Plaque generally grows in an eccentric manner within the intima and in certain instances can create significant obstruction to blood flow (Fig. 142.6, *left*). In such cases, as oxygen demand increases, tissue ischemia results, leading to angina and/or lower extremity claudication. Recently, in vivo studies using advanced imaging techniques, however, demonstrate that in most cases, the vessel wall remodels as plaque grows (see Fig. 142.6, *right*) so that the arterial lumen is mostly preserved, and the bulk of the atheromatous mass is abluminal. These studies show that traditional two-dimensional angiographic techniques vastly underestimate plaque burden. Of note, such studies along with careful histopathologic examinations, have led to the concept that the "quality" of the plaque may be more important than its quantity in predicting cardiovascular outcomes. Some plaques, particularly those with thick fibrous caps and cellular cores seem to be "stable" (Fig. 142.7, *left*), whereas others, particularly those with thin fibrous caps, abundant leukocytes, and necrotic, lipid-rich cores seem to be "unstable" and vulnerable to erosion and rupture (see Fig. 142.7, *right*).[21] Rupture refers to the sudden loss of integrity of the fibrous cap with release of plaque material into the lumen, often followed by acute occlusive thrombosis. Erosion is a more subtle concept referring to loss of endothelial cells at the shoulder of the lesion or minimal leakage of plaque through a partially disrupted cap. Plaque erosion may lead to sub-occlusive thrombus formation and/or intraplaque hemorrhage and thrombosis. Repeated cycles of erosion and intraplaque hemorrhage/thrombosis may account for the apparent stepwise growth of some lesions.

Widespread use of statins and adoption of lifestyles compatible with cardiovascular risk reduction may be responsible for a shift in the natural history of coronary plaque development that lowers risk of catastrophic rupture and occlusive thrombosis, but promotes erosions, micro-rupture and the formation of mini-thrombi, so-called "non-ST elevation" events. Understanding the factors that contribute to plaque vulnerability is thus an extremely important topic of research,[21] but one that is difficult to model in animals. Some key features that have emerged are the degree of angiogenesis within the plaque, balance of matrix-degrading enzymes and enzyme inhibitors, extent of apoptosis of cells within the plaque, deposition of calcium within the plaque, and level of systemic and local inflammation.

Plaque angiogenesis can be visualized in real time by ultrafast CT and MRI.[22] Based on analogy to tumor growth, it is not surprising that growing plaque requires a blood supply and that the neovessels within plaque may, like their counterparts in cancer, be leaky and unstable (see Chapter 122). This neovascular instability may contribute to plaque instability by facilitating entry of inflammatory cells, platelets, and plasma components, such as fibrinogen, cell-derived microvesicles (MV) and exosomes. In animal models, treatment with antiangiogenic agents significantly slows plaque growth. In some disease states such as diabetes, accelerated atherosclerosis may reflect a "microvascular" disease of the vasa vasora.

Integrity of the fibrous cap is maintained by a balance between collagen synthesis by smooth muscle cells and fibroblasts and collagen lysis by matrix-degrading enzymes. The predominant enzymes

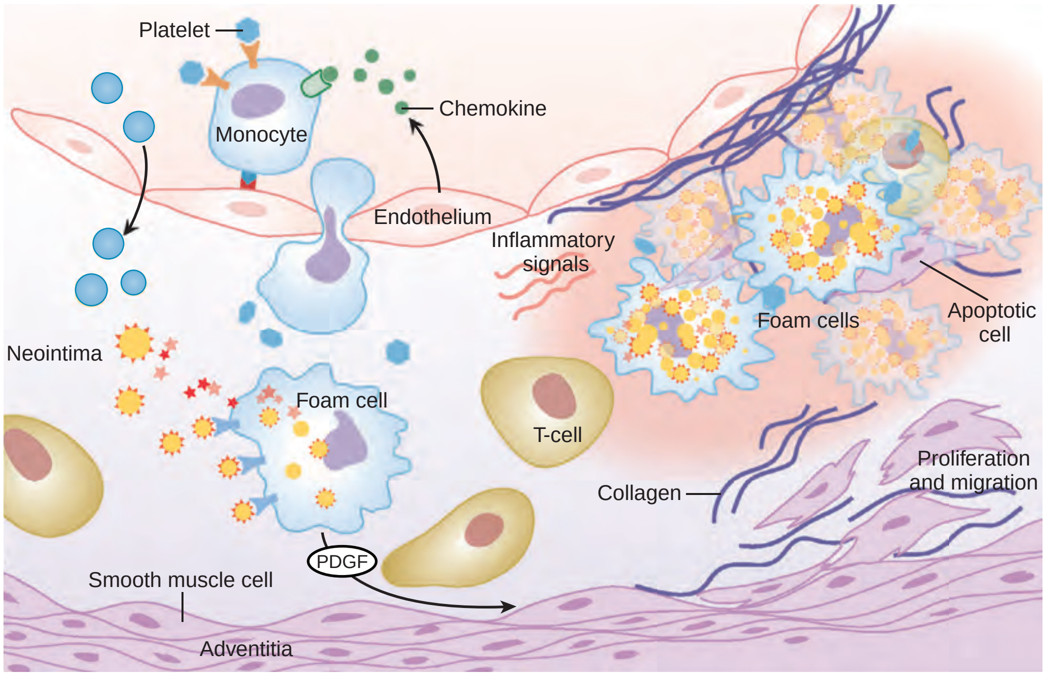

Figure 142.5 LATER EVENTS IN ATHEROGENESIS. Fatty streaks formed in the vessel wall via accumulation of foam cells (see Fig. 142.4) evolve over many years into complex plaque. In response to chemokines, monocytes continue to enter plaque, perhaps accompanied by platelets. T cells, B cells, and other inflammatory cells also accumulate. Cholesterol loading of macrophages induces apoptosis and apoptotic cells accumulate because of dysfunction of normal efferocytotic clearance pathways. Smooth muscle cells respond to platelet-derived growth factor (PDGF), TGFβ, and other signals and proliferate and migrate into the neointima. These cells produce collagen and other matrix components, contributing to plaque growth and formation of a fibrous cap. To support plaque growth, an angiogenic response is elicited from vasa vasora within the adventitia.

Figure 142.6 VESSEL WALL REMODELING CAN PRESERVE ARTERIAL LUMEN. On the left is a cross-section cartoon image of an artery containing a large eccentric plaque *(orange)*. The vessel has undergone minimal remodeling. The atheromatous lesion is extending into the arterial lumen and would be visible on an angiogram as an obstructing lesion. On the right is a lesion of similar mass, but its formation was accompanied by significant vessel wall remodeling so that the lesion extends mainly into the vessel wall, preserving the lumen. On an angiogram this would be nearly invisible.

Figure 142.7 UNSTABLE PLAQUE IS PRONE TO RUPTURE. On the left is a cross-section cartoon image of an artery with a plaque containing abundant smooth muscle cells and foam cells and a thick fibrous cap. On the right is a similar-size plaque, but with a thin fibrous cap that has ruptured allowing plaque contents to extrude into the lumen. This plaque contains smooth muscle cells and foam cells, as in the stable plaque on the left, but there is abundant angiogenesis, along with apoptotic and necrotic cells.

are members of the large family of zinc-dependent matrix metalloproteinases (MMPs) capable of degrading most matrix components, including collagen. These enzymes are tightly regulated by a network of activators and inhibitors and in settings in which activation exceeds inhibition, excessive matrix degradation may occur. Metalloproteases of the ADAM (a disintegrin and metalloprotease domain) family and ADAMTS (a disintegrin and metalloprotease domain with thrombospondin structural homology domains) family may also contribute to plaque instability. Although several clinical trials have studied MMP inhibitors in atherosclerosis, none have shown clear benefit to date.

A prominent feature of advanced atherosclerotic lesions is the presence of apoptotic cells, mostly of macrophage and smooth muscle cell origin. The nature of the pro-apoptotic signals within plaque is incompletely understood, but excess intracellular cholesterol can initiate the endoplasmic reticulum stress response leading to apoptosis.[23] OxLDL signaling through SRs and/or TLRs can also induce apoptosis. In most inflammatory sites, apoptotic leukocytes are quickly removed by phagocytes in a process known as *efferocytosis*. The efferocytotic macrophages are generally thought to be of the M2, anti-inflammatory type; thus, their engagement by apoptotic cells not only removes the apoptotic cell from the microenvironment, but also directly contributes to downregulation of the inflammatory state by inducing secretion of anti-inflammatory cytokines and effectors. In atherosclerotic plaque, this process seems to be inefficient so that apoptotic cells accumulate, contributing to the lipid load and releasing potentially toxic contents. In mouse models, TNFα is a major driver of inefficient efferocytosis and interfering with CD47, an anti-efferocytic protein on the surface of macrophages, improves clearance of apoptotic cells and plaque debris and ameliorates atherosclerosis.[24]

Although therapeutic interventions to stabilize vulnerable plaque or prevent plaques from becoming vulnerable have not yet materialized in humans, several imaging approaches have been studied in attempt to develop useful biomarkers to identify vulnerable plaque and therefore to identify patients who might benefit from aggressive antithrombotic and lipid-lowering therapeutic interventions. Neovascular imaging by CT or MRI are promising technologies, as are plaque characterization by optical coherence tomography, high resolution MRI, linear infrared imaging, and thermography.[22]

PLAQUE RUPTURE AND ACUTE ARTERIAL THROMBOSIS

The devastating complications of atherosclerosis, including acute coronary syndromes (ACS), stroke, gangrene, and sudden death result primarily from acute and subacute thrombosis occurring at the site of plaque rupture (Fig. 142.8). As described in later chapters in this section, treatment and prevention strategies using aggressive antiplatelet, anticoagulant, fibrinolytic, and/or mechanical approaches have been remarkably effective at reducing major cardiovascular events, but tremendous unmet needs still exist, particularly in the areas of primary and secondary prevention of thrombosis (see Chapters 143–146).

Pathophysiologic mechanisms underlying acute arterial thrombosis center on two key concepts: (1) exposure of prothrombotic materials to the local circulation as a consequence of plaque rupture acts as a thrombotic trigger, and (2) advanced atherosclerosis is associated with a systemic prothrombotic state that accelerates or enhances pathologic thrombosis.[25] The former mechanism undoubtedly plays a major role. Immunohistochemical studies have convincingly shown that plaque contains abundant tissue factor (TF), and acute anticoagulation therapy directed toward blocking thrombin generation or inhibiting thrombin has proven to be effective in ACS (see Chapter 145). Plaque TF is derived mainly from smooth muscle cells, fibroblasts, and activated macrophages. Studies have also suggested that platelets can synthesize TF RNA transcripts after stimulation by inflammatory mediators and thus may also contribute to the plaque procoagulant load; however functional TF expression by platelets is not clearly established. A significant proportion of plaque TF may be in the form of membrane-bound MV derived from apoptotic and/or activated cells (see next section for details).[26] Exposure of flowing blood to TF exposed in, or released from, ruptured plaque leads to rapid activation of factor Xa, thrombin generation, and activation of platelets (see Chapters 124 and 125). In addition to TF, other components of plaque that become exposed to blood at sites of rupture include collagen and oxidized phospholipids, both of which can activate platelets directly. Thus aggressive antiplatelet therapy with aspirin, ADP receptor P2Y12 inhibitors, glycoprotein αIIbβ3 inhibitors, and protease activated receptor-1 (PAR1) inhibitors are mainstays of the pharmacologic approach to treatment of ACS (see Chapters 143 and 145); and aspirin and P2Y12 inhibitors are of proven efficacy for secondary prevention.

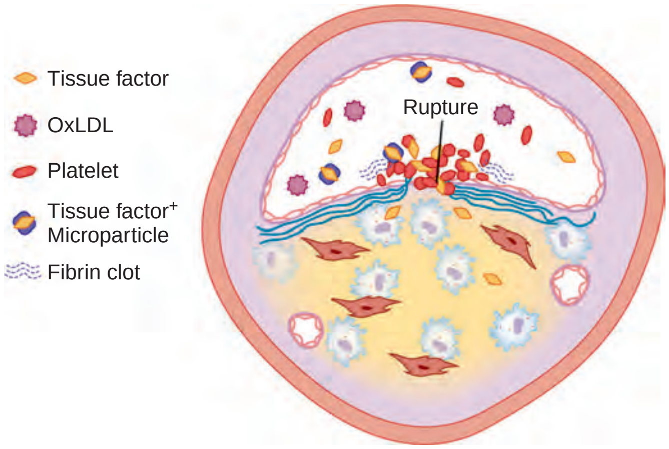

Figure 142.8 ACUTE PLATELET-RICH THROMBUS AT SITE OF PLAQUE RUPTURE. An atherosclerotic artery with a ruptured plaque (as described in Fig. 142.7) serves as a nidus for formation of an acute thrombus. Tissue factor (TF) contained in plaque or expressed on circulating microparticles (MPs) leads to thrombin generation and formation of fibrin at the site of rupture. Platelets accumulate at the rupture site and are activated by plaque components, such as collagen, forming an aggregate that, if large enough, can obstruct blood flow. Blood in patients with advanced atherosclerosis is prothrombotic, in part because of oxidized low-density lipoprotein (LDL)–induced release of TF-positive MPs from monocytes. Oxidized LDL (oxLDL) also interacts with platelets to make them more sensitive to activation and aggregation by plaque contents.

HYPERLIPIDEMIA, ATHEROSCLEROSIS, AND A SYSTEMIC PROTHROMBOTIC STATE

Platelet hyper-reactivity has long been thought to play a role in acute atherothrombosis. Clinical studies support an association between in vitro platelet reactivity and prognosis in patients with coronary disease, and it was shown during the 1970s that platelets from patients with familial hypercholesterolemia were more sensitive to activation by epinephrine or ADP. Similar findings were seen in platelets from mouse models of hyperlipidemia, such as the *apoe null* strain fed a high-fat diet. Of note, hyperlipidemic mice show accelerated time to form occlusive thrombi after experimental arterial injury compared with controls. This phenotype is likely the result of both enhanced platelet accumulation and fibrin deposition. In that context, much attention has been paid to identifying and characterizing receptors on the platelet surface that recognize specific classes of lipids and lipoproteins.[25] The receptors fall into two main groups: pattern recognition innate immune receptors, including CD36, SRA, TLR4, and LDL receptor–like protein (LRP)-8 (also known as *apoER2*), and G-protein coupled receptors, including receptors for lysophosphatidic acid (LPA), platelet-activating factor, and thromboxane (see Chapter 124).

CD36 (also known as *platelet glycoprotein IV* or *IIIb*) is of particular interest because of its known function on macrophages as a high affinity signaling receptor for oxLDL and because oxidized phospholipids are readily detectable in circulating plasma of experimental animals and patients with atherosclerosis and hyperlipidemia. Indeed, studies showed that oxLDL binds to CD36 on the surface of platelets in a specific, concentration- and time-dependent manner. At high concentrations, such as might occur during acute plaque rupture, oxLDL/CD36 signals activate platelets; however, at lower concentrations such as those observed in the circulation of individuals with atherosclerosis, oxLDL/CD36 signals augment platelet aggregation responses to low doses of “classic” platelet agonists, such as ADP and collagen. CD36 signaling in platelets involves multiple coordinated pathways including generation of intracellular ROS. In addition, CD36 also blocks natural anti-activation, inhibitory pathways in platelets mediated by cyclic nucleotides. Intracellular crosstalk between CD36 and pathways downstream of the collagen receptor GPVI may also augment procoagulant responses and thereby enhance platelet-dependent fibrin formation and secondary hemostasis in the atherogenic microenvironment (see Chapter 124).

Atherosclerotic plaque and so-called “minimally” oxidized LDL particles contain LPA, biologically active lipids generated by the action of phospholipases on LDL and cell membrane lipids. Platelets express at least three different G-protein-coupled LPA receptors, but the in vivo relevance of this system has not been demonstrated. Ex vivo studies, however, demonstrated that at high concentrations, minimally oxidized LDL sensitized platelets to aggregate in response to other agonists. Epidemiologic studies have also associated levels of soluble phospholipase A2 with cardiovascular risk. In addition to participating in LPA biosynthesis, this family of enzymes generates free fatty acids from phospholipids that serve as substrates for cyclooxygenase and lipoxygenases, producing both pro- and antiatherogenic eicosanoids.

In addition to platelet hyper-reactivity, it is also quite likely that systemic dysregulation of the coagulation cascade contributes to the prothrombotic state associated with advanced atherosclerosis. This is consistent with studies showing that atherosclerosis is associated with increased risk for venous thromboembolic disorders. Elevated levels of circulating D-dimer and thrombin-antithrombin complexes have been reported in patients with ACS, and D-dimer levels tend to track with hsCRP. Large-scale population studies have identified elevated fibrinogen and factor VIII levels as risk factors for atherosclerosis. A key initiator of thrombin generation in these settings may be circulating TF (see Fig. 142.8) in the form of TF-expressing MVs.[26] MVs are 200 to 1000 nm diameter vesicular fragments that bud off from cells during either activation or apoptosis. MVs generated from platelets, monocytes, erythrocytes, leukocytes, or endothelial cells during vascular injury become incorporated into developing thrombi in vivo. MVs, mostly of platelet origin, can be detected in the circulation of normal human subjects, but markedly increased numbers of circulating MVs have been reported in patients with a variety of inflammatory and prothrombotic disorders including ACS. Furthermore, MVs characteristically have PS externalization on the surface which aids in the capacity to bind to platelet CD36 and enhance platelet reactivity via the same mechanism as oxLDL.

It is important to note that MVs derived from other cells (e.g., monocytes, macrophages, smooth muscle cells, and tumor cells) are an additional source of circulating TF. A mechanistic link between atherogenesis and thrombosis may be oxLDL, which in vitro can induce TF-positive MV generation from blood-derived monocytes. Of interest, a large clinical trial (JUPITER) testing the efficacy of statins in subjects with normal LDL, but elevated levels of hsCRP, showed that rates of venous thrombosis, as well as coronary events, were significantly decreased. In animal models, statins decrease circulating levels of oxLDL and MV levels, as well as levels of other prothrombotic and proinflammatory biomarkers, even in the absence of lowering cholesterol, suggesting that oxLDL-mediated prothrombotic activities may be important targets for thrombo-prevention in patients with atherosclerosis. These studies also support those showing that statins may have anti-inflammatory and antithrombotic activities independent of lipid lowering. Since HMGCoA reductase is also the limiting step in the biosynthesis of isoprenoids, it has been postulated that statins may dampen signaling pathways mediated by small molecular weight G proteins (e.g., Ras) in which membrane targeting by protein isoprenylation is required (see Fig. 142.2).

In mice, the contact activating system and intrinsic coagulation pathway have been shown to participate in arterial thrombosis after injury and to have proatherogenic properties.[27] Targeting these systems is attractive in that patients with known deficiencies in factor XII or contact system proteins that have no obvious phenotype and do not have a bleeding diathesis, thus, presumably an antithrombotic effect could be achieved without altering normal hemostasis (see Chapters 125, 135, and 143).

CROSS TALK BETWEEN COAGULATION AND INFLAMMATION SYSTEMS IMPACT ATHEROGENESIS

As noted previously, atherosclerosis can be thought of as a chronic, low-grade inflammatory disease of the artery wall. Clinical studies based on biomarkers such as hsCRP, MPO, and IL6, suggest that advanced atherosclerosis is associated with a systemic state of chronic inflammation and that the degree of inflammation reflects the level of risk for major complications, possibly because the more inflamed the plaque, the more vulnerable the lesion. It is also now clear that mediators of inflammation, such as IL1, LPA, oxLDL, and circulating MVs may interact with platelets and the coagulation cascade to promote a hypercoagulable, prothrombotic state. Furthermore, mediators of coagulation, such as thrombin, TF/factor VIIa complexes, and factor Xa, may contribute to the proinflammatory state by interacting with protease-activated receptors on endothelial cells and leukocytes. Activated platelets can contribute to inflammation by facilitating monocyte adhesion to endothelium and by secreting proinflammatory molecules. Thus, bidirectional crosstalk between the inflammation and coagulation systems enhance both pathways and promotes atherosclerosis.

Neutrophils also contribute to platelet activation and venous thrombosis through formation of procoagulant neutrophil extracellular traps (NETs), but the contributions of neutrophils to atherothrombosis is not well-established. Clinical studies have suggested a link between platelet-neutrophil complex formation and cardiovascular disease, and in aged mice, NETs have been shown to promote atherosclerosis and plaque erosion through a mitochondrial oxidant stress pathway.

Not surprisingly, patients with systemic autoimmune inflammatory disorders, including rheumatoid arthritis, Wegener’s granulomatosis, and lupus erythematosus have been shown to have accelerated atherosclerosis, as assessed by biomarkers such as ultrasound evidence of carotid artery intima-medial thickening, as well as major cardiovascular events. Obesity, a risk factor for atherosclerosis, is now known to be a systemic inflammatory disorder with evidence of inflammation readily detectable within obese central adipose tissue. Obese patients also have elevated, circulating levels of coagulation and inflammation biomarkers, including plasminogen activator inhibitor-1 (PAI-1).

Given these observations, there has been renewed interest in exploring the use of anti-inflammatory agents and antithrombotic agents to slow the progress of atherosclerosis. The approach has been tempered by clinical studies showing small increases in atherosclerotic complications in patients taking COX inhibitors (especially those with preferential activity against COX2), but this may relate to the specific target and the complication of altered eicosanoid production, perhaps changing the balance, away from anti-atherothrombotic end products, such as prostacyclin and resolvins, and toward pro-atherothrombotic products, such as thromboxane, HETE, and lipoxins. Also, although aspirin and ADP receptor antagonists reduce risk for major cardiovascular events, no studies have shown an impact on burden of atheroma.

A randomized clinical trial (CANTOS) explored the efficacy of blocking the IL-1β pro-inflammatory signaling pathway with an FDA-approved monoclonal antibody, canakinumab, in more than 10,000 patients with previous myocardial infarction and elevated CRP levels. The study showed significant reductions in hsCRP levels along with a modest reduction in the primary composite outcome of non-fatal MI, stroke, or cardiovascular death. A trial of the nonspecific anti-inflammatory agent methotrexate (CIRT) showed no cardiovascular benefit, while a secondary prevention trial using colchicine (COLCOT) showed a modest benefit. These studies demonstrate proof of principle for targeting inflammation pathways in atherothrombosis. However, currently available approaches are cumbersome, expensive, and associated with long term risks that may not be acceptable for most patients.

GUT MICROBIOME AND ATHEROTHROMBOSIS

A very promising avenue of research in atherothrombosis is the gut microbiome. Elegant studies using mouse models and human subjects have identified a "metaorganismal" pathway that contributes both to the development of plaque[28] and to the prothrombotic state associated with atherosclerosis.[29] Diets rich in phosphatidylcholine, choline, and carnitine can be metabolized by specific genera of microbes to generate trimethylamine (TMA) through microbial choline TMA lyases. TMA enters the portal circulation and is then converted to trimethylamine n-oxide (TMAO) in the liver by flavin monooxidase enzymes. TMA and TMAO levels in blood associate strongly with both risk of cardiovascular disease and arterial thrombosis in human subjects, and TMAO was shown to promote platelet activation in vitro and thrombosis in animal models. Mechanistically, TMAO increases intracellular calcium levels in platelets; however, the receptor for TMAO has not yet been identified. Importantly, diet influences the constitution of the gut microbiome, as well as the ability to generate TMA and TMAO. Human subjects on vegan diets have reduced capacity to generate TMA/TMAO than do carnivores and omnivores, and this can be restored by adding back meat, eggs, or carnitine to the diet. Interestingly, atherothrombotic risk in mice and humans could be transmitted from susceptible to resistant strains by fecal microbiome transplant, and resistant strains could be converted to susceptible ones by antibiotic or dietary manipulation of the microbiome. Furthermore, transient knockdown or genetic overexpression of flavin monooxygenase in mice promotes the complementary TMAO levels and prothrombotic states in vivo. Choline analogs were subsequently shown to inhibit microbial TMA lyase and lower TMAO levels, thus decreasing platelet reactivity. These studies suggest that microbial enzymes and/or ecosystems could be targeted for atherothrombosis treatment and prevention strategies and this remains an active area of research.

HEMATOPOIESIS AND ATHEROTHROMBOSIS

The bone marrow niche is sensitive to hyperlipidemia. Atherogenic-prone LDL receptor null mice fed a high fat diet show signs of elevated prothrombotic immature reticulated platelets, thrombocytosis, and increased platelet reactivity. Production of these cells could be related to modulation of the thrombopoietin pathway by cholesterol in megakaryocytes or megakaryocyte progenitors. In mice or humans with diabetes and hyperlipidemia, levels of reticulated platelets are increased. Although the mechanisms of elevated platelet production in these settings is not well understood, it could contribute to thrombotic risk in atherogenic conditions.

Whole genome and whole exome sequencing have revealed that clonal hematopoiesis of indeterminate potential (CHIP), that is expansion of somatic blood cell clones in the absence of other hematologic abnormality, is quite common and increases in prevalence progressively with age. While initial interest in CHIP focused on its relationship to development of malignant hematopoiesis, recent studies revealed a significant association with atherosclerotic cardiovascular disease.[30] Prospective and retrospective case-control studies showed two- to fourfold increase in the risk of coronary heart disease and myocardial infarction, with mutations in *DNMT3A*, *TET2*, *ASXL1*, and *JAK2* each associated with increased risk. Bone marrow transplant studies in atherogenic mice using donors deficient in at least some of these genes also showed enhanced atherogenesis. Mechanisms underlying this phenomenon are under intense investigation and may include disordered macrophage function, abnormal cellular metabolism, and thrombocytosis.

PLAQUE REGRESSION

Pharmacologic approaches to decrease the amount of arterial plaque in patients with established atherosclerosis has proved to be an elusive goal. Intravenous ultrasound has shown that aggressive lowering of LDL cholesterol with high-dose statins and rigorous dietary alterations can halt plaque progression and, in some cases, cause some plaque regression.[4] As noted previously, strategies to enhance RCT or to induce macrophage emigration from plaque are being developed, and strategies to stabilize plaque by targeting the neovasculature, cellular apoptosis, and efferocytosis are being considered. Specific antioxidant approaches based on fundamental understanding of the oxidation processes relevant to atherosclerosis remain viable as well, and much effort is being put into developing new animal models to study plaque regression.

ADDITIONAL FUTURE DIRECTIONS

Enthusiasm for large-scale genome-wide association studies (GWAS) as discovery platforms to identify novel genes and pathways that could be targeted with therapeutic or preventive effect has waned as multiple expensive studies have failed to produce impressive results. The most consistent data to come from GWAS identified a large genomic region on chromosome 9p21 as a risk site, but identification of specific genes has not yet been accomplished with certainty. More recently, approaches moving beyond GWAS have coupled whole genome or whole exome sequencing of highly selective subjects (such as genetically isolated Icelanders[31] or subjects with high or low lipoprotein levels) followed by deep sequencing of specific candidate genes in larger cohorts. This approach has yielded new data identifying potential novel anti-atherothrombosis targets; for example, loss of function variants of asialoglycoprotein receptor-1, NPC1L1, and APOC3 were found to be associated with decreased levels of non-HDL cholesterol and decreased risk of coronary artery disease.

An area of research that has generated intriguing data of potential relevance to atherosclerosis diagnostics and therapeutics is the potential role of noncoding RNAs, such as microRNA (miR), long non-coding RNAs (LncRNA), and circular RNAs. MiRs are small non-coding RNAs that regulate gene expression in a sequence-specific manner by post-transcriptional mechanisms. Dozens of miRs that are expressed in highly regulated, tissue-specific manners, and that regulate expression of genes involved in all aspects of atherosclerosis, including hepatic lipoprotein homeostasis; macrophage, endothelial cell, and smooth muscle cell and mechanosensory functions; and cytokine expression have been identified.[9] Therapeutic interventions based on specific miRs are under development, including, as noted previously, an inhibitor of miR-33 to raise HDL levels and promote RCT. Unbiased "omics" studies to identify expression levels of miR-mRNA pairs that associate with cardiovascular risk or with circulating lipoprotein levels also show promise for both biomarker development and therapeutic target discovery.

Although B cells are not prominent cellular constituents of plaque, B1 subclass cells responsible for innate antibody generation, are present in plaque from humans and experimental animals. These cells produce innate IgM antibodies, including a prevalent species called E06 that reacts with oxLDL. E06 and other autoantibodies against plaque constituents may be protective, perhaps by facilitating clearance of oxLDL via pathways that do not lead to foam cell formation, and/or by interfering with oxLDL-mediated activation of circulating monocytes and platelets.[15] These studies were exemplified by the reduction of atherosclerosis in hyperlipidemic murine models expressing a single chain variant of E06. Based on these observations, passive immunization strategies against oxLDL are also being considered.

CHAPTER 143

ANTITHROMBOTIC DRUGS

Iqbal H. Jaffer and Jeffrey I. Weitz

Arterial or venous thromboembolism is a major cause of morbidity and mortality. Arterial thrombosis is the most common cause of acute myocardial infarction, ischemic stroke, and limb gangrene, whereas deep vein thrombosis can lead to pulmonary embolism, which can be fatal, and to post-thrombotic syndrome. Most arterial thrombi are superimposed on disrupted atherosclerotic plaque because plaque rupture exposes thrombogenic material in the plaque core to the blood.[1] This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that can temporarily or permanently occlude blood flow (see Chapter 143). In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption.[1] Although they can develop after surgical trauma to veins or secondary to indwelling central venous catheters, venous thrombi usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses, where they are triggered by stasis. Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps. Endothelial cells lining the valve cusps become activated and express adhesion molecules on their surface. These adhesion molecules tether tissue factor–bearing leukocytes and micro particles to the surface of activated endothelial cells, where the tissue factor triggers coagulation (see Chapter 121). Local thrombus formation is exacerbated by reduced clearance of activated clotting factors because of impaired blood flow. If the calf vein thrombi extend into more proximal veins of the leg, thrombus fragments can dislodge, travel to the lungs, and produce a pulmonary embolism.

Arterial and venous thrombi are composed of platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low-shear conditions, contain relatively few platelets and are composed predominantly of fibrin and trapped red cells. Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi are red in color, reflecting the trapped red cells.

Antithrombotic drugs are used for the prevention and treatment of thrombosis. Targeting the components of thrombi, these agents include (1) antiplatelet drugs, which inhibit platelets; (2) anticoagulants, which attenuate coagulation; and (3) fibrinolytic agents, which induce fibrin degradation (Fig. 143.1). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis are focused mainly on antiplatelet agents, although in the acute setting they often include anticoagulants and fibrinolytic agents. The observations that the addition of low-dose rivaroxaban, an oral factor Xa inhibitor, to dual-antiplatelet therapy reduces recurrent ischemic events in patients with acute coronary syndrome, and its addition to aspirin reduces the risk of major adverse coronary and limb events in patients with coronary or peripheral artery disease, highlight the potential usefulness of anticoagulants on top of antiplatelet agents for secondary prevention (see Chapter 145 and 146).

Anticoagulants are the mainstay of prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi. Antiplatelet drugs are less effective than anticoagulants in this setting because of the limited platelet content of venous thrombi. Fibrinolytic therapy is used in selected patients with venous thromboembolism. For example, patients with severe pulmonary embolism as evidenced by hypotension benefit from systemic or catheter-directed fibrinolytic therapy. Catheter-directed fibrinolytic therapy also can be used as an adjunct to anticoagulants for the treatment of patients with deep vein thrombosis involving the iliac and femoral veins.

This chapter is focused on antithrombotic agents. In addition to describing antiplatelet, anticoagulant, and fibrinolytic drugs that are in current use, new agents in advanced stages of development also are discussed.

ANTIPLATELET DRUGS

Role of Platelets in Arterial Thrombosis

In healthy vasculature, circulating platelets are maintained in an inactive state by nitric oxide (NO) and prostacyclin released by endothelial cells lining the blood vessels (see Chapter 121). In addition, endothelial cells also express CD39—an ecto-ADPase—on their surface, which degrades adenosine diphosphate (ADP) released from activated platelets. When the vessel wall is damaged, the release of these substances is impaired and the subendothelial matrix is exposed. Platelets adhere to exposed collagen and to von Willebrand factor via glycoprotein (GP) VI and GPIb–IX, respectively; receptors are constitutively expressed on the platelet surface (see Chapter 124). Adherent platelets undergo a change in shape, secrete ADP from their dense granules, and synthesize and release thromboxane A_2. Released ADP and thromboxane A_2, which are platelet agonists, activate ambient platelets and recruit them to the site of vascular injury.

Disruption of the vessel wall also exposes tissue factor–expressing cells to the blood. Tissue factor initiates coagulation (see Chapter 125). Activated platelets potentiate coagulation by binding clotting factors and supporting the assembly of activation complexes that enhance thrombin generation. In addition to converting fibrinogen to fibrin, thrombin amplifies its own generation and serves as a potent platelet agonist, thereby recruiting additional platelets to the site of injury.

When platelets are activated, GPIIb/IIIa ($\alpha_{IIb}\beta_3$), the most abundant receptor on the platelet surface, undergoes a conformational change that enables it to ligate fibrinogen (see Chapter 124). Divalent fibrinogen molecules bridge adjacent platelets together to form platelet aggregates. Fibrin strands, generated through the action of thrombin, then weave these aggregates together to form a platelet–fibrin mesh.

Antiplatelet drugs target various steps in this process (Fig. 143.2). The commonly used drugs include aspirin, thienopyridines (clopidogrel and prasugrel), ticagrelor, cangrelor, dipyridamole, GPIIb/IIIa antagonists, and vorapaxar. Each is briefly described in the following.

Aspirin

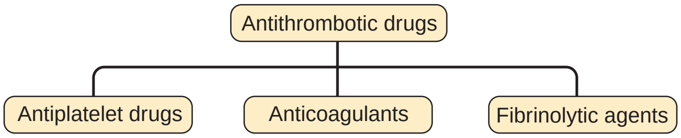
The most widely used antiplatelet agent is aspirin. As a cheap and effective antiplatelet drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action

Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet cyclooxygenase-1 (COX-1), a critical enzyme in the biosynthesis of thromboxane A_2 (see Fig. 143.2). At high doses (about 1 g/day), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells. In endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator, and inhibitor of platelet aggregation.

Indications

Aspirin is widely used for secondary prevention of cardiovascular events in patients with coronary artery disease, cerebrovascular disease, or peripheral vascular disease. Compared with placebo, aspirin produces about a 25% reduction in the risk of cardiovascular death, myocardial infarction, or stroke in these patients. Aspirin is of limited benefit for primary prevention in subjects without established cardiovascular disease.[2] If used for primary prevention, aspirin should be restricted for those at high risk of cardiovascular events.[2]



Antithrombotic drugs
Antiplatelet drugs
Anticoagulants
Fibrinolytic agents

Figure 143.1 CLASSIFICATION OF ANTITHROMBOTIC DRUGS.

Dosages

Aspirin is usually administered at doses of 75 to 325 mg once daily. There is no evidence that higher-dose aspirin is more effective than lower aspirin doses, and some analyses suggest reduced efficacy with higher doses. Because the side effects of aspirin are dose-related, daily aspirin doses of 75 to 150 mg are recommended for most indications. When rapid platelet inhibition is required, an initial aspirin dose of at least 160 mg should be given.

Side Effects

The most common side effects are gastrointestinal and range from dyspepsia to erosive gastritis or peptic ulcers with associated bleeding. These side effects are, at least to some extent, dose related. The use of enteric-coated or buffered aspirin in place of plain aspirin does

Figure 143.2 SITES OF ACTION OF ANTIPLATELET DRUGS. Aspirin inhibits thromboxane A_2 (TXA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Clopidogrel, prasugrel, ticagrelor, and cangrelor block $P2Y_{12}$, a key adenosine diphosphate (ADP) receptor on the platelet surface. Therefore, these agents also attenuate platelet recruitment. Vorapaxar inhibits type 1 protease-activated receptor (PAR-1), the major thrombin receptor on platelets. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen binding to activated glycoprotein (GP) IIb/IIIa. *vWF*, von Willebrand factor.

not eliminate the prostaglandin-mediated gastrointestinal side effects. The risk of major bleeding with aspirin ranges from 1% to 3% per year and is higher when aspirin is used in conjunction with anticoagulants, such as warfarin. When dual antiplatelet therapy is used, low-dose aspirin should be given (75 to 100 mg daily). Eradication of *Helicobacter pylori* infection and concomitant administration of proton pump inhibitors may reduce the risk of upper gastrointestinal bleeding, particularly in patients with a history of peptic ulcer disease.

Aspirin should not be administered to patients with aspirin allergy characterized by bronchospasm. This problem occurs in about 0.3% of the general population and is more common in those with chronic urticaria, asthma, nasal polyps, or chronic rhinitis. Hepatic and renal toxicity is observed with aspirin overdose.

Aspirin Resistance

The term *aspirin resistance* has been used to describe both clinical and laboratory phenomena.[3] Clinical aspirin resistance is defined as the failure of aspirin to protect patients from ischemic vascular events. This is not a helpful definition, because it is made after a breakthrough adverse cardiovascular event occurs. Furthermore, it is not realistic to expect aspirin, which blocks only thromboxane A_2–induced platelet activation, to prevent all vascular events.

Aspirin resistance also has been described biochemically as a failure of the drug to produce its expected inhibitory effects on tests of platelet function, such as thromboxane A_2 synthesis or arachidonic acid–induced platelet aggregation. Poor adherence is a common cause of apparent aspirin resistance (see Chapter 128). Even in those taking the drug, however, the tests used for the diagnosis of aspirin resistance are not well standardized. Furthermore, there is no definitive evidence that these tests identify patients at risk of recurrent vascular events, or that resistance can be reversed either by giving higher doses of aspirin or by adding other antiplatelet drugs. Until such information is available, testing for aspirin resistance remains a research tool.

ADP Receptor Antagonists

$P2Y_{12}$ is the major ADP receptor on platelets. Agents that inhibit $P2Y_{12}$ include oral agents such as the thienopyridines and ticagrelor, and cangrelor, which is a parenteral inhibitor.

Thienopyridines

The thienopyridines include clopidogrel and prasugrel, as well as ticlopidine, which is rarely used.

Mechanism of Action

The thienopyridines are structurally related drugs that selectively inhibit ADP-induced platelet aggregation by irreversibly blocking $P2Y_{12}$ (see Fig. 143.2). Clopidogrel and prasugrel are prodrugs that must be metabolized by the hepatic cytochrome P450 (CYP) enzyme system to acquire activity. Consequently, their onset of action is delayed unless loading doses are given. The metabolic activation of prasugrel is more efficient than that of clopidogrel. Consequently, prasugrel produces a more rapid, greater, and more uniform $P2Y_{12}$ blockade than clopidogrel.

Indications

When compared with aspirin in patients with recent ischemic stroke, myocardial infarction, or peripheral arterial disease, clopidogrel reduced the risk of cardiovascular death, myocardial infarction, and stroke by 8.7%. Therefore, clopidogrel is slightly more effective than aspirin, but it is more expensive. Clopidogrel and aspirin are often combined to capitalize on their capacity to block complementary pathways of platelet activation. For example, dual antiplatelet therapy with the combination of aspirin plus clopidogrel is recommended after stent implantation in the coronary arteries for management of acute coronary syndrome (see Chapter 145) or in the arteries of the leg for management of acute limb ischemia (see Chapter 146).

The combination of clopidogrel and aspirin also is effective in patients with unstable angina. Thus in 12,562 such patients, the risk of cardiovascular death, myocardial infarction, or stroke was 9.3% in those randomized to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone, a 20% relative risk reduction.[4] However, combining clopidogrel with aspirin increases the risk of major bleeding to about 2% per year. This bleeding risk persists even if the daily dose of aspirin is 100 mg or less. Therefore, the combination of clopidogrel and aspirin should be used only when there is a clear benefit. For example, this combination has not proven to be superior to clopidogrel alone in patients with acute ischemic stroke or to aspirin alone for primary prevention in those at risk for cardiovascular events.

When compared with clopidogrel in 13,608 patients with acute coronary syndromes undergoing percutaneous coronary intervention (PCI), prasugrel reduced the combined rate of cardiovascular death, myocardial infarction, or stroke from 12.1% to 9.9%, a decrease driven mainly by a reduction in nonfatal myocardial infarction.[5] However, prasugrel increased the rate of major bleeding and fatal bleeding, particularly in patients over the age of 65 years, in those weighing less than 60 kg, and in those with a history of stroke.[5] Therefore, prasugrel should not be used in patients with these characteristics. Prasugrel was compared with clopidogrel in 7243 aspirin-treated patients under the age of 75 years with unstable angina or myocardial infarction without ST-segment elevation. At a median follow-up of 17 months, the primary endpoint, the composite of cardiovascular death, myocardial infarction, and stroke had occurred in 13.9% of the prasugrel group and in 16% of the clopidogrel group, a difference that was not statistically significant.[6] Rates of major bleeding and intracranial bleeding were similar with the two treatment regimens. Therefore, prasugrel has no advantage over clopidogrel in medically managed patients with acute coronary syndrome.

Dosing

Clopidogrel is given once daily at a dose of 75 mg. Because its onset of action is delayed for several days, loading doses of clopidogrel are given when rapid ADP receptor blockade is desired. For example, patients undergoing coronary artery stenting are often given a loading dose of 600 mg, which produces inhibition of ADP-induced platelet aggregation within 6 hours. Prasugrel is given as a loading dose of 60 mg followed by 10 mg once daily. Patients older than 75 years or weighing less than 60 kg should receive a daily prasugrel dose of 5 mg.

Side Effects

Gastrointestinal and hematologic side effects, other than bleeding, are rare with clopidogrel and prasugrel.

Clopidogrel Resistance

There is considerable between-patient variability in the capacity of clopidogrel to inhibit ADP-induced platelet aggregation.[7] Reduced responsiveness to clopidogrel is termed *clopidogrel resistance* and platelets from patients with this phenomenon exhibit high reactivity to ADP. Reduced responsiveness to clopidogrel reflects, at least in part, genetic polymorphisms in CYP2C19, which is critical for metabolic activation of clopidogrel in the liver. Loss-of-function *CYP2C19*2* and *CYP2C19*3* alleles are found in 2% of Whites, 4% of Blacks, and 14% of Asians, and the levels of the active metabolite of clopidogrel are reported to be up to 33% lower in carriers of either of these alleles than in those with healthy alleles. Patients with clopidogrel resistance are reported to have a higher risk of ischemic complications after PCI, including myocardial infarction and stent thrombosis. Based on these findings, some experts recommend pharmacogenetic testing and point-of-care assessment of platelet reactivity to predict or assess clopidogrel responsiveness. However, attempts to manage such patients with higher doses of clopidogrel or with additional antiplatelet drugs have not resulted in improved outcomes. Instead, patients with clopidogrel resistance may benefit from a switch to prasugrel, which produces more uniform inhibition of ADP-induced platelet aggregation, or to ticagrelor.

Ticagrelor

An orally active agent belonging to the cyclopentyl-triazolopyrimidine class, ticagrelor acts as a direct inhibitor of $P2Y_{12}$.

Mechanism of Action

Ticagrelor reversibly binds to $P2Y_{12}$ at a location distinct from the ADP binding site and blocks ADP-mediated receptor activation in a noncompetitive fashion, likely through an allosteric mechanism. Because it does not require metabolic activation, ticagrelor has a more rapid onset of action than clopidogrel or prasugrel.

Indications

When compared with clopidogrel in 18,624 patients with acute coronary syndromes, ticagrelor reduced the rate of cardiovascular death, myocardial infarction, or stroke from 11.7% to 9.8%.[8] All-cause mortality was also reduced with ticagrelor compared with clopidogrel (4.5% and 5.9%, respectively; $P < .001$), but ticagrelor produced more major bleeding not related to bypass surgery (2.8% and 2.2%, respectively).[8] An invasive strategy was planned for 72% of the patients entered in the trial. In this subset, the primary composite endpoint occurred in 9% of patients randomized to ticagrelor and in 10.7% of those given clopidogrel, a 16% relative risk reduction.[9] Rates of major bleeding were similar with ticagrelor and clopidogrel (11.6% and 16.5%, respectively; $P = .88$). Therefore ticagrelor also was superior to clopidogrel in patients undergoing coronary interventions.

If cost is not an issue and patients are compliant with twice-daily dosing, ticagrelor is a reasonable alternative to clopidogrel in patients with acute coronary syndrome, regardless of whether they are managed medically or undergo PCI with stent implantation. For these indications, ticagrelor should be given for at least 1 year. It also is reasonable to use ticagrelor in place of clopidogrel in patients with clopidogrel resistance or in those who develop in-stent thrombosis despite clopidogrel therapy.

Dosing

Ticagrelor is given as a 180-mg oral loading dose followed by 90 mg twice daily. The dose does not need adjustment in patients with renal impairment, but caution is needed in patients with hepatic impairment or in those receiving potent inhibitors or inducers of CYP3A4 because ticagrelor is metabolized in the liver via CYP3A4. Ticagrelor is usually administered in conjunction with aspirin; the daily aspirin dose should not exceed 100 mg.[10]

Side Effects

In addition to bleeding, the most common side effects of ticagrelor include dyspnea, which can develop in up to 15% of patients, and bradyarrhythmia. The dyspnea, which tends to occur soon after initiating ticagrelor, is usually self-limited and mild in intensity but can be persistent and may necessitate drug discontinuation in some patients. Although the exact mechanism responsible for these side effects is unknown, they may be adenosine-mediated because ticagrelor inhibits its reuptake.

Cangrelor

Cangrelor is the only available parenteral inhibitor of $P2Y_{12}$.

Mechanism of Action

Cangrelor is a rapidly acting reversible inhibitor of $P2Y_{12}$. It has an immediate onset of action after intravenous administration, a half-life of 3 to 5 minutes, and an offset of action within 1 hour.

Indications

Cangrelor is licensed for use in patients undergoing PCI, in whom it produces rapid ADP receptor blockade in those who have not received pretreatment with clopidogrel, prasugrel, or ticagrelor and are not receiving a GPIIb/IIIa inhibitor.

Dosing

Cangrelor is administered as a 30 μg/kg intravenous bolus before PCI followed by an infusion of 4 μg/kg/min for at least 2 hours or for the duration of PCI, whichever is longer. When transitioning to oral $P2Y_{12}$ inhibitor therapy, ticagrelor can be given at a loading dose of 180 mg at any time during the cangrelor infusion or immediately after discontinuation. In contrast, loading doses of prasugrel or clopidogrel (60 and 600 mg, respectively) should be given only after cangrelor is stopped because cangrelor blocks the interaction of their active metabolites with $P2Y_{12}$.

Side Effects

The major side effect of cangrelor is bleeding.

Dipyridamole

Dipyridamole is a relatively weak antiplatelet agent on its own. An extended-release formulation of dipyridamole combined with low-dose aspirin, a preparation known as Aggrenox, is used for the prevention of stroke in patients with transient ischemic attacks.

Mechanism of Action

By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cyclic AMP (cAMP). Increased levels of cAMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. This produces a further increase in local cAMP levels because the platelet adenosine A_2 receptor is coupled to adenylate cyclase (Fig. 143.3).

Indications

Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone, or with placebo, in patients with an ischemic stroke or transient ischemic attack. The combination reduced the risk of stroke by 22.1% compared with aspirin alone and by 24.4% compared with dipyridamole alone. In a second trial, researchers compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or myocardial infarction occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone. When Aggrenox was compared with clopidogrel, however, there was no difference in efficacy,

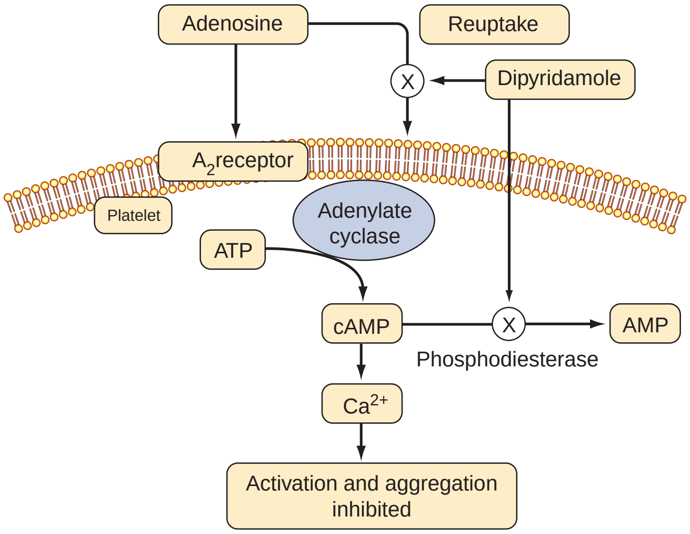

Figure 143.3 MECHANISM OF ACTION OF DIPYRIDAMOLE. Dipyridamole increases levels of cyclic adenosine monophosphate (cAMP) in platelets by blocking the reuptake of adenosine and by inhibiting phosphodiesterase-mediated cAMP degradation. By promoting calcium uptake, cAMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation. *AMP*, Adenosine monophosphate; *ATP*, adenosine triphosphate.

and there was more intracranial bleeding with Aggrenox.[11] Although Aggrenox is used for stroke prevention, because of its vasodilatory effects and the paucity of data supporting the use of dipyridamole in patients with symptomatic coronary artery disease, Aggrenox should not be used for stroke prevention in such patients.

Dosing

Aggrenox is given twice daily. Each capsule contains 200 mg of extended-release dipyridamole and 25 mg of aspirin.

Side Effects

Because dipyridamole has vasodilatory effects, it must be used with caution in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension also can occur. These symptoms often subside with continued use of the drug.

GPIIb/IIIa Receptor Antagonists

As a class, parenteral GPIIb/IIIa receptor antagonists have an established niche in patients with acute coronary syndromes. The three agents in this class are abciximab, eptifibatide, and tirofiban.

Mechanism of Action

A member of the integrin family of adhesion receptors, GPIIb/IIIa is found on the surface of platelets and megakaryocytes. With about 40,000 to 80,000 copies per platelet, GPIIb/IIIa is the most abundant receptor (see Chapter 124). Consisting of a noncovalently linked heterodimer, GPIIb/IIIa is inactive on resting platelets. When platelets are activated, inside-outside signal transduction pathways trigger a conformational activation of the receptor. Once activated, GPIIb/IIIa binds adhesive molecules, such as fibrinogen and, under high shear conditions, von Willebrand factor. Binding is mediated by Arg-Gly-Asp (RGD) sequences found on fibrinogen and von Willebrand factor, as well as by the Lys-Gly-Asp (KGD) sequence located within a unique dodecapeptide domain on the γ-chains of fibrinogen. Once bound, fibrinogen and/or von Willebrand factor bridge adjacent platelets together to induce platelet aggregation.

Although abciximab, eptifibatide, and tirofiban all target the GPIIb/IIIa receptor, they are structurally and pharmacologically distinct (Table 143.1). Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of GPIIb/IIIa. Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast to abciximab, eptifibatide, and tirofiban are synthetic small molecules. Eptifibatide is a cyclic heptapeptide that binds GPIIb/IIIa because it incorporates the KGD motif, whereas tirofiban is a nonpeptidic tyrosine derivative that acts as an RGD mimetic. Abciximab has a long half-life and can be detected on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have shorter half-lives.

In addition to targeting the GPIIb/IIIa receptor, abciximab also inhibits the closely related $\alpha_v\beta_3$ receptor, which binds vitronectin, and $\alpha_M\beta_2$, a leukocyte integrin. In contrast, eptifibatide and tirofiban are specific for GPIIb/IIIa. Inhibition of $\alpha_v\beta_3$ and $\alpha_M\beta_2$ may endow abciximab with antiinflammatory and/or antiproliferative properties that extend beyond platelet inhibition.

Indications

These agents are used in high-risk patients undergoing PCI, particularly those with ST-segment elevation acute myocardial infarction who have not been adequately pretreated with antiplatelet drugs or in those requiring rapid platelet inhibition. Tirofiban and eptifibatide are occasionally used upstream to intervention in high-risk patients with unstable angina.

TABLE 143.1 **Features of GPIIb/IIIa Antagonists**

Feature	GPIIb/IIIa Antagonists		
Generic name	Abciximab	Eptifibatide	Tirofiban
Trade name	ReoPro	Integrilin	Aggrastat
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GPIIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 h)	Long (2.0 h)
Platelet-bound half-life	Long (days)	Short	Short
Renal clearance	No	Yes	Yes
Dosing	0.25 mg/kg bolus followed by a 12-h infusion of 10 µg/min	Two 180 µg/kg boluses given 10 min apart	25 µg/kg boluses followed by an 18-h infusion of 0.15 µg/kg/min
Adjustment for renal impairment	No	Yes	Yes

KGD, Lys-Gly-Asp; *RGD*, Arg-Gly-Asp.

Dosing

All the GPIIb/IIIa antagonists are given as an intravenous bolus followed by an infusion. Because they are cleared by the kidneys, the doses of eptifibatide and tirofiban must be reduced in patients with renal impairment.

Side Effects

In addition to bleeding, thrombocytopenia is the most serious complication. Thrombocytopenia is immune-mediated and is caused by antibodies directed against neoantigens on GPIIb/IIIa that are exposed upon antagonist binding (see Chapter 129). With abciximab, thrombocytopenia occurs in up to 5% of patients. Thrombocytopenia is severe in about 1% of these individuals. Thrombocytopenia is less common with the other two agents, occurring in about 1% of treated patients.

Vorapaxar

An orally active inhibitor of type 1 protease-activated receptor (PAR-1), vorapaxar inhibits the major thrombin receptor on platelets.[12,13]

Mechanism of Action

Thrombin is a potent platelet activator that acts through PARs (see Chapter 124).[14] PAR-1 is the highest-affinity thrombin receptor on platelets; PAR-1 also is expressed on endothelial cells and atherosclerotic plaques.[15] Vorapaxar is a synthetic analog of himbacine, which is a natural product. Given orally, vorapaxar is rapidly absorbed from the gastrointestinal tract and inhibits platelet PAR-1 in a reversible manner; however, because of its long half-life (8 to 12 days) and its high-affinity interaction with PAR-1, vorapaxar is effectively an irreversible inhibitor of PAR-1.

Indications

Vorapaxar is indicated for the reduction of thrombotic cardiovascular events in patients with a history of myocardial infarction or peripheral artery disease and no history of intracranial hemorrhage, stroke, or transient ischemic attack. The drug is often administered in conjunction with aspirin and/or clopidogrel. Vorapaxar is contraindicated in patients with a prior history of intracranial bleeding, stroke, or transient ischemic attack.

Dosing

Vorapaxar is given orally at a dose of 2.08 mg once daily.

Side Effects

The major side effect is bleeding, including intracranial and fatal bleeding.

ANTICOAGULANTS

There are both parenteral and oral anticoagulants. Currently available parenteral anticoagulants include heparin, low-molecular-weight heparin (LMWH), fondaparinux, and direct thrombin inhibitors (hirudin, bivalirudin, and argatroban). The oral anticoagulants include the vitamin K antagonists, of which warfarin is the agent most often used in North America, and the direct oral anticoagulants (DOACs), which are also termed non-vitamin K antagonist oral anticoagulants (NOACs) that target thrombin (dabigatran etexilate) or factor Xa (rivaroxaban, apixaban, and edoxaban).[14]

Parenteral Anticoagulants

Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells. Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and *N*-acetyl-D-glucosamine residues.

Mechanism of Action

Heparin acts as an anticoagulant by activating antithrombin (previously known as *antithrombin III*) and accelerating the rate at which antithrombin inhibits clotting enzymes, particularly thrombin and factor Xa (see Chapter 121). Antithrombin, the obligatory plasma cofactor for heparin, is a 58,000-Da single-chain polypeptide that is a member of the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of 2.6 ± 0.4 μM, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence that is found on one-third of the chains of commercial heparin (Fig. 143.4); heparin chains lacking this pentasaccharide sequence have little or no anticoagulant activity. Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude, but it has little effect on the rate of thrombin inhibition by antithrombin (Fig. 143.5). To catalyze thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously. The formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin–antithrombin complex.

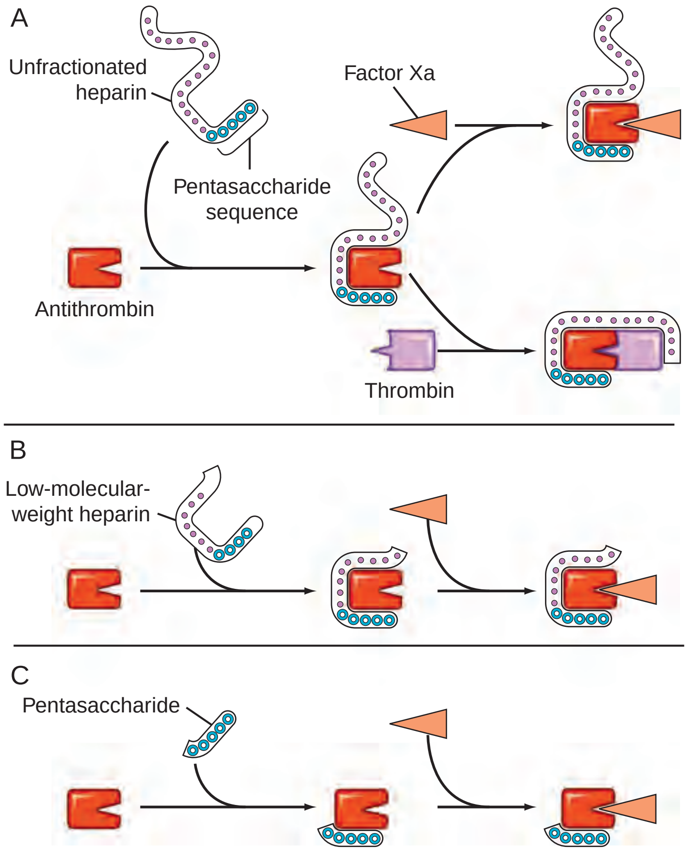

Figure 143.4 MECHANISM OF ACTION OF HEPARIN, LOW-MOLECULAR-WEIGHT HEPARIN (LMWH), AND FONDAPARINUX. (A) Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which correspond to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all the heparin chains are long enough to do this. (B) LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin does because, with a mean molecular weight of 4500 to 5000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. (C) The synthetic pentasaccharide fondaparinux only accelerates factor Xa inhibition by antithrombin because it is too short to bridge antithrombin to thrombin.

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which correspond to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin together. With a mean molecular weight of 15,000 and a range of 5000 to 30,000, most of the chains of unfractionated heparin are long enough to produce this bridging effect. Consequently, by definition, heparin has equal capacity to promote the inhibition of thrombin and factor Xa by antithrombin and is assigned an anti-factor Xa to anti-factor IIa (thrombin) ratio of 1:1.

In addition to activating antithrombin, heparin also catalyzes heparin cofactor II. This 66,000-Da serpin, which is found in plasma at a concentration of 1.2 ± 0.4 μM, is a specific inhibitor of thrombin (see Chapter 125). Two features account for the specificity of heparin cofactor II. First, the reactive site of heparin cofactor II contains the sequence Leu444–Ser445, a peptide bond that is not

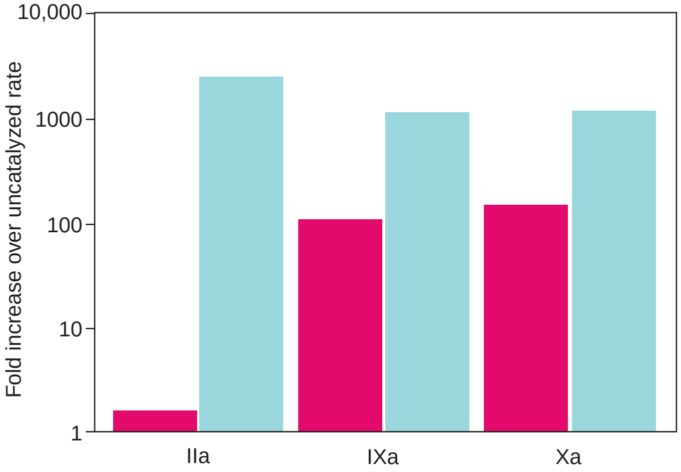

Figure 143.5 COMPARISON OF THE STIMULATORY EFFECTS OF PENTASACCHARIDE AND UNFRACTIONATED HEPARIN ON CATALYSIS OF ANTITHROMBIN-MEDIATED INHIBITION OF THROMBIN (IIa), FACTOR IXa (IXa), AND FACTOR Xa (Xa). Second-order rate constants of inhibition of factor IIa, IXa, or Xa by antithrombin, measured in the presence of heparin *(green bars)* or fondaparinux *(pink bars)* were divided by those determined in the absence of glycosaminoglycan and are plotted as fold increases over the uncatalyzed rate of inhibition. *(From Wiebe EM, Stafford AR, Fredenburgh JC, et al. Mechanism of catalysis of inhibition of factor IXa by antithrombin in the presence of heparin or pentasaccharide. J Biol Chem. 2003;278(37):35767–35774.)*

readily susceptible to cleavage by coagulation proteases other than thrombin. Second, heparin cofactor II possesses a unique anionic sequence at its N-terminal. In its unactivated state, this sequence forms an intramolecular bond with the positively charged glycosaminoglycan binding site located on the body of heparin cofactor II. When heparin or dermatan sulfate, a glycosaminoglycan that interacts only with heparin cofactor II, binds to heparin cofactor II, this N-terminal sequence is displaced which enables its tethering to a positively charged domain on thrombin known as *exosite 1*. This tethering interaction occurs only with thrombin and facilitates thrombin inhibition by heparin cofactor II (Fig. 143.6).

Maximum catalysis of heparin cofactor II by heparin requires heparin chains composed of at least 26 saccharide units, which corresponds to a molecular weight of 7800. Longer heparin chains activate heparin cofactor II to a greater extent than shorter chains because the longer chains are of sufficient length, not only to bind to heparin cofactor II, but also to bind to thrombin to form a ternary complex. The formation of this ternary complex brings thrombin and heparin cofactor II into close apposition.

The interaction of heparin with heparin cofactor II is not mediated by the antithrombin-binding pentasaccharide sequence. Because heparin lacks a specific heparin cofactor II binding domain, heparin's affinity for heparin cofactor II is lower than that for antithrombin. Consequently, 10-fold higher heparin concentrations are needed to promote thrombin inhibition by heparin cofactor II than thrombin inhibition by antithrombin. Therefore, heparin cofactor II only contributes to the anticoagulant activity of heparin when the drug is given in high doses.

Heparin causes the release of tissue factor pathway inhibitor (TFPI) from the endothelium. A factor Xa-dependent inhibitor of tissue factor–bound factor VIIa, TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter chains.

Pharmacology

Heparin must be given parenterally. It is usually administered subcutaneously or by continuous intravenous infusion. When used for therapeutic purposes, the intravenous route is most often employed.

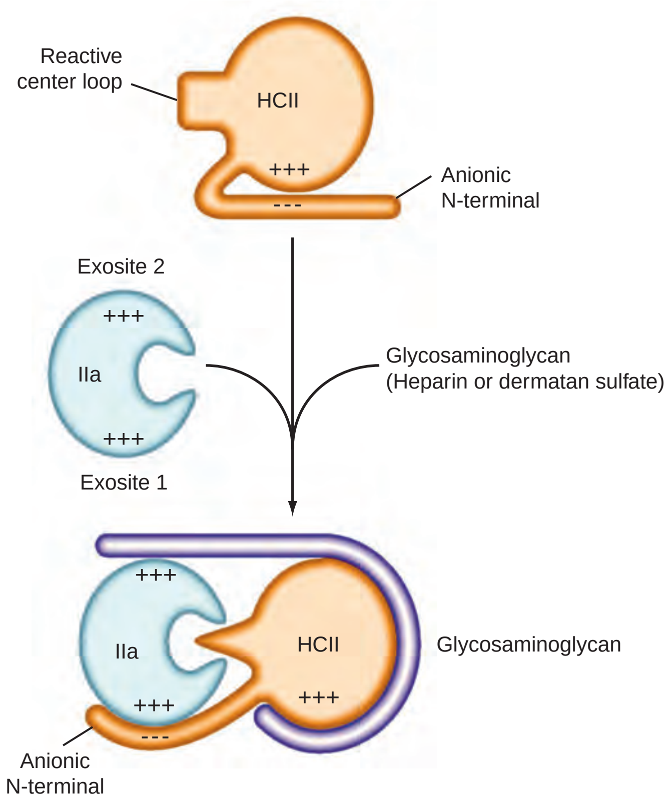

Figure 143.6 CATALYSIS OF HEPARIN COFACTOR II (HCII) BY GLYCOSAMINOGLYCANS. In its unactivated form, the acidic N-terminal tail of HCII is tethered to the positively charged glycosaminoglycan-binding site on the body of the serpin. The binding of heparin or dermatan sulfate to this binding site displaces the N-terminal tail, thereby facilitating the interaction of this anionic domain with exosite 1 on thrombin. Glycosaminoglycan binding also evokes a conformational change in the reactive center loop of HCII that contributes to the formation of the HCII–thrombin complex. Longer heparin chains bind not only to HCII but also to the heparin-binding domain on thrombin, so-called exosite 2. Heparin-mediated bridging of HCII to thrombin enhances the rate of inhibition. Consequently, longer heparin chains that contain at least 26 saccharide units promote thrombin inhibition by HCII to a greater extent than shorter chains. Unlike heparin, dermatan sulfate does not need to bind to thrombin for maximal enhancement in the rate of thrombin inhibition, because shorter dermatan sulfate fragments are just as active as longer ones.

If heparin is given subcutaneously for treatment of thrombosis, the dose of heparin must be high enough to overcome the limited bioavailability associated with this method of delivery.

After entering the circulation, heparin binds to a variety of plasma proteins other than antithrombin, which decreases its anticoagulant activity. The levels of heparin-binding proteins vary between patients because some of these proteins are acute-phase reactants whose levels are elevated in ill patients, whereas others, such as high-molecular-weight multimers of von Willebrand factor, are released when platelets or endothelial cells are activated by thrombin. Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity. A large amount of PF4 in the vicinity of platelet-rich arterial thrombi can neutralize the anticoagulant activity of heparin.

Because the levels of heparin-binding proteins vary between patients, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently, coagulation monitoring is essential to ensure that a therapeutic response is obtained when heparin is administered for treatment purposes.

Heparin is cleared through a combination of a rapid, saturable, and a much slower first-order mechanism. The saturable phase of heparin clearance reflects binding to endothelial cell receptors and macrophages.

Bound heparin is internalized and depolymerized. The slower, nonsaturable mechanism of clearance is largely renal. At therapeutic doses, a large proportion of heparin is cleared through the rapid, saturable, dose-dependent mechanism. The complex kinetics of clearance renders the anticoagulant response to heparin nonlinear at therapeutic doses, with both the intensity and duration of effect rising disproportionately with increasing dose. Thus, the apparent biological half-life of heparin increases from approximately 30 minutes after an intravenous bolus of 25 units/kg, to 60 minutes with an intravenous bolus of 100 units/kg, to 150 minutes with a bolus of 400 units/kg.

Monitoring

Heparin therapy can be monitored using the activated partial thromboplastin time (aPTT), anti-factor Xa level, or the activated clotting time (ACT). Although the aPTT is the test most often employed for this purpose, there are problems with this assay. aPTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for testing can influence the results. Consequently, laboratories must establish a therapeutic aPTT range with each reagent–coagulometer combination by measuring the aPTT and anti-factor Xa level in plasma samples collected from heparin-treated patients. For most of the aPTT reagents and coagulometers in current use, therapeutic heparin levels are achieved with a two- to threefold prolongation of the aPTT.

Anti-factor Xa levels also can be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 units/mL. Although this test is gaining in popularity, anti-factor Xa assays have yet to be standardized, and results can vary between laboratories.

The ACT is used to monitor heparin when high doses are given (>100 units/kg) to patients undergoing PCI or cardiac surgery with cardiopulmonary bypass (CPB) and those requiring extracorporeal membrane oxygenation (ECMO). The ACT varies depending on which device is used. For PCI, the target ACT is 250 to 300 seconds in patients not receiving GPIIb/IIIa inhibitors and 200 to 250 seconds if a GPIIb/IIIa inhibitor is given. For CPB, a target ACT longer than 480 seconds is desirable, whereas for ECMO, the target ACT ranges from 140 to 240 seconds.

Up to 25% of heparin-treated patients with venous thromboembolism require more than 35,000 units/day to achieve a therapeutic aPTT. These patients are considered heparin resistant. It is useful to measure anti-factor Xa levels in these patients because many will have a therapeutic anti-factor Xa level despite a subtherapeutic aPTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both of which are acute-phase proteins, shorten the aPTT but have no effect on anti-factor Xa levels. Heparin therapy in patients who exhibit this phenomenon is best monitored using anti-factor Xa levels instead of the aPTT. Patients with congenital or acquired antithrombin deficiency and those with unusually high levels of heparin-binding proteins often require very high doses of heparin to achieve a therapeutic aPTT or anti-factor Xa level. If there is good correlation between the aPTT and the anti-factor Xa levels, either test can be used to monitor heparin therapy.

Dosing

For prophylaxis, heparin is usually given in fixed doses of 5000 units subcutaneously two or three times daily. With these low doses, coagulation monitoring is unnecessary. In contrast, monitoring is essential when heparin is given in therapeutic doses because a subtherapeutic anticoagulant response has been associated with a higher risk of recurrent thrombosis. Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with venous thromboembolism and both reduced the time required to achieve a therapeutic aPTT. Weight-adjusted heparin nomograms also have been evaluated in patients with acute coronary syndrome.

Unmonitored twice-daily subcutaneous heparin proved as effective and safe as once-daily LMWH for initial treatment of venous thromboembolism in one study.[15] High doses of heparin were used; treatment was started with a dose of 333 units/kg followed by 250 units/kg twice daily thereafter. This regimen may be an option for patients with renal insufficiency where LMWH or fondaparinux is problematic.

TABLE 143.2 Pharmacokinetic and Biophysical Limitations of Heparin

Limitations	Mechanism
Poor bioavailability at low doses	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins whose levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by platelet factor 4 released from activated platelets
Limited activity against factor Xa incorporated in the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin–antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin bound to fibrin

Limitations

Heparin has pharmacokinetic and biophysical limitations (Table 143.2). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Heparin binding to cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin–antithrombin complex to (1) inhibit factor Xa when it is incorporated into the prothrombinase complex, the complex that converts prothrombin to thrombin, and (2) inhibit thrombin bound to fibrin. Consequently, factor Xa bound to activated platelets within platelet-rich thrombi has the potential to generate thrombin, even in the face of heparin. Once this thrombin binds to fibrin, it too is protected from inhibition by the heparin–antithrombin complex. Clot-associated thrombin can then trigger thrombus growth by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI. Further compounding the problem is the potential for heparin neutralization by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus.

Side Effects

The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

Bleeding

The risk of heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk of bleeding, as does recent surgery or trauma. Heparin-treated patients with serious bleeding can be given protamine sulfate to neutralize the heparin. Protamine sulfate, a mixture of basic polypeptides originally isolated from salmon sperm, binds heparin with high affinity, and the resultant protamine-heparin complexes are then cleared. Typically, 1 mg of protamine sulfate neutralizes 100 units of heparin. Protamine sulfate is given intravenously. Anaphylactoid reactions to protamine sulfate can occur, and drug administration by slow intravenous infusion is recommended to reduce the risk of these problems.

Thrombocytopenia

Heparin can cause thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process that is triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein (Table 143.3). These antibodies, which usually are of the immunoglobulin G subtype, bind simultaneously to the heparin–PF4 complex and to platelet Fc receptors (see Chapter 131). Such binding activates the platelets and generates

TABLE 143.3 Features of Heparin-Induced Thrombocytopenia

Features	Details
Thrombocytopenia	Platelet count of 100,000/µL or less or a decrease in platelet count of 50% or more
Timing	Platelet count falls 5–10 days after starting heparin
Type of heparin	More common with unfractionated heparin than LMWH
Type of patient	More common in surgical patients than medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

LMWH, Low-molecular-weight heparin.

TABLE 143.4 Management of Heparin-Induced Thrombocytopenia

Stop all heparin

Give an alternative anticoagulant, such as argatroban, bivalirudin, danaparoid, fondaparinux or rivaroxaban.

Do not give platelet transfusions.

Do not give warfarin until the platelet count returns to its baseline level. If warfarin is administered, give vitamin K to restore the INR to normal.

Evaluate for thrombosis, particularly deep vein thrombosis.

INR, International normalized ratio.

platelet microparticles. Circulating microparticles are prothrombotic because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.

HIT can be associated with thrombosis, either arterial or venous. Venous thrombosis, which manifests as deep vein thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischemic stroke or acute myocardial infarction. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin–PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive, but they can be positive in the absence of any clinical evidence of HIT. The most specific diagnostic test is the serotonin release assay. This test is performed by quantifying serotonin release when washed platelets loaded with labeled serotonin are exposed to patient serum in the absence or presence of varying concentrations of heparin. If the patient serum contains the HIT antibody, heparin addition induces platelet activation and subsequent serotonin release.

Management of HIT is outlined in Table 143.4. Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis.[16] The agents most often used for this indication are parenteral direct thrombin inhibitors, such as argatroban or bivalirudin, or parenteral factor Xa inhibitors, such as fondaparinux or danaparoid. Oral factor Xa inhibitors, such as rivaroxaban, have been used successfully to manage HIT.

Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation that can lead to consumption of protein C. If these patients are given warfarin without a concomitant parenteral anticoagulant to suppress thrombin generation, the further decrease in protein C levels induced by warfarin can trigger skin necrosis. To avoid this problem, patients with HIT should be treated with a direct thrombin inhibitor or fondaparinux until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the thrombin inhibitor or fondaparinux can be discontinued when the anticoagulant response to warfarin has been therapeutic for at least 2 days. HIT also is covered extensively in Chapter 131.

TABLE 143.5 Advantages of Low-Molecular-Weight Heparin Over Heparin

Advantages	Consequence
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment
Dose-independent clearance	Simplified dosing
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients
Lower risk of heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration
Lower risk of osteoporosis	Safer than heparin for extended administration

Osteoporosis

Treatment with therapeutic doses of heparin for over 1 month can cause a reduction in bone density. This complication has been reported in up to 30% of patients given long-term heparin therapy, and symptomatic vertebral fractures occur in 2% to 3% of these individuals.

Elevated Levels of Transaminases

Therapeutic doses of heparin frequently cause a modest elevation in the serum levels of hepatic transaminases, without a concomitant increase in the level of bilirubin. The levels of transaminases rapidly return to normal when the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is about 5000, one-third the mean molecular weight of unfractionated heparin. LMWH has several advantages over heparin (Table 143.5) and is used instead of heparin for most indications.

Mechanism of Action

Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to about 17 saccharide units, at least about half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (see Fig. 143.4). However, these chains retain the capacity to accelerate factor Xa inhibition by antithrombin because this activity is largely the result of the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently, LMWH catalyzes factor Xa inhibition by antithrombin more than thrombin inhibition. Depending on their unique molecular weight distributions, LMWH preparations have anti-factor Xa to anti-factor IIa ratios ranging from 2:1 to 4:1.

Pharmacology

Although usually given subcutaneously, LMWH also can be administered intravenously if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin. These advantages reflect the fact that shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins. Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, the clearance of LMWH is dose-independent, and its plasma half-life is longer. Based on the measurement of anti-factor Xa levels, LMWH has a plasma half-life of about 4 hours. LMWH is cleared almost exclusively by the kidneys, and the drug can accumulate in patients with renal insufficiency.

LMWH exhibits about 90% bioavailability after subcutaneous injection. Because LMWH binds less avidly than heparin to heparin-binding proteins in plasma, LMWH produces a more predictable dose response, and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given subcutaneously once or twice daily without coagulation monitoring, even when the drug is given in treatment doses. These properties render LMWH more convenient than unfractionated heparin. Capitalizing on this feature, studies in patients with venous thromboembolism have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin. Outpatient treatment with LMWH streamlines care, reduces health care costs, and increases patient satisfaction.

Monitoring

In most patients, LMWH does not require coagulation monitoring. If monitoring is necessary, anti-factor Xa levels must be measured because most LMWH preparations have little effect on the aPTT. Therapeutic anti-factor Xa levels with LMWH range from 0.5 to 1.2 units/mL when measured 3 to 4 hours after drug administration. When LMWH is given in prophylactic doses, peak anti-factor Xa levels of 0.2 to 0.5 units/mL are desirable.

Indications for LMWH monitoring include renal insufficiency and morbid obesity. LMWH monitoring in patients with a creatinine clearance of 50 mL/min or less is advisable to ensure that there is no drug accumulation. Although weight-adjusted LMWH dosing appears to produce therapeutic anti-factor Xa levels in patients who are overweight, this approach has not been evaluated extensively in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester. Monitoring also is important in high-risk settings, such as in patients with mechanical mitral valves who are given LMWH for the prevention of valve thrombosis.

Dosing

The doses of LMWH recommended for prophylaxis or treatment vary depending on the LMWH preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 units are often used, whereas doses of 2500 to 3000 units are given when the drug is administered twice daily. For treatment of venous thromboembolism, a dose of 150 to 200 units/kg is given if the drug is administered once daily. If a twice-daily regimen is employed, a dose of 100 units/kg is given. In patients with unstable angina, LMWH is given subcutaneously on a twice-daily basis at a dose of 100 to 120 units/kg.

Side Effects

The major complication of LMWH is bleeding. Meta-analyses suggest that the risk of major bleeding is lower with LMWH than with unfractionated heparin. HIT and osteoporosis are less common with LMWH than with unfractionated heparin.

Bleeding

The risk of bleeding with LMWH is increased with concomitant use of antiplatelet or fibrinolytic drugs. Recent surgery, trauma, or underlying hemostatic defects also increase the risk of bleeding with LMWH.

Although protamine sulfate can be used as an antidote for LMWH, protamine sulfate incompletely neutralizes the anticoagulant activity of LMWH because it binds only the longer chains of LMWH. Because longer chains are responsible for the catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti-factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti-factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind to protamine sulfate. Consequently, patients at high risk for bleeding may be more safely treated with continuous intravenous unfractionated heparin than with subcutaneous LMWH. In addition to the potential for complete reversal with protamine sulfate, the short half-life of intravenous heparin also is an advantage if major bleeding occurs.

Thrombocytopenia

The risk of HIT is about fivefold lower with LMWH than with heparin. LMWH binds less avidly to platelets and causes less PF4 release. Furthermore, with a lower affinity for PF4 than heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies. LMWH should not be used to treat patients with HIT, because most HIT antibodies exhibit cross-reactivity with LMWH, and there are case reports of thrombosis when patients with HIT were treated with LMWH.

Osteoporosis

The risk of osteoporosis is lower with long-term LMWH than with heparin. For extended treatment, therefore, LMWH is a better choice than heparin because of the lower risk of both osteoporosis and HIT.

Fondaparinux

A synthetic analog of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (Table 143.6). Fondaparinux is licensed for (1) thromboprophylaxis in medical, general surgical, and high-risk orthopedic patients and (2) as an alternative to heparin or LMWH for initial treatment of patients with established venous thromboembolism. In some countries, fondaparinux also is approved as an alternative to heparin or LMWH for the treatment of patients with acute coronary syndrome.

Mechanism of Action

As a synthetic analog of the antithrombin-binding pentasaccharide sequence found in heparin and LMWH, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (see Fig. 143.4) and is too short to bridge thrombin to antithrombin. Consequently, fondaparinux catalyzes factor Xa inhibition by antithrombin and does not enhance the rate of thrombin inhibition.

TABLE 143.6 Comparison of Low-Molecular-Weight Heparin and Fondaparinux

Features	LMWH	Fondaparinux
Molecular mass (Da)	4500–6000	1728
Catalysis of factor Xa inhibition	Yes	Yes
Catalysis of thrombin inhibition	Yes	No
Bioavailability after subcutaneous administration (%)	90	100
Plasma half-life (h)	4	17
Renal excretion	Yes	Yes
Induces release of TFPI	Yes	No
Neutralized by protamine sulfate	Partially	No

LMWH, Low-molecular-weight heparin; *TFPI*, tissue factor pathway inhibitor.

Pharmacology

Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, the clearance of fondaparinux is dose-independent, and its plasma half-life is about 17 hours. The drug is given subcutaneously once daily. Because fondaparinux is cleared unchanged via the kidneys, it is contraindicated in patients with a creatinine clearance of less than 30 mL/min, and it should be used with caution in those with a creatinine clearance less than 50 mL/min.

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dose of 2.5 mg once daily for the prevention of venous thromboembolism. For initial treatment of established venous thromboembolism, fondaparinux is given at a dose of 7.5 mg once daily. The dose can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg once daily for those weighing more than 100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for the initial treatment of patients with deep vein thrombosis or pulmonary embolism and produces similar rates of bleeding.

Although not licensed for this indication in the United States, fondaparinux has been used in place of heparin or LMWH in patients with acute coronary syndrome. When the prophylactic dose of fondaparinux (2.5 mg daily) was compared with treatment doses of enoxaparin in patients with non–ST-segment elevation acute coronary syndrome, there was no difference in the rate of cardiovascular death, myocardial infarction, or stroke at 9 days.[17] However, the rate of major bleeding was 50% lower with fondaparinux than with enoxaparin, a difference that likely reflects the fact that the dose of fondaparinux was lower than that of enoxaparin. In patients with acute coronary syndrome who require PCI, there is a risk of catheter thrombosis with fondaparinux unless adjunctive heparin is given.

Side Effects

Fondaparinux does not cause HIT, and, in contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Although fondaparinux has been used successfully for HIT treatment, large clinical trials are lacking, and the drug is not licensed for this indication.

The major side effect of fondaparinux is bleeding. There is no antidote for fondaparinux. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux because it fails to bind to the drug. Andexanet alfa reverses fondaparinux but is not licensed for this indication. Recombinant activated factor VII reverses the anticoagulant effects of fondaparinux in volunteers, but it is unknown whether this agent will control fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors

Heparin and LMWH are indirect inhibitors of thrombin because their activity is mediated by antithrombin. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, these agents bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include hirudin derivatives (lepirudin and desirudin), argatroban, and bivalirudin (Table 143.7). Lepirudin and desirudin are no longer available. Argatroban is licensed for the treatment of patients with HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing cardiac surgery or PCI, including those with HIT.

Argatroban

A univalent inhibitor that targets the active site of thrombin, argatroban is metabolized in the liver. Consequently, this drug must be used with caution in patients with hepatic insufficiency. Argatroban is not cleared via the kidneys, so this drug is safer than lepirudin for patients with HIT who have renal insufficiency.

TABLE 143.7 Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

	Hirudin	Bivalirudin	Argatroban
Molecular mass (Da)	7000	1980	527
Site(s) of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (min)	60	25	45

Argatroban is administered by continuous intravenous infusion and has a plasma half-life of about 45 minutes. The aPTT is used to monitor its anticoagulant effect, and the dose is adjusted to achieve an aPTT 1.5 to 3 times the baseline value, but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate the transitioning of patients from argatroban to warfarin. This problem can be circumvented by using the levels of factor X to monitor warfarin in place of the INR. Alternatively, the argatroban infusion can be stopped for 2 to 3 hours before INR determination.

Bivalirudin

A synthetic 20-amino acid analog of hirudin, bivalirudin is a divalent thrombin inhibitor. Thus the N-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its C-terminal tail binds to exosite 1. Bivalirudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors. Bivalirudin is degraded by peptidases and is partially excreted via the kidneys. When given in high doses for PCI or cardiac surgery, the anticoagulant activity of bivalirudin is monitored using the ACT. With lower doses, its activity can be assessed using the aPTT.

Studies comparing bivalirudin with heparin plus GPIIb/IIIa antagonists suggest that bivalirudin produces less bleeding. This feature plus its short half-life makes bivalirudin an attractive alternative to heparin in patients undergoing PCI, and it is licensed for this indication. Bivalirudin also is approved for the management of patients with HIT who require PCI or cardiac surgery.

ORAL ANTICOAGULANTS

Current oral anticoagulant practice dates to the mid-to late 1930s when the vitamin K antagonists were discovered because of investigations into the cause of hemorrhagic disease in cattle. Characterized by a decrease in prothrombin levels, this disorder is caused by the ingestion of hay containing spoiled sweet clover. Hydroxycoumarin, which was isolated from bacterial contaminants in the hay, interferes with vitamin K metabolism, thereby causing a syndrome like vitamin K deficiency. A variety of coumarin derivatives is available. The agent most widely used in North America is warfarin.

The repertoire of oral anticoagulants has expanded with the introduction of the DOACs. These agents include dabigatran, which inhibits thrombin, and rivaroxaban, apixaban, and edoxaban, which inhibit factor Xa.[14] The DOACs are licensed for thromboprophylaxis after hip or knee replacement, stroke prevention in patients with atrial fibrillation, and for treatment and secondary prevention of venous thromboembolism.

Warfarin

A water-soluble vitamin K antagonist, warfarin was initially developed as a rodenticide. Like other vitamin K antagonists, warfarin interferes with the synthesis of the vitamin K-dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. Warfarin also reduces the synthesis of the vitamin K-dependent anticoagulant proteins, proteins C, S, and Z.

Mechanism of Action

All the vitamin K-dependent clotting factors possess glutamic acid residues at their N-termini. A posttranslational modification adds a carboxyl group to the γ-carbon of these residues to generate γ-carboxyglutamic acid. This modification is essential for the expression of the activity of these clotting factors because it permits their calcium-dependent binding to negatively charged phospholipid surfaces. The γ-carboxylation process is catalyzed by a vitamin K-dependent carboxylase. Thus, vitamin K from the diet is reduced to vitamin K hydroquinone by vitamin K reductase (Fig. 143.7). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide replaces the hydrogen on the γ-carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which is then reduced to vitamin K by vitamin K epoxide reductase (VKOR).

Warfarin inhibits VKOR, thereby blocking the γ-carboxylation process. This results in the synthesis of vitamin K-dependent clotting proteins that are only partially γ-carboxylated. Warfarin acts as an anticoagulant because these partially γ-carboxylated proteins have reduced or absent biologic activity. The onset of action of warfarin is delayed until the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin depends on a reduction in the functional levels of factor X and prothrombin, clotting factors that have half-lives of 24 and 72 hours, respectively. Because of the delay in achieving an antithrombotic effect, initial treatment with warfarin is supported by concomitant administration of a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, in patients with established thrombosis or at high risk for thrombosis. This strategy also helps to prevent warfarin-induced skin necrosis (see later).

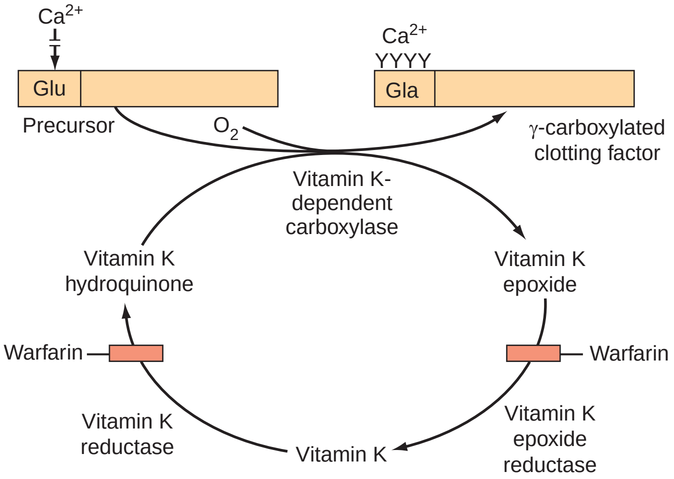

Figure 143.7 THE VITAMIN K CYCLE AND ITS INHIBITION BY WARFARIN. Dietary vitamin K is reduced by vitamin K reductase to generate vitamin K hydroquinone. Vitamin K hydroquinone serves as a cofactor for the vitamin K–dependent carboxylase that converts glutamic acid residues at the N-termini of the vitamin K–dependent precursors to γ-carboxyglutamic acid residues, thereby creating the so-called Gla domain. By binding calcium, the Gla domain is critical for the interaction of the vitamin K-dependent clotting factors with negatively charged phospholipid membranes. During vitamin K-dependent carboxylation, vitamin K is oxidized to vitamin K epoxide. Vitamin K epoxide is then converted to vitamin K by vitamin K epoxide reductase. Vitamin K antagonists, such as warfarin, interfere with this cycle by inhibiting vitamin K epoxide reductase and vitamin K reductase. Of these two enzymes, vitamin K antagonists more readily block vitamin K epoxide reductase than vitamin K reductase. Consequently, supplemental vitamin K can overcome the inhibitory effects of vitamin K antagonists.

Pharmacology

Warfarin is a racemic mixture of R and S isomers; of these, the S isomer is more active. Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in the blood peak about 90 minutes after drug administration. Racemic warfarin has a plasma half-life of 36 to 42 hours, and over 97% of circulating warfarin is bound to albumin. Only unbound warfarin is biologically active.

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. Oxidative metabolism of the more active S isomer is mediated by CYP2C9.[18] Two relatively common variants, *CYP2C9*2* and *CYP2C9*3*, have reduced activity. Patients with these variants require a lower maintenance dose of warfarin. The target of warfarin is VKOR. Polymorphisms in the C1 subunit of this enzyme (VKORC1) also can render patients less or more responsive to the anticoagulant effects of warfarin.[18] These findings have prompted a recommendation that patients starting on warfarin should be tested for these polymorphisms and that this information should be incorporated into their warfarin-dosing algorithms. Whether this approach will increase the efficacy and/or safety of warfarin therapy is uncertain.

In addition to genetic factors, diet, drugs, and various disease states influence the anticoagulant effect of warfarin. Fluctuations in dietary vitamin K intake affect the activity of warfarin. A wide variety of drugs can alter the absorption, clearance, or metabolism of warfarin. Because of the variability in the anticoagulant response to warfarin, coagulation monitoring is essential to ensure that a therapeutic response is obtained.

Monitoring

Warfarin therapy is most often monitored using the prothrombin time, a test that is sensitive to reductions in the levels of prothrombin, factor VII, and factor X.[19] The test is performed by adding thromboplastin, a reagent that contains tissue factor, phospholipid, and calcium, to citrated plasma and determining the time to clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of the vitamin K-dependent clotting factors. Consequently, less sensitive thromboplastins will prompt the administration of higher doses of warfarin to achieve a target prothrombin time. This is problematic because higher doses of warfarin increase the risk of bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time assay. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time, and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for prothrombin time determination to reductions in the levels of the vitamin K-dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.

For most indications, warfarin is administered in doses that produce a target INR of 2.0 to 3.0.[19] An exception is patients with mechanical heart valves in the mitral position, where a target INR of 2.5 to 3.5 is recommended.[20] Vitamin K antagonists have a narrow therapeutic window. Thus, studies in atrial fibrillation demonstrate an increased risk of cardioembolic stroke when the INR falls below 1.7 and an increase in bleeding with INR values over 4.5. Likewise, a study with patients receiving long-term warfarin therapy for unprovoked venous thromboembolism demonstrated a higher rate of recurrent venous thromboembolism when the warfarin dose was adjusted to achieve a target INR of 1.5 to 1.9 than with a target INR of 2.0 to 3.0. Rates of major bleeding were similar.

Dosing

Warfarin is usually started at a dose of 5 to 10 mg. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Initial prolongation of the INR reflects a reduction in the functional levels of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have been reduced into the therapeutic range with warfarin.

Because warfarin has a narrow therapeutic window, frequent coagulation monitoring is essential to ensure that a therapeutic anticoagulant response is obtained. Even patients with stable warfarin dose requirements should have their INR determined every 2 to 4 weeks.[20] More frequent monitoring is necessary when new medications are introduced because many drugs enhance or reduce the anticoagulant effects of warfarin.

Side Effects

Like all anticoagulants, the major side effect of warfarin is bleeding. A rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities. Consequently, warfarin should be avoided during pregnancy, particularly during the first trimester.

Bleeding

At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding also can occur.

To minimize the risk of bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 4.5, warfarin should be withheld until the INR returns to the therapeutic range. If the INR is over 4.5, a therapeutic INR can be achieved more rapidly by the administration of low doses of sublingual vitamin K.

Patients with serious bleeding should be given 5 to 10 mg of vitamin K by slow intravenous infusion. Additional vitamin K should be given until the INR is in the normal range. Treatment with vitamin K should be supplemented with prothrombin complex concentrate to replace the missing vitamin K–dependent clotting factors.[20]

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation into the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary system.

Skin Necrosis

A rare complication of warfarin, skin necrosis usually is seen 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically, the center of the lesion becomes progressively necrotic. Examination of skin biopsies taken from the border of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis is seen in patients with congenital or acquired deficiencies of protein C or protein S. Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis. Why the thrombosis is localized to the microvasculature of fatty tissues is unclear.

Treatment involves discontinuation of warfarin and reversal with vitamin K if needed. An alternative anticoagulant, such as heparin, LMWH, or a DOAC such as rivaroxaban or apixaban, should be given. Protein C concentrates or recombinant activated protein C can be given to patients with protein C deficiency to accelerate healing of the skin lesions; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, skin grafting is necessary when there is extensive skin loss.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started in low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days.

Pregnancy

Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk of embryopathy is highest if warfarin is given in the first trimester of pregnancy. Central nervous system abnormalities also can occur with exposure to coumarins at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential problems, warfarin is rarely used in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis.

Warfarin does not pass into breast milk. Consequently, warfarin can safely be administered to nursing mothers.

Special Problems

Patients with a lupus anticoagulant or those who need urgent or elective surgery present special challenges. Although observational studies have suggested that patients with thrombosis complicating the antiphospholipid syndrome required higher-intensity warfarin regimens to prevent recurrent thromboembolic events, randomized trials demonstrated that targeting an INR of 2.0 to 3.0 is as effective as higher-intensity treatment and produces less bleeding. Monitoring warfarin therapy can be problematic in patients with antiphospholipid antibody syndrome if the lupus anticoagulant prolongs the baseline INR.

If patients receiving long-term warfarin treatment require an elective invasive procedure, warfarin can be stopped 5 days before the procedure to allow the INR to return to normal levels. Those at high risk for recurrent thrombosis can be bridged with once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. The last dose of LMWH should be given 12 to 24 hours before the procedure, depending on whether LMWH is administered twice or once daily, respectively. After the procedure, warfarin can be restarted.

Direct Oral Anticoagulants

The DOACs have a rapid onset of action and half-lives that permit once- or twice-daily administration. Designed to produce a predictable level of anticoagulation, DOACs are more convenient to administer than warfarin because they are given in fixed doses without the need for routine monitoring of coagulation. As a class, the DOACs are at least as effective as warfarin and produce less serious bleeding, particularly less intracranial hemorrhage.[21,22]

Mechanism of Action

DOACs are small molecules that bind reversibly to the active site of their target enzyme. Table 143.8 summarizes the pharmacologic features of these agents.

Dosages

For prevention of stroke in patients with nonvalvular atrial fibrillation, rivaroxaban is given at a dosage of 20 mg once daily, with a reduction to 15 mg once daily in patients with a creatinine clearance of 15 to 49 mL/min; dabigatran is given at a dosage of 150 mg twice daily, with a reduction to 75 mg twice daily in those with a creatinine

TABLE 143.8 **Comparison of the Pharmacological Properties of Dabigatran, Rivaroxaban, Apixaban, and Edoxaban**

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Target	Thrombin (IIa)	Factor Xa	Factor Xa	Factor Xa
Active drug	No	Yes	Yes	Yes
Onset time (h)	0.5–2	2–4	3–4	1–3
Half-life (h)	12–17	5–13	~12	10–14
Renal excretion (%)	80	33	27	50

clearance of 15 to 30 mL/min; apixaban is given at a dosage of 5 mg twice daily, with a reduction to 2.5 mg twice daily for patients with at least two of the "ABC" criteria (i.e., *a*ge over 80 years, *b*ody weight under 60 kg, and *c*reatinine over 1.5 g/dL); and edoxaban is given at a dosage of 60 mg once daily for patients with a creatinine clearance of 50 to 95 mL/min and with a reduction to 30 mg once daily for patients with any one of the following criteria: creatinine clearance 15 to 50 mL/min, a body weight of 60 kg or less, or use of potent P-GP inhibitors, such as verapamil or quinidine.

Dabigatran, rivaroxaban, apixaban, and edoxaban are also licensed for the treatment of patients with VTE. Dabigatran and edoxaban are started after patients have received at least a 5-day course of treatment with a parenteral anticoagulant such as LMWH; dabigatran is given at a dose of 150 mg twice daily provided the creatinine clearance is over 30 mL/min, and the dosage regimen for edoxaban is identical to that used in patients with atrial fibrillation. In contrast, rivaroxaban and apixaban can be given in all-oral regimens; rivaroxaban is started at a dose of 15 mg twice daily for 21 days and is then reduced to 20 mg once daily thereafter, whereas apixaban is started at a dose of 10 mg twice daily for 7 days and is then reduced to 5 mg twice daily thereafter. For long-term secondary prevention, the dosage of apixaban can be lowered to 2.5 mg twice daily and the dose of rivaroxaban can be lowered to 10 mg once daily, doses that have safety profiles similar to those of placebo and aspirin, respectively.

Dabigatran, rivaroxaban, and apixaban are licensed for thromboprophylaxis after elective hip or knee replacement surgery; edoxaban is not licensed for this indication except in Japan. Thromboprophylaxis is started after surgery and is often continued for 30 days in patients undergoing hip replacement and for 10 to 14 days in patients undergoing knee replacement. In lower-risk patients undergoing hip or knee replacement surgery, a 5-day course of rivaroxaban followed by a 30-day course of aspirin at a dose of 81 mg daily appears to be as effective and safe as extended thromboprophylaxis with rivaroxaban. Dabigatran is given at a dose of 220 mg once daily, whereas rivaroxaban and apixaban are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively.

Very low dose rivaroxaban (2.5 mg twice daily) in combination with aspirin (81 mg once daily) is licensed for lowering the risk for major adverse cardiovascular events in patients with chronic coronary or peripheral artery disease (see Chapter 145 and 146). None of the other DOACs is approved for this indication.

Monitoring

Although administered without routine monitoring, it is helpful to determine the anticoagulant activity of the DOACs in some situations,[23] such as assessment of adherence, detection of accumulation or overdose, identification of bleeding mechanisms, and determination of activity before surgery or intervention. For qualitative assessment of anticoagulant activity, the prothrombin time can be used for factor Xa inhibitors and the aPTT for dabigatran. Rivaroxaban and edoxaban prolong the prothrombin time more than apixaban does. In fact, because apixaban has such a limited effect on the prothrombin time, anti-factor Xa assays are needed to assess its activity.[23] The effect of the drugs on tests of coagulation varies depending on the reagents used to perform the tests. Chromogenic anti-factor Xa assays and the diluted thrombin clotting time or ecarin clotting or chromogenic assays with appropriate calibrators provide quantitative assays to measure plasma levels of the factor Xa inhibitors and dabigatran, respectively.

Side Effects

As with any anticoagulant, bleeding is the most common side effect of the DOACs. Although the risk of intracranial bleeding is lower with the DOACs than with warfarin, the risk for gastrointestinal bleeding is higher with dabigatran (at the 150-mg, twice-daily dose), rivaroxaban, and edoxaban (at the 60-mg, once-daily dose) than with warfarin.[22] Dyspepsia occurs in up to 10% of patients treated with dabigatran; this problem improves with time and can be minimized by taking the drug with food.

Periprocedural Management

Like warfarin, the DOACs must be stopped before surgical procedures associated with a moderate or high risk for bleeding.[24,25] The drugs should be withheld for 1 to 2 days or longer if renal function is impaired. After surgery, patients should receive thromboprophylaxis with LMWH until hemostasis is restored, at which point the DOACs can be restarted.

Cardiac procedures such as atrial fibrillation ablation or pacemaker implantation can safely be performed without interruption of the DOACs. However, it may be prudent to hold the dose on the morning of the day of the procedure to avoid intervention at peak drug levels.

Management of Bleeding

With minor bleeding, withholding one or two doses of drug is usually sufficient. With more serious bleeding, the approach is similar to that with warfarin, except that vitamin K administration is of no benefit; the anticoagulant and any antiplatelet drugs should be withheld, the patient should be resuscitated with fluids and blood products as necessary, and the bleeding site should be identified and managed. Coagulation testing will determine the extent of anticoagulation, and renal function should be assessed so that the half-life of the drug can be calculated.[26] Timing of the last dose of anticoagulant is important, and oral-activated charcoal may help prevent absorption of drugs administered in the past 4 hours, particularly in cases of overdose. If bleeding continues or is life-threatening, or if it occurs in a critical organ (e.g., the eye) or in a closed space (e.g., the pericardium or retroperitoneum), reversal of the anticoagulant should be considered.

Idarucizumab is licensed for dabigatran reversal in patients with serious bleeding or in those requiring urgent surgery or intervention. A humanized antibody fragment, idarucizumab binds dabigatran with 350-fold higher affinity than that of dabigatran for thrombin to form an essentially irreversible complex that is cleared by the kidneys. Idarucizumab, which is given intravenously as a 5-g bolus, rapidly reverses the anticoagulant effects of dabigatran and normalizes the aPTT, diluted thrombin time, or ecarin clot time.[27,28]

Andexanet alfa is available for reversal of rivaroxaban, apixaban, and edoxaban. A recombinant variant of factor Xa without catalytic activity, andexanet serves as a decoy to sequester oral factor Xa inhibitors until they are cleared from the circulation.[29–32] Low- or high-dose intravenous andexanet regimens are used. The low dose regimen starts with a bolus of 400 mg followed by an infusion of 4 mg/min for up to 120 minutes, whereas the high-dose regimen starts with a bolus of 800 mg followed by an infusion of 8 mg/min for up to 120 minutes. The low-dose regimen is used for reversal of doses of rivaroxaban or apixaban of 10 or 5 mg or less, respectively, or for any dose of rivaroxaban or apixaban if the last dose was taken more than 8 hours prior to presentation. The high-dose regimen is used to reverse rivaroxaban or apixaban doses over 10 and 5 mg, respectively, if the last dose was taken less than 8 hours since the presentation, or for reversal if the dose of rivaroxaban or apixaban or the timing of the last dose is unknown. Andexanet alfa is expensive and is not available in all countries and in all hospitals. Because of its cost, andexanet alfa is often reserved for reversal in patients with intracranial bleeds or for bleeds into a closed space such as retroperitoneal or pericardial bleeds. If andexanet is unavailable, the results of prospective cohort studies suggest that 4-factor prothrombin complex concentrate (25 to 50 units/kg) also is effective at restoring hemostasis. If there is continued bleeding, activated prothrombin complex concentrate (50 units/kg) or recombinant factor VIIa (90 µg/kg) can be considered.[31,32]

Neither andexanet alfa nor 4-factor prothrombin complex concentrate has been evaluated for reversal in patients requiring urgent surgery or intervention. Furthermore, andexanet alfa not only reverses oral factor Xa inhibitors but also reverses heparin and LMWH. This could be problematic in patients who require cardiac surgery or vascular surgery, procedures where heparin is used routinely. To circumvent this problem, most surgical procedures and interventions can be done without reversal and 4-factor prothrombin complex concentrate can be given if necessary. For patients requiring surgery to stop bleeding, such as those with a ruptured aortic aneurysm or with bleeding secondary to polytrauma, upfront 4-factor prothrombin concentrate administration can be considered.

At an earlier stage of development than andexanet, ciraparantag is a synthetic, cationic small molecule that binds rivaroxaban, apixaban, and edoxaban, as well as dabigatran, heparin, LMWH, and fondaparinux.[33–35] When given as an intravenous bolus to volunteers who took rivaroxaban, apixaban, or edoxaban, ciraparantag reduced the whole-blood clotting time in a concentration-dependent manner.[34,35] Additional studies are needed before ciraparantag will be approved.

Pregnancy

As small molecules, the DOACs can pass through the placenta. Consequently, these agents are contraindicated in pregnancy, and when used by women of childbearing potential, appropriate contraception is important. Small amounts of rivaroxaban pass into breast milk, and it is unknown whether the other DOACs also do so. Therefore, DOACs should not be used in nursing mothers.

Novel Anticoagulants in Development

Although the DOACs are a major advance over warfarin, the search for more effective and safer anticoagulants continues. Evidence that factor XI and factor XII—components of the contact system—are important for thrombosis but less so for hemostasis has prompted the development of anticoagulants that target these factors.[36,37] Ongoing studies are evaluating antisense oligonucleotides, inhibitory antibodies, and small molecule inhibitors of factor XI.

FIBRINOLYTIC DRUGS

Role of Fibrinolytic Therapy

Used to degrade thrombi, fibrinolytic drugs can be administered systemically, or they can be delivered via catheters directly into the substance of the thrombus. Systemic delivery is used for treatment of acute myocardial infarction, acute ischemic stroke, and most cases of massive pulmonary embolism. The goal of therapy is to produce rapid thrombus dissolution, thereby restoring antegrade blood flow. In the coronary circulation, restoration of blood flow reduces morbidity and mortality by limiting myocardial damage, whereas in the cerebral circulation, rapid thrombus dissolution decreases the neuronal death and brain infarction that produce irreversible brain injury. For patients with massive pulmonary embolism, the goal of fibrinolytic therapy is to restore pulmonary artery perfusion.

Peripheral artery thrombi and thrombi in the proximal deep veins of the leg are most often treated using a catheter-directed approach. Catheters with multiple side holes can be used to deliver fibrinolytic drugs. In some cases, intravascular devices that fragment and extract the thrombus are used to hasten treatment.

Mechanism of Action

Commonly used fibrinolytic agents include streptokinase, recombinant tissue-type plasminogen activator (rt-PA), which is also known as alteplase or activase, and two recombinant derivatives of rt-PA, tenecteplase and reteplase. All of these agents act by converting the proenzyme, plasminogen, to plasmin, the active enzyme (Fig. 143.8). Plasmin then degrades the fibrin matrix of thrombi, thereby producing soluble fibrin degradation products.

Endogenous fibrinolysis is regulated at two levels. Plasminogen activator inhibitors, particularly the type 1 form, known as PAI-1, prevent excessive plasminogen activation by regulating the activity of tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA). Once plasmin is generated, plasmin inhibitors, particularly α_2-antiplasmin, regulate it. The plasma concentration of plasminogen is twofold higher than that of α_2-antiplasmin. Consequently, with pharmacologic doses of plasminogen activators, the concentration of plasmin that is generated can exceed that of α_2-antiplasmin. In addition to degrading fibrin, unregulated plasmin also can degrade fibrinogen and other clotting factors. This process, which is known as the systemic lytic state, reduces the hemostatic potential of the blood and increases the risk of bleeding.

The endogenous fibrinolytic system is geared to localize plasmin generation to the fibrin surface. Both plasminogen and t-PA bind to fibrin to form a ternary complex that promotes efficient plasminogen activation. In contrast to free plasmin, plasmin generated on the fibrin surface is relatively protected from inactivation by α_2-antiplasmin, a feature that promotes fibrin dissolution. Furthermore, C-terminal lysine residues exposed as plasmin degrades fibrin serve as binding sites for additional plasminogen and t-PA molecules. This creates positive feedback that enhances plasmin generation. When used pharmacologically, the various plasminogen activators capitalize on these mechanisms to a lesser or greater extent.

There are two pools of plasminogen: circulating plasminogen and fibrin-bound plasminogen (Fig. 143.9). Plasminogen activators that preferentially activate fibrin-bound plasminogen are considered fibrin specific. In contrast, nonspecific plasminogen activators do not discriminate between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in the generation of unopposed plasmin that can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase is a nonspecific agent.

Streptokinase

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, streptokinase forms a 1:1 stoichiometric complex with plasminogen.

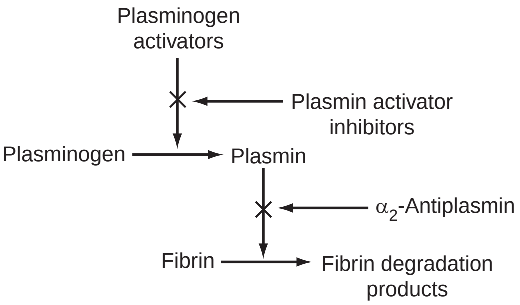

Figure 143.8 FIBRINOLYTIC SYSTEM AND ITS REGULATION. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. Type 1 plasminogen activator inhibitor (PAI-1) inhibits the plasminogen activators, whereas α_2-antiplasmin serves as the major inhibitor of plasmin.

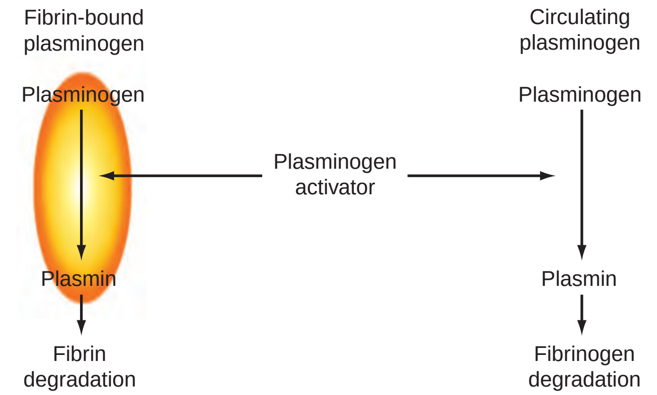

Figure 143.9 CONSEQUENCES OF ACTIVATION OF FIBRIN-BOUND OR CIRCULATING PLASMINOGEN. The fibrin specificity of plasminogen activators reflects their capacity to distinguish between fibrin-bound and circulating plasminogen. This, in turn, reflects their affinity for fibrin. Plasminogen activators with high affinity for fibrin preferentially activate fibrin-bound plasminogen. This results in the generation of plasmin on the fibrin surface. Fibrin-bound plasmin, which is protected from inactivation by α_2-antiplasmin, degrades fibrin to yield soluble fibrin degradation products. In contrast, plasminogen activators with little or no affinity for fibrin do not distinguish between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in systemic plasminemia and subsequent degradation of fibrinogen and other clotting factors.

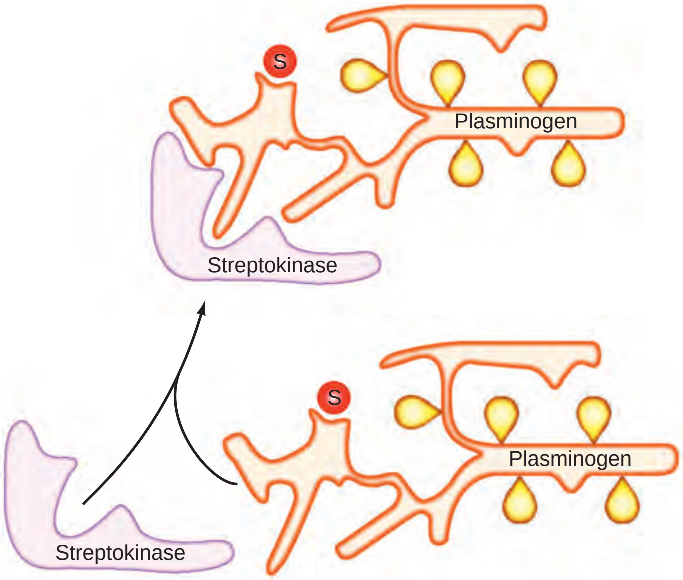

Figure 143.10 MECHANISM OF ACTION OF STREPTOKINASE. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site. The streptokinase–plasmin(ogen) complex then serves as the activator of additional plasminogen molecules.

Formation of this complex induces a conformational change in plasminogen that exposes its active site (Fig. 143.10). This conformationally altered plasminogen then converts additional plasminogen molecules to plasmin.

Streptokinase has no affinity for fibrin, and the streptokinase–plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates sufficient amounts of plasmin to overwhelm α_2-antiplasmin. Unopposed plasmin not only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.

When given systemically to patients with acute myocardial infarction, streptokinase reduces mortality. For this indication, the drug is usually given as an intravenous infusion of 1.5 million units over 30 to 60 minutes. Patients who receive streptokinase can develop antibodies against the drug, as can patients with prior streptococcal infection. These antibodies can reduce the effectiveness of streptokinase.

Allergic reactions occur in about 5% of patients treated with streptokinase. These may manifest as a rash, fever, chills, and rigors. Although anaphylactic reactions can occur, these are rare. Transient hypotension is common with streptokinase and has been attributed to plasmin-mediated release of bradykinin from kallikrein. The hypotension usually responds to leg elevation and administration of intravenous fluids and low doses of vasopressors, such as dopamine or norepinephrine.

Alteplase (Activase)

A recombinant form of single-chain t-PA, alteplase has a molecular weight of 68,000. Alteplase is rapidly converted into its two-chain form by plasmin. Although single- and two-chain forms of t-PA have equivalent activity in the presence of fibrin, in its absence, single-chain t-PA has 10-fold lower activity.

Alteplase consists of five discrete domains (Fig. 143.11). The N-terminal A-chain of two-chain alteplase contains four of these domains: residues 4 through 50 make up the finger domain, a region that resembles the finger domain of fibronectin; residues 50 through 87 are homologous with epidermal growth factor; and residues 92 through 173 and 180 through 261, which have homology to the kringle domains of plasminogen, are designated as the first and second kringle domains, respectively. The fifth alteplase domain is the protease domain; it is located on the C-terminal B-chain of two-chain alteplase.

The interaction of alteplase with fibrin is mediated by the finger domain and, to a lesser extent, by the second kringle domain. The affinity of alteplase for fibrin is considerably higher than that for fibrinogen. Consequently, the catalytic efficiency of plasminogen activation by alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen. This phenomenon helps to localize plasmin generation to the fibrin surface.

Although alteplase preferentially activates plasminogen in the presence of fibrin, alteplase is not as fibrin selective as was first predicted. Its fibrin specificity is limited because, like fibrin, (DD)E, the major soluble degradation product of cross-linked fibrin, binds alteplase and plasminogen with high affinity. Consequently, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by alteplase. Whereas plasmin generated on the fibrin surface results in thrombolysis, plasmin generated on the surface of circulating (DD)E degrades fibrinogen. Fibrinogenolysis results in the accumulation of fragment X, a high-molecular-weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis. This phenomenon may contribute to alteplase-induced bleeding.

A trial comparing alteplase with streptokinase for treatment of patients with acute myocardial infarction demonstrated significantly lower mortality with alteplase than with streptokinase, although the absolute difference was small. The greatest benefit was seen in patients less than 75 years of age with anterior myocardial infarction who presented less than 6 hours after symptom onset.

For treatment of acute myocardial infarction or acute ischemic stroke, alteplase is given as an intravenous infusion over 60 to 90 minutes. The total dose of alteplase usually ranges from 90 to 100 mg. Allergic reactions and hypotension are rare, and alteplase is not immunogenic.

Tenecteplase

A genetically engineered variant of t-PA, tenecteplase was designed to have a longer half-life than t-PA and to be resistant to inactivation by PAI-1. To prolong its half-life, a new glycosylation site was added

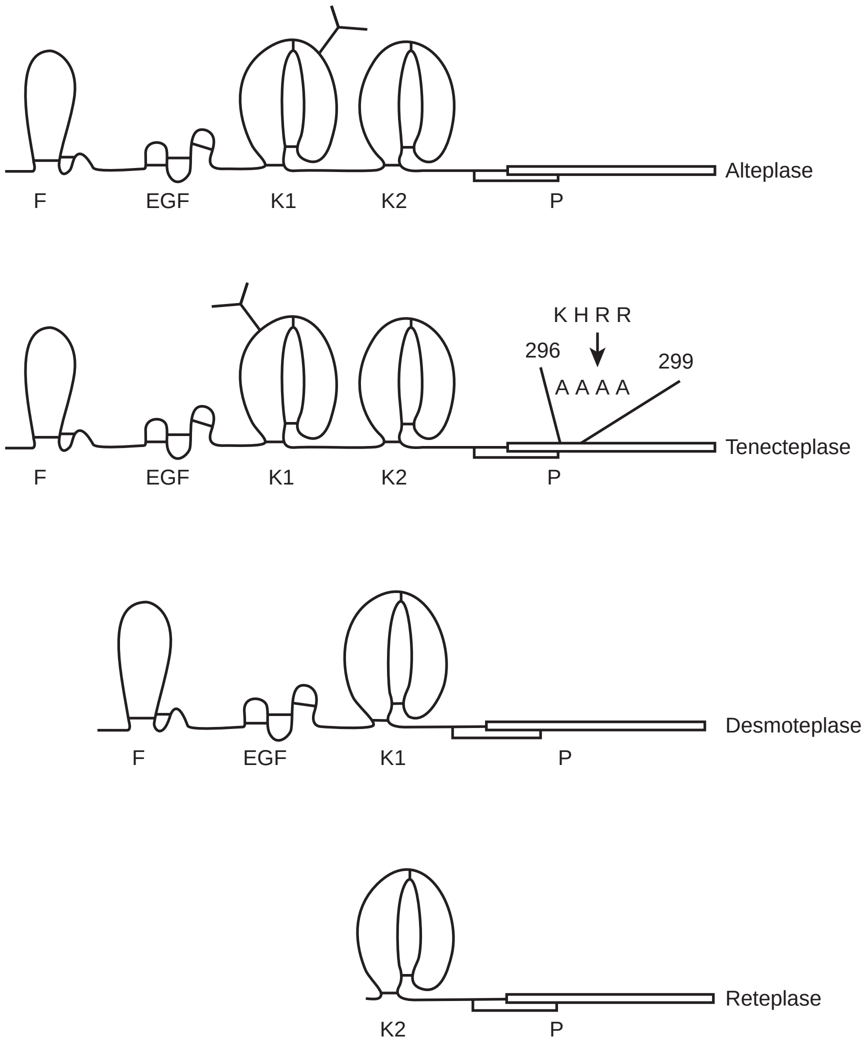

Figure 143.11 DOMAIN STRUCTURES OF ALTEPLASE (TISSUE-TYPE PLASMINOGEN ACTIVATOR [T-PA]), TENECTEPLASE, DESMOTEPLASE, AND RETEPLASE. The finger (F), epidermal growth factor (EGF), first and second kringle (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetra-alanine substitution in the protease domain renders tenecteplase resistant to inhibition by type 1 plasminogen activator inhibitor. Desmoteplase differs from alteplase and teneteplase in that it lacks a K2 domain. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

to the first kringle domain (see Fig. 143.11). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetra-alanine substitution was introduced at residues 296 to 299 in the protease domain, the region responsible for the interaction of t-PA with PAI-1.

Tenecteplase is more fibrin specific than t-PA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of t-PA. Consequently, (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as t-PA. As a result, tenecteplase produces less fibrinogenolysis than t-PA.

For coronary fibrinolysis, tenecteplase is given as a single intravenous bolus. In a large phase III trial in which almost 17,000 patients were enrolled, the 30-day mortality rate with single-bolus tenecteplase was similar to that with accelerated dose t-PA.[38] Although rates of intracranial hemorrhage also were similar with both treatments, patients given tenecteplase had fewer noncerebral bleeds and a reduced need for blood transfusions compared with those treated with t-PA. The improved safety profile of tenecteplase likely reflects its enhanced fibrin specificity. These properties have prompted studies comparing tenecteplase with alteplase in patients with acute ischemic stroke.[39]

Reteplase

A recombinant t-PA derivative, reteplase is a single-chain variant that lacks the finger, epidermal growth factor, and first kringle domains (see Fig. 143.11). This truncated derivative has a molecular weight of 39,000. Reteplase binds fibrin more weakly than t-PA because it lacks the finger domain. Because it is produced in *Escherichia coli*, reteplase is not glycosylated. This endows it with a plasma half-life longer than that of t-PA. Consequently, reteplase is given as two intravenous boluses, which are separated by 30 minutes. Clinical trials have demonstrated that reteplase is at least as effective as streptokinase for treatment of acute myocardial infarction, but the agent is not superior to t-PA.[40]

Desmoteplase

A recombinant form of the full-length plasminogen activator isolated from the saliva of the vampire bat, desmoteplase (see Fig. 143.11) is more fibrin specific than t-PA.[41] Although preliminary studies with desmoteplase for treatment of acute ischemic stroke were promising, further development has been halted.

CONCLUSIONS AND FUTURE DIRECTIONS

Arterial and venous thrombosis reflects a complex interplay among the vessel wall, platelets, the coagulation system, and the fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may contribute to thrombogenesis. A better understanding of the biochemistry of blood coagulation and advances in structure-based drug design have identified new targets and resulted in the development of novel antithrombotic drugs. Well-designed clinical trials have provided detailed information on which drugs to use and when to use them. Despite these advances, however, arterial and venous thromboembolic disorders remain a major cause of morbidity and mortality. Therefore the search for better targets and more potent or more convenient antiplatelet, anticoagulant, and fibrinolytic drugs continues.

CHAPTER 144

STROKE

Emer McGrath, Michelle Canavan, and Martin O'Donnell

Stroke is the second leading cause of mortality worldwide and a leading cause of acquired adult disability. Primary stroke subtypes include ischemic stroke, intracerebral hemorrhage (ICH), and subarachnoid hemorrhage (SAH). Each stroke subtype has differing etiologies, outcomes, and management strategies. In the past 30 years, there have been major advances in the diagnosis (emergence of widely available neuroimaging) and treatment of acute stroke. In addition, there is increased awareness of the importance of covert stroke (stroke on neuroimaging without a history of acute clinical stroke). This chapter provides an overview of stroke, with a primary focus on ischemic stroke, which is the most common cause of stroke worldwide.

DEFINITION

Stroke is defined by the World Health Organization (WHO) as "rapidly developing clinical signs of focal (or global) disturbance of cerebral function, lasting 24 hours or longer or leading to death with no apparent cause other than that of vascular origin." This definition is conventionally considered to include ischemic stroke, ICH, and SAH. However, due to advances in our knowledge about the nature, timing, and clinical presentation of stroke and its mimics, as well as significant advances in neuroimaging, in 2013 the American Heart Association (AHA)/American Stroke Association (ASA) proposed an updated definition of central nervous system (CNS) infarction (including hemorrhagic infarction) defined as "brain, spinal cord, or retinal cell death attributable to ischemia, based on: (1) pathological, imaging, or other objective evidence of cerebral, spinal cord, or retinal focal ischemic injury in a defined vascular distribution; or (2) clinical evidence of cerebral, spinal cord, or retinal focal ischemic injury based on symptoms persisting ≥24 hours or until death, and other etiologies have been excluded." According to the AHA/ASA, "a transient ischemic attack (TIA) is defined as a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction."

EPIDEMIOLOGY

Frequency

The WHO estimates that approximately 14 million people suffer a stroke each year, and of these, more than five million die and another five million people are left permanently disabled. Although age-specific stroke mortality rates worldwide have declined between 1990 and 2016, predominantly due to a decline in high-income countries, the reduction in age-standardized stroke incidence rates has been far less over that time period, indicating that the global burden of stroke remains high. Indeed, the estimated global lifetime risk of stroke among those aged 25 years or older increased from 22.8% in 1990 to 25% in 2016, and the incidence of stroke in some lower-income regions (e.g., east Asia and Southern sub-Saharan Africa) increased between 1990 and 2016. Worldwide, stroke shows significant geographical variation, in terms of incidence (and temporal trends), case fatality, and case mix (i.e., stroke subtypes). Overall, because of the aging population and population growth, the absolute numbers of individuals with prevalent stroke, stroke-related mortality, and global stroke-related disability remain high and continue to increase.

Traditional Risk Factors for Stroke

Both ischemic stroke and ICH are associated with several potentially modifiable risk factors, including hypertension, diabetes mellitus, smoking, poor diet, and physical inactivity. The INTERSTROKE study, which included 6000 participants from 22 countries, reported that 10 key risk factors are associated with 90% of the population-attributable risk (PAR) of ischemic stroke, namely hypertension, smoking, waist-to-hip ratio, diet, physical activity level, diabetes mellitus, alcohol intake, psychosocial stress/depression, and cardiac causes such as atrial fibrillation and ratio of apolipoprotein B to apolipoprotein A1 (Table 144.1). Of these risk factors, five were associated with 80% of the PAR for all stroke (hypertension, smoking, abdominal obesity, physical inactivity, and diet), and each was an important risk factor for both ischemic and hemorrhagic stroke. Thus a large proportion of stroke is potentially preventable through population-based interventions aimed at modifying these risk factors. Hypertension is the strongest risk factor for both ischemic stroke and ICH and, arguably, the most modifiable through lifestyle intervention (e.g., reducing salt intake) and use of antihypertensive medications.

PATHOBIOLOGY

Stroke can be classified into ischemic stroke (Fig. 144.1) and hemorrhagic stroke. Hemorrhagic stroke is further subtyped into ICH (Fig. 144.2) and SAH. In North America and Europe, approximately 87% of strokes are due to ischemia, with the remaining 13% due to hemorrhage.

Etiological Classification of Ischemic Stroke

Unlike acute coronary syndrome, which is primarily due to large vessel atherosclerosis (see Chapter 145), the underlying mechanisms for ischemic stroke are more heterogeneous. The most used etiological classification is the Trial of Org 10172 in Acute Stroke Treatment (TOAST) classification system which focuses on the pathophysiological mechanism of ischemic stroke and is based on clinical features and the results of diagnostic investigations (brain imaging, cardiac investigations, and neurovascular imaging). The five etiological subcategories in the TOAST classification system include large-artery stroke, cardioembolism, small-artery occlusion (or lacunar ischemic stroke), stroke of other determined etiology, and stroke of undetermined etiology.

Large Artery Stroke

Large artery stroke is usually a consequence of atherosclerosis in the extracranial (carotid or vertebral) and/or intracranial arteries (e.g., middle cerebral or basilar artery), with plaque rupture and thrombus formation. Ischemic stroke may result from artery-to-artery thromboembolism with distal occlusion or, less commonly, by acute occlusion with resultant hypoperfusion (e.g., watershed infarction). Large vessel atherosclerosis accounts for approximately 20% of all ischemic stroke in high-income countries and is predominantly extracranial in origin. Intracranial atherosclerosis has been reported to account for

TABLE 144.1 Traditional Risk Factors for Ischemic Stroke

Risk Factor	OR (99% CI)
Hypertension (self-reported history)	2.37 (2.00–2.79)
Current smoking[a]	2.32 (1.91–2.81)
Diabetes mellitus	1.60 (1.29–1.99)
Ratio of ApoB to Apo A1	2.40 (1.86–3.11)
Obesity (waist to hip ratio)	1.69 (1.38–2.07)
Regular physical activity	0.68 (0.51–0.91)
Diet risk score	1.34 (1.09–1.65)

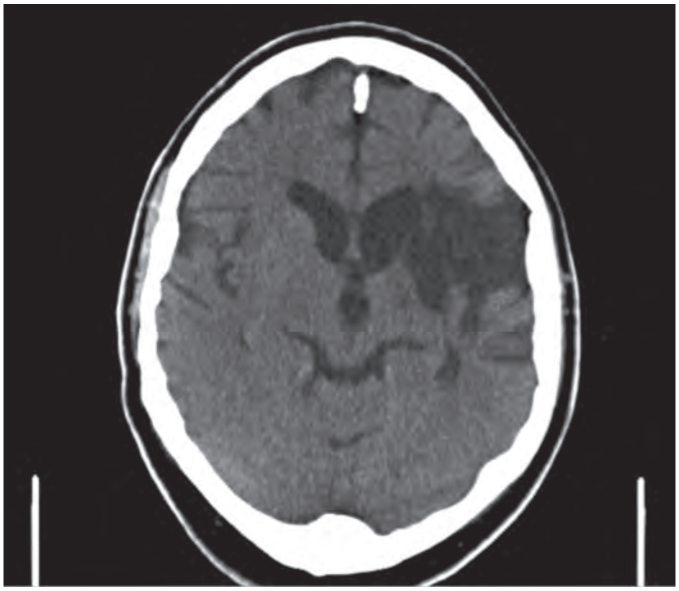

Figure 144.2 COMPUTED TOMOGRAPHY OF BRAIN WITH LEFT HEMISPHERIC ISCHEMIC STROKE.

up to 33% to 50% of ischemic strokes in parts of Asia (e.g., China and Thailand), but it is a much less common cause of acute stroke in North America and Europe. Arterial dissection, the third leading cause of ischemic stroke in young people, can lead to ischemic stroke by either local occlusion or distal thromboembolism. Predisposing factors for dissection include trauma and underlying collagen vascular disorders, such as fibromuscular dysplasia and Ehlers-Danlos syndrome. Less common large vessel mechanisms of ischemic stroke include moyamoya disease, Fabry disease, and large vessel arteritis (e.g., Takayasu arteritis and giant cell arteritis).

Cardioembolism

Approximately 14% to 30% of all ischemic strokes are caused by cardioembolism, with marked regional variation (see Chapter 14). Several conditions predispose to cardioembolism, originating from the venous system (paradoxical embolism), intracardiac (e.g., atrial fibrillation), or postcardiac (aortic arch disease).

Precardiac

Paradoxical emboli occur when emboli that arise in the venous circulation (e.g., from a deep vein thrombus) cross into the arterial circulation through a patent foramen ovale (PFO), atrial septal defect (ASD), or a pulmonary arteriovenous malformation (AVM). A PFO is found in up to 20% of the general population. Several observational studies have reported an association between first ischemic stroke and PFO, particularly in younger patients, and percutaneous PFO closure reduces the risk of recurrent stroke in patients younger than 60 years of age, indicating that PFO is a risk factor for recurrent ischemic stroke. Atrial septal aneurysm, a protrusion of part of the atrial septum through the fossa ovalis into the right or left atria, is associated with an increased risk of ischemic stroke, particularly when it occurs simultaneously with a PFO.

Intracardiac

Left-sided cardiac sources of emboli include left atrial thrombus secondary to atrial fibrillation or flutter (see Chapter 146), left ventricle thrombus after a transmural myocardial infarction (see Chapter 145), akinetic segments of myocardium with a low ejection fraction in the setting of an old myocardial infarction, cardiac tumors such as left atrial myxoma, and abnormalities of the mitral valve (both native and artificial). Atrial fibrillation or flutter is a significant risk factor for stroke, associated with a fivefold increase in risk. In North America and Europe, approximately 25% of all ischemic strokes are attributed to atrial fibrillation, a proportion that increases with older age (see Chapter 147). After acute myocardial infarction, mural thrombi can arise in the presence of left ventricular aneurysms, akinetic segments of left ventricular myocardium or new-onset atrial fibrillation or flutter. Congestive heart failure is an independent risk factor for stroke and is associated with a twofold to threefold increase in the relative risk of ischemic stroke. Valvular heart disease can involve both native (e.g., rheumatic heart disease) and prosthetic heart valves. Of native valvular disease, mitral stenosis has the strongest association with ischemic stroke; mitral annular calcification and mitral valve prolapse have weaker associations. Mitral stenosis is also commonly associated with atrial fibrillation, further increasing the risk of ischemic stroke. Emboli can also arise from valvular vegetations in nonbacterial thrombotic endocarditis or infective endocarditis. Mechanical mitral and aortic valves are associated with a sufficiently high risk for ischemic stroke that indefinite oral anticoagulant therapy is indicated. Rheumatic heart disease still accounts for half of all cases of endocarditis in some regions of the world (e.g., India and Africa). Several epidemiological studies have shown a link between ischemic stroke and *Trypanosoma cruzi* infection (Chagas disease) in South America.

Postcardiac

Atherosclerotic plaques in the aortic arch proximal to the left subclavian artery can be postcardiac sources of emboli, either atheromatous debris or platelet emboli, which then enter the cerebral circulation resulting in ischemic stroke. Severe aortic arch atheromas (>4 mm in diameter) are associated with a fourfold increase in the risk of ischemic stroke and peripheral embolism. Although anatomically a large vessel source, aortic arch disease is usually included in cardiac causes of ischemic stroke because it is typically identified via transesophageal echocardiography.

Small Vessel Disease

Approximately 20% of all ischemic strokes are due to lacunar or small vessel infarcts. Lacunar infarcts are the result of occlusion of small, deep penetrating arteries, such as the lenticulostriate branches of the anterior cerebral and middle cerebral arteries. The terminal pathophysiological mechanism underlying small artery occlusion is believed to be local thrombosis secondary to microatheroma (lipid laden macrophages, cholesterol deposits, and subintimal fibroblast proliferation) and lipohyalinosis (the intermediate stage between fibrinoid necrosis and microatheroma, which has characteristics of both arterial atheromatous lipid deposits and arteriolar hyalinization disease). Growing evidence supports a concept that damage to the glycocalyx by factors such as hyperglycemia, hypertension, and smoking contributes to vascular endothelial damage (see Chapter 142). Other causes of small artery occlusion include microemboli from atherosclerotic plaques, polycythemia vera (see Chapter 70), antiphospholipid antibodies (see Chapter 139), amyloid angiopathy (see Chapter 93), cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL), Sneddon syndrome, and various types of small vessel arteritis. The combination of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) is an inherited progressive disorder characterized by mitochondrial dysfunction and early onset of stroke, typically before the age of 40. The mitochondrial angiopathy hypothesis suggests that the lesions are secondary to ischemia which is caused by mitochondrial and vascular dysfunction of cerebral small arteries.

Ischemic Stroke of Other Determined Etiology

Cerebral Venous Sinus Thrombosis

Cerebral venous sinus thrombosis accounts for less than 1% of ischemic strokes and typically affects younger people. The superior sagittal, transverse, and cavernous sinuses are those most commonly affected by thrombosis. Venous thrombosis results in localized edema and venous infarction, which often becomes hemorrhagic and may raise intracranial pressure (ICP). Reported risk factors for cerebral venous sinus thrombosis include inherited thrombophilia (see Chapter 138); acquired prothrombotic states such as antiphospholipid syndrome (see Chapter 139), pregnancy and the puerperium (see Chapter 141) and hypercoagulability of malignancy; infections such as otitis, sinusitis, and mastoiditis; chronic inflammatory conditions such as granulomatosis with polyangiitis and sarcoidosis; and trauma such as a head injury, dehydration, and injury to the jugular veins or sinuses during neurosurgical procedures.

Intracerebral Hemorrhage

ICH accounts for approximately 10% to 15% of all strokes (a larger proportion is reported in middle- and low-income countries) and can be classified as either primary or secondary, depending on the underlying cause. Primary ICH accounts for approximately 80% to 90% of cases and is the result of spontaneous rupture of small intracerebral blood vessels, usually damaged by chronic hypertension (and other vascular risk factors) or amyloid angiopathy. Antithrombotic therapy, particularly anticoagulant therapy, is an important risk factor for ICH (see Chapter 143). Secondary ICH occurs as a result of vascular abnormalities (ruptured saccular aneurysm, AVM), tumors (e.g., cavernous angioma, intracerebral neoplasm), impaired coagulation (e.g., due to use of oral anticoagulants or bleeding disorders such as hemophilia [see Chapter 134] or von Willebrand disease [see Chapter 133]), hemorrhagic transformation of ischemic stroke, septic emboli, vasculitis, moyamoya disease, and alcohol or illicit drug use (e.g., cocaine, amphetamines).

Subarachnoid Hemorrhage

SAH refers to bleeding within the subarachnoid space, which is the space between the arachnoid and pia mater. It accounts for approximately 3% to 5% of all strokes and is mostly caused by rupture of an intracranial aneurysm (approximately 80% to 85% of cases). Idiopathic nonaneurysmal perimesencephalic hemorrhage accounts for approximately 10% of cases, while the remaining 5% are due to rare causes such as inflammatory lesions of cerebral arteries (e.g., mycotic aneurysm, polyarteritis nodosa, primary angiitis), noninflammatory lesions of intracerebral vessels (e.g., arterial dissection, cerebral AVMs, cerebral amyloid angiopathy, cerebral venous thrombosis, moyamoya disease), vascular lesions of the spinal cord (saccular aneurysm of the spinal artery, spinal AVM), coagulopathy (e.g., hemophilia, von Willebrand disease), sickle cell disease (see Chapters 42 and 43), tumors (e.g., malignant glioma), trauma, and drug use (e.g., cocaine, anticoagulants and sympathomimetic agents).

Covert Stroke

Clinically overt stroke is considered to represent only a fraction of all episodes of cerebral infarction. The advent of contemporary magnetic resonance imaging (MRI) sequences has identified a large burden of subclinical cerebrovascular disease, which includes covert infarction, white matter hyperintensities, enlarged perivascular spaces, cerebral atrophy, and microbleeds. Covert stroke is common; for example, a systematic review of eight population-based studies reported a prevalence of silent brain infarcts in an older population of 8% to 28%. Moreover, covert stroke has been associated with an increased risk of cognitive decline, dementia, depression, and gait impairment. (See box on What Is Cryptogenic Ischemic Stroke?)

Hematological Disorders and Ischemic Stroke

Inherited Thrombophilia

In general, studies have reported either no association or a modest association between inherited thrombophilia and ischemic stroke (see

WHAT IS CRYPTOGENIC ISCHEMIC STROKE?

In some cases, the cause of stroke cannot be definitively determined and the stroke is classified as "stroke of undetermined etiology." A stroke may be classified in this category when one of the following two conditions is met: (1) an extensive evaluation is negative, which includes large vessel imaging and complete cardiovascular assessment; or (2) the diagnostic evaluation is incomplete. The most important determinant of the proportion of patients labeled as having cryptogenic stroke is the extent of the etiological diagnostic testing, including transesophageal echocardiography. In studies where an extensive etiological work-up was undertaken, the proportion of patients designated as having cryptogenic stroke is small (5%–15%). In older patients with complete evaluation, paroxysmal atrial fibrillation is suspected to be the most common underlying cause of ischemic stroke in older adults with "cryptogenic" ischemic stroke.

Chapter 138). Meta-analyses of observational studies have failed to demonstrate a significant association between the factor V Leiden mutation and ischemic stroke in adults, although some small case-control studies have reported an increased risk of ischemic stroke in those with the factor V Leiden mutation using oral contraceptives. Two large prospective population studies, the Physicians' Health Study and the Cardiovascular Health Study, failed to demonstrate a significant association between the prothrombin gene mutation G20210A and ischemic stroke risk, although a large meta-analysis of 19 case control studies reported a modest association. There is no prospective evidence to definitively support an association between protein C, protein S, or antithrombin deficiency and ischemic stroke risk in adults.

Antiphospholipid Syndrome

Antiphospholipid syndrome is reviewed in Chapter 139. Stroke is the main acute arterial thrombotic complication of antiphospholipid syndrome and is reported to be the initial clinical manifestation in 13% of patients subsequently diagnosed with antiphospholipid syndrome. However, the overall association between antiphospholipid antibodies (without other features of the syndrome) and ischemic stroke is less certain. Anticardiolipin antibodies have been associated with ischemic stroke in some studies, especially in young women, but not in others. The lupus anticoagulant is a more potent risk factor for ischemic stroke. For example, in the Risk of Arterial Thrombosis in Relation to Oral Contraceptives (RATIO) study, the odds ratio (OR) for an association between lupus anticoagulant and ischemic stroke was 43.1 (95% confidence interval [CI], 12.2 to 152.2) compared with an OR of 2.3 (95% CI, 1.4 to 3.7) for anti–β_2-glycoprotein I antibodies and no significant association for anticardiolipin antibodies. Current AHA guidelines recommend antiplatelet therapy for secondary prevention of ischemic stroke in patients with cryptogenic ischemic stroke who do not meet the criteria for antiphospholipid syndrome but who have positive antiphospholipid antibodies. For patients with cryptogenic ischemic stroke who meet the diagnostic criteria for antiphospholipid syndrome and who have persistently moderate to high antiphospholipid antibody titers for longer than 12 weeks, oral anticoagulant therapy for secondary prevention of ischemic stroke can be considered (see Chapter 139). The most recent American College of Chest Physicians (ACCP) guidelines recommend oral anticoagulant therapy with a vitamin K antagonist dose-adjusted to achieve a target international normalized ratio (INR) of 2 to 3 for the latter group. Oral factor Xa inhibitors such as rivaroxaban or apixaban are not currently recommended as alternatives to warfarin (see Chapter 143) in this patient population because a recent randomized trial (TRAPS) was stopped early because of an increased risk of recurrent thrombotic events, including stroke, in patients treated with rivaroxaban compared with warfarin.

Sickle Cell Disease

Sickle cell disease is associated with an increased risk of stroke, particularly in those homozygous for the sickle cell gene (see Chapters 42 and 43). The risk of stroke is 11% at 20 years of age, 15% at 30 years, and 24% at 45 years. The most common mechanism underlying ischemic stroke in sickle cell disease is believed to be large artery arteriopathy secondary to hyperplasia of the intima from repeated endothelial injury.

Myeloproliferative Disorders

Myeloproliferative disorders, such as polycythemia vera and essential thrombocytopenia (see Chapters 70 and 71), are uncommon conditions associated with an increased risk of stroke. In a randomized controlled trial of daily aspirin in 518 patients with polycythemia vera, the rate of combined ischemic and hemorrhagic stroke over 3 years was 1.2% in the aspirin group compared with 3.8% in the control group. Defective platelet function in these disorders also results in an increased risk of ICH (see Chapter 128).

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is an uncommon systemic disorder associated with an increased risk of ischemic stroke (see Chapter 132). It is characterized by a pentad of thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, and neurological abnormalities, including ischemic stroke.

Paraproteinemia

Paraproteinemia, including Waldenström macroglobulinemia (Chapter 92), multiple myeloma (see Chapter 91), and POEMS syndrome (characterized by a plasma cell proliferative disorder, typically myeloma, along with polyneuropathy, organomegaly, endocrinopathy and skin changes) are also associated with an increased risk of ischemic stroke and hemorrhagic stroke (due to thrombocytopenia).

Genetic Risk Factors

A substantial body of evidence from twin, family, and animal studies supports a genetic contribution to stroke risk. Based on genome-wide association studies (GWAS), many alleles with small effect sizes together contribute to an increased stroke risk. A meta-analysis of GWAS from more than 12,000 patients with ischemic stroke identified three loci with genome-wide significance for ischemic stroke: PITX2 and ZFHX3, previously associated with an increased risk of atrial fibrillation, were associated with an increased risk of ischemic stroke; and HDAC9 was associated with an increased risk of large artery stroke. Another meta-analysis reported that APOEε2 carrier status was associated with an increased burden of white matter hyperintensities (a marker for prior cerebrovascular disease) and risk of ischemic stroke. A third more recent meta-analysis of 12 GWAS reported four significant loci, including the previously reported PITX2 and ZFHX3 loci for cardioembolic stroke and HDAC9 for large artery stroke, along with ABO for all ischemic strokes.

The concordance rate for stroke is 65% higher in monozygotic twins than in dizygotic twins, with a range of 12.8% to 19.0% in monozygotic twins and 3.6% to 13.0% in dizygotic twins. A family history of stroke increases the risk of ischemic stroke by approximately 75% and the presence of a first-degree relative with a history of hemorrhagic stroke is associated with a sixfold increase in risk of hemorrhagic stroke. Several monogenic disorders have been associated with an increased risk of ischemic stroke, including Marfan syndrome and Ehlers-Danlos syndrome (predisposing to extracranial artery dissection), Fabry disease, familial moyamoya disease, homocystinuria, Menkes disease, sickle cell disease, hereditary endotheliopathy with retinopathy, nephropathy, and stroke (HERNS), and MELAS. Rare mendelian forms of stroke have been described such as CADASIL and CARASIL, which manifest as small vessel ischemic stroke. However, most monogenic disorders are infrequent and thus have limited impact on the wider population despite their marked effect on individual risk in young populations.

CLINICAL MANIFESTATIONS

Clinical Presentation

Stroke is a clinical diagnosis, supported by the results of neuroimaging (computed tomography [CT] or MRI of brain). CT of the brain may be normal in patients with acute ischemic stroke and cases of MRI-negative stroke also occur. With advances in neuroimaging, an increasing proportion of patients presenting with transient neurological deficits (previously diagnosed as TIA) have small infarcts identifiable on high-quality MRI. Clinically, stroke is characterized by the sudden onset of a focal neurological deficit lasting more than 24 hours or leading to death due to a presumed vascular cause. Common presenting features are lateralizing weakness of the upper extremities and/or lower extremities, facial weakness, speech abnormalities (aphasia, dysarthria), visual loss (monocular visual loss or homonymous hemianopia), reduced level of consciousness, ataxia, diplopia, vertigo, and headache (ICH). Several clinical conditions can mimic stroke. Among patients admitted to a hospital with a suspected stroke, only approximately two-thirds are subsequently diagnosed with stroke. Common stroke mimics include migraine, seizure, syncope, hypoglycemia, primary or secondary brain tumors, transient global amnesia, and toxic-metabolic disturbances with delirium.

Ischemic Stroke Versus Intracerebral Hemorrhage

Ischemic stroke and ICH can have similar presentations. Some clinical features are more typically associated with ICH (e.g., coma, neck stiffness, seizures, vomiting, and headache) than ischemic stroke; however, neuroimaging is required to discriminate between ischemia and hemorrhage. Therefore emergent CT or MRI of brain is mandatory in all patients presenting with suspected acute stroke.

Measuring Stroke Severity

Many scales are available for measuring stroke severity, including the Scandinavian Stroke Scale, the Canadian Stroke Scale, and the National Institutes of Health Stroke Scale (NIHSS). The NIHSS is the scale most widely used in clinical practice. Other scales (e.g., Hunt and Hess, and Fisher) are used to measure stroke severity in patients with SAH.

Risk of Stroke After Transient Ischemic Attack

The ABCD2 score is a validated clinical score for predicting the risk of stroke in patients presenting with TIA and was designed for use in primary care settings. Points are assigned for each of the following risk factors: age older than 60 years (1 point); blood pressure 140/90 mmHg or greater on first evaluation (1 point); clinical symptoms of focal weakness (2 points) or speech impairment without weakness (1 point); duration of 10 to 59 minutes (1 point) or 60 minutes or more (2 points), and diabetes mellitus (1 point). In combined validation cohorts, the 2-day risk of stroke was 0% for scores of 0 or 1, 1.3% for scores of 2 or 3, 4.1% for scores of 4 or 5, and 8.1% for scores of 6 or 7.

INVESTIGATIONS

Computed Tomography of the Brain

Neuroimaging is required to distinguish between ischemic and hemorrhagic stroke. On CT of the brain, early features of ischemia can include loss of distinction between the gray and white matter border, sulcal effacement, loss of definition of the insula, evolving areas of hypodensity, and hyperdense vessel sign due to thromboembolism in a vessel (e.g., middle cerebral artery, basilar artery). Scoring systems (e.g., Alberta Stroke Program Early CT Score [ASPECTS] score) may be used to quantify the burden of ischemia, which predicts the risk of ICH in patients receiving thrombolysis. SAH is not reliably excluded by CT alone. If the index of suspicion for SAH is high, a lumbar puncture for cerebrospinal fluid (CSF) evaluation is required to reliably exclude this diagnosis.

Magnetic Resonance Imaging

MRI is superior to CT for detecting acute ischemia; however, patient contraindications or lack of availability outside specialist stroke centers may limit its use in the acute setting. Diffusion-weighted imaging (DWI) may identify acute ischemia within 1 hour of symptom onset. For diagnosis of ICH, MRI with gradient related echo or susceptibility-weighted imaging has been reported to yield results that exhibit 96% concordance with those of CT of the brain.

Neurovascular Imaging

Extracranial and intracranial stenosis may be detected using ultrasound, CT angiography, magnetic resonance angiography, or conventional angiography. Ultrasound is a noninvasive, relatively inexpensive, and widely available imaging modality but is dependent on ultrasonographer experience and skill. Transcranial doppler may be used to detect intracranial large vessel stenosis and arterial vasospasm after aneurysmal SAH; it can also be used to risk-stratify patients with carotid stenosis based on the presence of high-intensity transient signals (HITSs) due to microemboli.

Cardiac Work-Up

An electrocardiogram can identify atrial fibrillation/flutter or evidence of previous myocardial infarction, whereas in-hospital telemetry monitoring can identify a larger proportion of patients with paroxysmal atrial fibrillation (see Chapter 147). Based on the recent CRYSTAL AF and EMBRACE trials, all patients with cryptogenic ischemic stroke or TIA should have ambulatory cardiac monitoring for at least 30 days after ischemic stroke to improve rates of detection of paroxysmal atrial fibrillation. Longer durations of cardiac monitoring result in higher diagnostic yield, but the optimal duration is unclear. Transthoracic echocardiography (e.g., to detect left ventricular thrombus, left atrial dilatation as a marker of occult atrial fibrillation, or PFO), has a low yield in patients with no prior cardiac history and a normal cardiac examination. The routine use of transesophageal echocardiography is controversial; however, this is an essential investigation in patients with suspected endocarditis. A PFO can be identified with a bubble study when performing transthoracic or transesophageal echocardiography. If a PFO is detected and additional work-up is negative (i.e., cryptogenic stroke), the possibility of deep vein thrombosis in the lower extremities or pelvis should be explored by compression ultrasonography and magnetic resonance venography, respectively. Although transesophageal echocardiography identifies potential etiologies of ischemic stroke in a relatively large proportion of patients, such as PFO, atrial septal aneurysm, or aortic arch disease, the treatment implications of some of these findings are less certain. All patients presenting with stroke should have vascular risk factor profiling, including measurement of blood pressure, fasting lipids, blood glucose, and hemoglobin A1c (HbA1c). All patients should have a screening complete blood count, and troponin level and the coagulation profile should be checked. Other useful tests, depending on clinical suspicion, include erythrocyte sedimentation rate, antiphospholipid antibody panel, blood cultures, antineutrophilic cytoplasmic antibodies, antinuclear antibodies, homocysteine, lipoprotein a, lumbar puncture with CSF analysis for infectious or inflammatory vasculopathies, and CT of the chest, abdomen, and pelvis in cases of suspected hypercoagulability of malignancy.

THERAPY

A complete review of the management of stroke is beyond the scope of this chapter. Instead, we provide an overview of the acute and chronic management of stroke.

Reperfusion Therapy for Acute Ischemic Stroke

Thrombolysis for Acute Ischemic Stroke

Intravenous tissue plasminogen activator (tPa) is the most rigorously evaluated thrombolytic intervention in acute ischemic stroke. Current guidelines recommend administration of tPa in patients with acute ischemic stroke presenting within 3 hours of symptom onset (Table 144.2). Based on the results of the ECASS III trial, current guidelines recommend administration of tPa to eligible patients up to 4.5 hours after symptom onset, provided none of the following additional exclusion criteria are met: age older than 80 years, severe stroke (NIHSS >25), history of both prior stroke and diabetes mellitus, use of oral anticoagulant therapy at time of acute stroke regardless of INR, or imaging evidence of ischemic injury involving more than one-third of the middle cerebral artery territory. The main complication of tPa is ICH. In the Third International Stroke Trial (IST-3), which enrolled patients up to 6 hours after symptom onset, there was an increased risk of spontaneous ICH and death at 7 days in the intervention group compared with the control group, although total mortality was similar between the two groups at 6 months. Based on the results of the WAKE-UP trial, AHA guidelines now recommend use of MRI in individuals with stroke symptoms on awakening or with an unclear time of onset greater than 4.5 hours from last known well time to identify individuals with diffusion-positive, fluid attenuated inversion recovery (FLAIR)-negative lesions who can benefit from intravenous thrombolysis within 4.5 hours of recognition of stroke symptoms.

Mechanical Thrombectomy

Several randomized trials have demonstrated benefit of early intra-arterial (IA) mechanical thrombectomy in addition to intravenous thrombolysis compared with intravenous thrombolysis alone in patients with acute ischemic stroke due to large proximal artery occlusion. Current guidelines recommend IA mechanical thrombectomy for patients meeting the following criteria: (1) small infarct size (e.g., an ASPECTS score ≥6) with no evidence of hemorrhage on neuroimaging, (2) evidence of a causative proximal large artery occlusion in the anterior circulation on vessel imaging (via CT or magnetic resonance angiography), (3) persistent and potentially disabling neurologic deficit with NIHSS of 6 or greater, (4) symptom onset within the past 6 hours, (5) prestroke modified Rankin score of 0 to 1 (indicating minimal to no disability), and (6) rapid access to a stroke center with the necessary expertise in use of stent retriever devices. Mechanical thrombectomy can also be considered in carefully selected patients with evidence of diffusion perfusion mismatch on neuroimaging or mismatch between clinical deficits and imaging features up to 24 hours from the time of onset of stroke symptoms, including individuals with posterior circulation strokes. Compared with intravenous thrombolysis alone, IA treatment resulted in significantly higher rates of functional independence at 90 days, with no significant difference in the risk of symptomatic ICH or death between treatment groups. The number needed to treat for one additional person to reach functional independence ranged from 3 to 7.5. Most patients who are eligible for mechanical thrombectomy should be treated with intravenous thrombolysis prior to thrombectomy. However, patients who are not eligible for intravenous thrombolysis (e.g., patients with infective endocarditis) should still be considered for mechanical thrombectomy if they meet the aforementioned eligibility criteria.

TABLE 144.2 Eligibility Criteria for Thrombolysis in Acute Ischemic Stroke

Eligibility Criteria
Diagnosis of ischemic stroke causing measurable neurological deficit
The neurological signs should not be minor and isolated. Caution should be exercised in treating a patient with major deficits.
Onset of symptoms <3 h before beginning treatment
The neurological signs should not be clearing spontaneously
The symptoms of stroke should not be suggestive of subarachnoid hemorrhage
The patient or family members should understand the potential risks and benefits from treatment.
Contraindications to Thrombolysis
Evidence of intracranial hemorrhage on CT
Head trauma or prior stroke in previous 3 months
Myocardial infarction in the previous 3 months
Gastrointestinal or urinary tract hemorrhage in previous 21 days
Arterial puncture at a noncompressible site in the previous 7 days
Major surgery in the previous 14 days
History of previous intracranial hemorrhage
Elevated blood pressure (systolic >185 mmHg and diastolic >110 mmHg)
Evidence of active bleeding or acute trauma (fracture) on examination
Taking an oral anticoagulant with INR ≥1.7
If receiving heparin in previous 48 h, aPTT must be in normal range:
Platelet count ≥100,000 mm^3
Blood glucose concentration ≥50 mg/dL (2.7 mmol/L)
Seizure with postictal residual neurological impairments
CT shows a multilobar infarction (hypodensity >{1/3} cerebral hemisphere).

aPTT, activated partial thromboplastin time; *CT*, Computed tomography; *INR*, international normalized ratio.

Intra-Arterial Fibrinolysis

Rescue IA fibrinolysis is an option for recanalization in patients with large-artery occlusion who have not responded to mechanical thrombectomy or intravenous tPa, although use of IA t-Pa is currently not FDA approved.

Acute Stroke Unit

Organized stroke unit (OSU) care in a dedicated, geographically identified ward with multidisciplinary teams that exclusively manage patients with stroke is associated with improved outcomes in patients with acute stroke. A meta-analysis of 26 trials ($n = 5592$) investigating OSU care reported a reduction in death (OR 0.86; 95% CI 0.76 to 0.98) and death or dependency at 1 year (OR 0.82; 95% CI

0.73 to 0.92), independent of age, sex, or stroke severity. Organized stroke care is associated with improved outcome for several reasons, including a reduced risk of medical complications such as deep vein thrombosis (due to earlier mobilization) and a reduced risk of aspiration pneumonia, fever, urinary tract infection, falls, and delirium. Prompt evaluation of swallowing function and compliance with speech pathology safe swallowing guidelines help to reduce the risk of aspiration pneumonia in patients with stroke.

Blood Pressure in Acute Stroke

Although hypertension is the most important risk factor for both ischemic and hemorrhagic stroke, the optimal approach to managing blood pressure in the acute setting remains uncertain. Several randomized controlled trials have evaluated blood pressure lowering in acute ischemic stroke, and meta-analyses of these trials indicate no benefit of lowering blood pressure in the acute phase of ischemic stroke. Current AHA guidelines recommend cautious introduction of antihypertensive therapy in those with an initial blood pressure greater than 220/120 mmHg, unless there is an alternative indication for blood pressure lowering (e.g., hypertensive encephalopathy, aortic dissection) or the patients have received thrombolytic therapy, when a blood pressure target of less than 180/105 mmHg is recommended for the initial 24 hours post treatment. The INTERACT II trial enrolled patients with spontaneous ICH within 6 hours of symptom onset and systolic blood pressure between 150 and 220 mmHg. There was no difference in the risk of death or major disability between patients randomized to intensive treatment (target systolic blood pressure <140 mmHg) compared with less than 180 mmHg, although it was safe and an ordinal analysis of functional outcomes (modified Rankin score) suggested improved functional outcomes with a blood pressure target of less than 140 mmHg. In the ATACH phase III trial of patients with ICH within 4.5 hours of symptom onset, an acute blood pressure lowering target of 110 to 139 mmHg was not superior to a target of 140 to 179 mmHg for reduction in death and disability.

Antithrombotic Therapy in Acute Ischemic Stroke

Based on the results of two large randomized controlled trials, the IST and Chinese Acute Stroke Trial (CAST), early antiplatelet therapy with aspirin reduces the risk of recurrent stroke and death in patients with acute ischemic stroke. In general, therapeutic parenteral anticoagulant therapy is not indicated in acute ischemic stroke, except for cerebral venous sinus thrombosis. Therapeutic heparin is commonly used in patients with acute ischemic stroke and extracranial carotid or vertebral artery dissection, or symptomatic extracranial vertebral or carotid artery atherosclerotic stenosis with crescendo TIAs from artery-to-artery embolism while awaiting carotid endarterectomy (CEA). Other potential situations when anticoagulation may be considered in acute ischemic stroke include acute basilar artery thrombosis, acute left ventricular thrombus, or small volume cardioembolic strokes in patients with atrial fibrillation who were not on therapeutic anticoagulation at the time of stroke, although the evidence guiding clinical decision making on antithrombotic therapy in these patients is limited. The CADISS trial, which included 250 patients with symptomatic carotid and vertebral artery dissection, reported no difference in the risk of recurrent stroke or death between patients randomized to antiplatelet and anticoagulant therapy. However, significant limitations of this study include a small sample size, failure to confirm a diagnosis of dissection in 20% of participants, and low rates of recurrent stroke. Consequently, the generalizability of the findings is limited.

Carotid Endarterectomy and Stenting

The European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET) are the largest trials to evaluate CEA in patients with recent ischemic stroke and TIA. Based on the results of these trials, current guidelines recommend CEA in patients with symptomatic 70% to 99% stenosis of the ipsilateral carotid artery and estimated life expectancy of 5 years or longer, provided that the perioperative morbidity and mortality are estimated to be less than 6%. Although patients with 50% to 69% stenosis also derive benefit from CEA, it is only recommended for selected patients based on age, comorbidities, time from stroke/TIA, and operative risk. Time from symptom onset to CEA is the primary determinant of the absolute risk reduction obtained with this procedure, with maximal benefit realized when CEA is performed within the first 2 weeks after symptom onset. Although CEA is the gold standard for patients with symptomatic significant carotid stenosis, carotid angioplasty and stenting is an alternative option for patients with greater than 70% stenosis considered to be a high operative risk for CEA.

Intracranial Stenting

Two trials to date have failed to show a benefit of intracranial stenting in patients with symptomatic significant (≥70%) intracranial stenosis. The SAMMPRIS trial reported no benefit of endovascular stenting (self-expanding stent) in addition to aggressive medical therapy compared with aggressive medical therapy alone. The trial was stopped early due to a higher rate of stroke and death at 30 days in the endovascular group. The VISSIT trial, which compared a balloon-expandable stent in addition to medical therapy with medical therapy alone, reported similar results, with higher rates of stroke or death at 30 days and at 1 year in the stented group.

Prevention of Venous Thromboembolism

See Chapters 140 and 141.

Acute Management of Intracerebral Hemorrhage

Management of ICH includes both medical and surgical components. Initial strategies include monitoring appropriate patients in an intensive care, intubation of those with reduced consciousness, discontinuation of antithrombotic therapy, immediate reversal of anticoagulant therapy (see Chapter 143), and administration of antipyretics for fever, insulin for hyperglycemia, and venous thromboembolism prophylaxis (e.g., intermittent pneumatic compression). Raised ICP can occur because of the hemorrhage itself or due to secondary edema. Management of increased ICP includes elevation of the head of the bed to 30 degrees, analgesia, and sedation. More aggressive therapies include osmotic diuresis with mannitol or hypertonic saline, drainage of CSF using a ventricular catheter (ventriculostomy), hyperventilation, neuromuscular blockade, and induction of pharmacologic coma with barbiturates or propofol. Antiepileptic therapy should be used for seizure control, but prophylaxis is not recommended in current guidelines. The STICH I and STITCH II surgical trials showed no benefit of early surgery compared with medical management within 48 to 96 hours of onset of spontaneous ICH. However, uncertainty remains in some patient groups, and current AHA guidelines suggest craniotomy for those with supratentorial hematoma with neurologic deterioration or coma, large hematoma with significant midline shift, or elevated ICP that is refractory to medical management. Surgical evacuation is recommended for patients with cerebellar hemorrhage greater than 3 cm in diameter (approximately 14 cm^3 in volume) or for those with evidence of neurological deterioration, brainstem compression, or hydrocephalus. Ventriculostomy with external drainage may be required for patients with intraventricular extension of ICH and a deteriorating level of consciousness. Based on the results of the large multicenter FAST trial, current guidelines suggest against the use of recombinant factor VIIa for acute ICH that is not associated with warfarin use outside of clinical trials. In the recent TICH-2 trial, use of tranexamic acid compared with placebo did not result in improved 90-day functional status or reduced mortality.

Stroke Rehabilitation

Intensive rehabilitation should commence as early as possible after acute stroke. Animal models of neuroplasticity suggest that training results in upregulation of growth-promoting factors primarily in the first 4 weeks after acute stroke, but recovery can continue for months or years after the acute event. High levels of patient (and family) motivation and engagement are associated with better outcomes from stroke rehabilitation. Substantial evidence supports a well-coordinated multidisciplinary team care (nursing, physical therapy, occupational therapy, speech therapy, dietician, and social work) approach for optimal delivery of stroke rehabilitation. This care can be provided in the stroke unit setting or by early supported discharge teams in the patient's own home. Both strategies have been shown to improve independence in stroke patients. For older patients with stroke, physical rehabilitation in a long-term care facility has been shown to improve independence.

Secondary Prevention of Ischemic Stroke

CASE STUDY

A 72-year-old man presented with right-sided weakness and expressive aphasia 4 weeks ago. CT scan of brain revealed an ischemic stroke in the left hemisphere. He was admitted to a stroke unit and was discharged home after completing a rehabilitation program. Investigations included ultrasound of the carotids (<20% stenosis of carotids), Holter monitoring (no arrhythmia), and transthoracic echocardiography with bubble study (small PFO). He is known to have hypertension; his serum glucose and HbA1c were normal. He was initiated on aspirin at the time of diagnosis. His blood pressure in clinic today is 152/92 mmHg, and he is currently receiving perindopril (8 mg daily). His fasting low-density lipoprotein (LDL) level was 140 mg/dL.

Antithrombotic Therapy

Current guidelines recommend aspirin, clopidogrel, or combination aspirin-dipyridamole for secondary prevention of noncardioembolic ischemic stroke. The MATCH trial, which compared clopidogrel (75 mg/day) plus aspirin (75 mg/day) with aspirin alone in patients with recent ischemic stroke or TIA, found no reduction in the risk of major vascular events over 18 months of follow-up but an increased risk of life-threatening and major bleeding in patients treated with combination therapy. Similar results were noted in the SPS3 trial, which included patients with recent symptomatic lacunar infarction. The subsequently published CHANCE trial reported a lower risk of recurrent stroke at 90 days in patients with TIA or minor ischemic stroke (NIHSS≤3) treated with the combination of clopidogrel (loading dose of 300 mg followed by 75 mg per day for 90 days) plus aspirin (75 mg/day for first 21 days) compared with aspirin alone. The international POINT trial also reported similar findings, with a reduced risk of major ischemic vascular events (ischemic stroke, myocardial infarction, and ischemic vascular death) with the combination of clopidogrel (initial dose 600 mg then 75 mg/day for 90 days) plus aspirin (50 to 325 mg/day) versus aspirin alone. In patients with atrial fibrillation or mechanical heart valves, oral anticoagulation is generally recommended for secondary prevention of ischemic stroke (see box on When Should Oral Anticoagulant Therapy Be Started After Acute Ischemic Stroke in Patients With Atrial Fibrillation?). The direct thrombin inhibitor dabigatran and the oral factor Xa inhibitor apixaban have been shown to be superior to warfarin, while the oral factor Xa inhibitors rivaroxaban and edoxaban have been shown to be noninferior to warfarin for the prevention of stroke and systemic embolism in patients with atrial fibrillation (see Chapter 143). These agents are commonly used in clinical practice and offer several advantages over warfarin, including a more rapid onset of action, more predictable anticoagulant effect enabling fixed daily dosing without the need for routine coagulation monitoring, and a lower risk of food and drug interactions. In addition, the risk of ICH is lower (albeit a small absolute reduction in risk) with the newer anticoagulants compared with warfarin. Oral anticoagulants are not superior to aspirin for the secondary prevention of stroke in patients with noncardioembolic (WARSS and ESPRIT), intracranial stenosis (WASID), or embolic stroke of undetermined source (NAVIGATE ESUS and RE-SPECT ESUS).

WHEN SHOULD ORAL ANTICOAGULANT THERAPY BE STARTED AFTER ACUTE ISCHEMIC STROKE IN PATIENTS WITH ATRIAL FIBRILLATION?

We initiate all patients on aspirin in the acute setting. In patients with atrial fibrillation who present with an acute transient ischemic attack or minor ischemic stroke in the absence of a large area of acute infarction, we usually initiate anticoagulant therapy immediately if the decision has been made to use anticoagulation. For those with severe stroke or moderate stroke with a large area of infarction, initiating aspirin is recommended without anticoagulant therapy in the acute phase. Anticoagulation can be cautiously introduced 7–14 days after stroke onset provided that hemorrhagic transformation of the infarct has been excluded on neuroimaging in those suspected to be at increased risk of ICH. For patients who have had large infarcts, evidence of hemorrhagic transformation, progression of stroke, or uncontrolled hypertension, further delays beyond 14 days after stroke may be required prior to initiation of therapy with oral anticoagulation. We stop aspirin once a therapeutic anticoagulant effect is achieved (immediately with introduction of a direct oral anticoagulant), unless there is a compelling indication for combining aspirin with an anticoagulant (e.g., recent coronary stent [see Chapter 145]). We do not bridge with treatment doses of heparin, and bridging therapy is unnecessary with the rapidly acting direct oral anticoagulants.

Lipid Modification

Current guidelines recommend statin therapy in patients with LDL of 100 mg/dL or greater. The SPARCL trial, which compared atorvastatin 80 mg daily with placebo, reported a reduced risk of recurrent stroke over 5 years of follow-up in the atorvastatin group. In the recent TST trial, there was a reduced risk of major cardiovascular events (ischemic stroke, myocardial infarction, need for urgent coronary or carotid revascularization, or cardiovascular death) in patients with large vessel atherosclerosis randomized to an LDL target of 70 mg/dL or less compared with an LDL target of 90 to 110 mg/dL.

Blood Pressure

PROGRESS, the largest trial of antihypertensive therapy for secondary stroke prevention, compared perindopril (with or without indapamide) with placebo. Combination therapy reduced blood pressure by 12/5 mmHg and stroke risk by 43% and produced a greater reduction in blood pressure and stroke risk compared with perindopril alone. Current guidelines recommend a target blood pressure of 140/90 mmHg or less for secondary stroke prevention.

Patent Foramen Ovale Closure

Based on evidence from several randomized controlled trials (CLOSE, REDUCE, RESPECT extended follow-up), PFO closure is currently considered an effective management option for prevention of recurrent stroke in carefully selected patients with cryptogenic ischemic stroke based on European consensus guidelines. Percutaneous PFO closure may be more effective than antiplatelet therapy alone in those 60 years of age or younger or those with an embolic appearing nonlacunar stroke on neuroimaging which is confirmed cryptogenic in origin following comprehensive stroke work-up (i.e., estimated high probability of a causal role of PFO with no other evident cause of stroke).

Lifestyle Modification

Lifestyle modification remains a cornerstone of stroke prevention. Important components include smoking cessation, moderate physical activity, weight reduction in overweight or obese patients, adopting a healthy heart diet with increased fruit and vegetable intake and reduced salt intake in those consuming high-salt diets, and moderate alcohol consumption.

PROGNOSIS

Prognosis after stroke depends on age, underlying stroke etiology, severity of the neurological deficit and level of dependence, and comorbidity burden. In a large cohort of more than 10,000 US patients hospitalized with ischemic stroke, 1- and 4-year mortality rates were 24.5% and 41.3%, respectively, with rates of recurrent stroke of 8.0% and 18.1% at 1 year and 4 years, respectively. Early death usually occurs due to neurological complications (e.g., cerebral edema, raised ICP) or medical complications of dependency and immobilization (e.g., aspiration pneumonia). Longer-term mortality is usually due to cardiovascular disease. Two-thirds of stroke survivors are left with chronic residual disability. In addition, patients with stroke are at an increased risk of myocardial infarction, venous thromboembolism, urinary tract infection, hip fracture, pneumonia, and subsequent rehospitalization. Common complications of stroke in the longer term include seizure disorders, cognitive impairment and dementia, depression, and chronic pain syndromes (e.g., central poststroke pain).

FUTURE DIRECTIONS

To date, our knowledge of the epidemiology of stroke has been derived from studies in North America and Europe, with comparatively fewer studies in middle- and low-income countries, although most of the global burden of stroke occurs in these regions. In addition, several large ongoing epidemiological collaborative studies (International Stroke Genetics Consortium) will clarify the role of genetics in the pathogenesis of stroke. Population-based interventions to reduce the burden of stroke will be an important focus of future research and will include evaluation of interventions to reduce salt intake and use of combination cardioprotective therapies (e.g., Polypill) in high-risk populations. For acute ischemic stroke, further studies are underway evaluating the use of tenecteplase as a more convenient alternative to tPa (alteplase) for thrombolysis. The role of mechanical thrombectomy compared with the combination of intravenous thrombolysis plus mechanical thrombectomy in patients with proximal vessel occlusions will also need to be evaluated, as well as the possibility of expanding the eligibility criteria for endovascular therapy, both within and beyond current time windows. The optimal blood pressure goal following endovascular therapy also remains to be determined.

LIST OF TRIAL ACRONYMS

ATACH	Antihypertensive Treatment of Acute Cerebral Hemorrhage
CADISS	Cervical Artery Dissection in Stroke Study
CHANCE	Clopidogrel with Aspirin in Acute Minor Stroke or Transient Ischemic Attack
CRYSTAL AF	Cryptogenic Stroke and Underlying Atrial Fibrillation
ECASS	European Cooperative Acute Stroke Study
ESPRIT	European/Australasian Stroke Prevention in Reversible Ischaemia Trial
FAST	Factor Seven for Acute Hemorrhagic Stroke Trial
INTERACT	Intensive Blood Pressure Reduction in Acute Cerebral Haemorrhage Trial
NAVIGATE ESUS	New Approach Rivaroxaban Inhibition of Factor Xa in a Global Trial Versus ASA to Prevent Embolism in Embolic Stroke of Undetermined Source
POINT	Platelet-Oriented Inhibition in New TIA and Minor Ischemic Stroke Trial
PROGRESS	Perindopril Protection Against Recurrent Stroke Study (PROGRESS)
RE-SPECT ESUS	Randomized, Double-Blind Evaluation in Secondary Stroke Prevention Comparing the Efficacy and Safety of the Oral Thrombin Inhibitor Dabigatran Etexilate versus Acetylsalicylic Acid in Patients With Embolic Stroke of Undetermined Source
SAMMPRIS	Stenting versus Aggressive Medical Therapy for Intracranial stenosis
SPARCL	Stroke Prevention by Aggressive Reduction in Cholesterol Levels Trial
SPS3	Secondary Prevention of Small Subcortical Strokes Trial
STITCH	Surgical Trial in IntraCerebral Hemorrhage
TICH	Tranexamic Aid for Hyperacute Primary IntraCerebral Hemorrhage
TRAPS	Trial of Rivaroxaban in AntiPhospholipid Syndrome
TST	Treat Stroke to Target
VISSIT	Vitesse Intracranial Stent Study for Ischemic Stroke Therapy
WARSS	Warfarin-Aspirin Recurrent Stroke Study
WASID	Warfarin-Aspirin Symptomatic Intracranial Disease Trial

CHAPTER 145

ACUTE CORONARY SYNDROMES

John W. Eikelboom and Jeffrey I. Weitz

Acute coronary syndrome (ACS) leads to millions of hospital admissions worldwide each year and is a leading cause of death. Antithrombotic therapies are a cornerstone in the immediate and long-term management of ACS, reducing the risk of myocardial infarction (MI) and death in both medically and invasively managed patients. This chapter reviews fibrinolytic, antiplatelet, and anticoagulant therapies in the treatment of patients with ACS and provides a practical guide to several common hemostatic and thrombotic problems encountered in this patient population.

CLASSIFICATION

The clinical classification of ACS is based on the electrocardiogram (ECG) at the time of presentation and blood levels of cardiac biomarkers (troponin, creatine kinase). Patients with ST-segment elevation on the ECG and elevated cardiac biomarkers are diagnosed with ST-segment elevation MI (STEMI). Patients with non–ST-segment elevation (NSTE) ACS are subdivided according to whether or not they have elevated blood levels of cardiac biomarkers; those with elevated cardiac biomarkers are diagnosed with non–ST-segment elevation MI (NSTEMI), and those without elevated cardiac biomarkers are diagnosed with unstable angina.[1–3]

PATHOPHYSIOLOGY

Atherothrombosis plays a central role in the pathogenesis of ACS.[4] Hypertension, dysglycemia, dyslipidemia, and toxins contained in tobacco cause endothelial injury. Lipid accumulation promotes an inflammatory response characterized by the recruitment of macrophages, smooth muscle cells, and fibroblasts to the site of injury and the formation of increasingly complex and unstable plaques with a necrotic core and fibrous cap. Disruption of the fibrous cap by shear forces and its degradation by enzymatic and cellular processes expose the plaque contents to the blood. Platelets adhere to exposed subendothelial proteins and become activated and aggregate. Exposed tissue factor induces thrombin generation on cellular surfaces, further promoting the formation of a platelet-fibrin thrombus that can occlude coronary blood flow. These processes are described in more detail in Chapter 142.

The clinical manifestations of coronary atherothrombosis are influenced by the extent and duration of obstruction to blood flow and the presence or absence of collateral circulation. Patients with small plaques that do not significantly impair blood flow generally remain asymptomatic. Patients with significant flow-limiting plaques may develop ischemic symptoms (e.g., chest pain, breathlessness) during exertion when myocardial oxygen demand exceeds supply. Patients with acute plaque disruption with superimposed thrombus formation that completely obstructs coronary blood flow typically present with STEMI unless there is a robust collateral circulation. If obstruction to blood flow is transient or partial, patients typically present with NSTE ACS. If myocardial ischemia results in ventricular fibrillation, sudden cardiac death supervenes.

ANTITHROMBOTIC MANAGEMENT

The goal of antithrombotic therapies in patients with ACS is to prevent new thrombus formation at the site of plaque disruption and facilitate lysis of intracoronary thrombus. Antithrombotic drugs are also used to prevent thrombus formation on the guide wires, catheters, and stents used to open occluded arteries and to prevent and treat left ventricular thrombus formation.

Although the pathophysiology is similar irrespective of whether patients present with STEMI or NSTE ACS, only STEMI patients benefit from immediate reperfusion therapy. This difference reflects the fact that most patients with NSTEMI do not have an occluded infarct-related coronary artery. Instead, they develop MI because of transient coronary artery occlusion or because of distal embolization of the thrombus.

REPERFUSION THERAPY FOR ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Effective approaches to coronary reperfusion include mechanical (primary percutaneous coronary intervention [PCI]) and pharmacologic (fibrinolytic therapy) methods.

Primary Percutaneous Coronary Intervention

Primary PCI is preferred over fibrinolytic therapy in patients with STEMI because it produces higher patency rates and does not cause intracranial bleeding. Unlike fibrinolysis, which only treats the thrombus, primary PCI also allows treatment of the underlying atherosclerotic plaque. In high-income countries, most patients with STEMI are treated with primary PCI. In middle- and low-income countries, many centers lack the facilities and expertise to perform urgent coronary interventions, and only a minority of STEMI patients worldwide is treated with primary PCI.[5,6] Patients undergoing primary PCI are routinely treated with antiplatelet and anticoagulant therapy (discussed in sections on Antiplatelet Therapy and Anticoagulant Therapy).

Fibrinolytic Therapy

Fibrinolytic drugs are plasminogen activators that initiate fibrinolysis by converting plasminogen to plasmin. Plasmin degrades fibrin resulting in clot lysis and recanalization of thrombotic occlusion. Restoration of coronary blood flow limits infarct size and improves myocardial function and survival.

The pharmacologic characteristics of the fibrinolytic drugs most used in the management of ACS are summarized in Table 145.1. Streptokinase was the first agent to be evaluated in large-scale randomized controlled trials. A non–fibrin-specific agent, streptokinase, indirectly activates plasminogen, whereas the more fibrin-specific agents alteplase, reteplase, and tenecteplase directly convert plasminogen to plasmin. Reteplase and tenecteplase have longer half-lives than alteplase, enabling them to be given by double- or single-bolus injection, respectively, which simplifies administration. The direct-acting fibrinolytic agents are more fibrin specific than streptokinase because they bind to fibrin, where they convert fibrin-bound plasminogen to plasmin. Consequently, these agents produce a less marked systemic lytic state than streptokinase, which has no fibrin affinity. Avoidance of a systemic lytic state, which is characterized by a reduction in the

TABLE 145.1 Pharmacologic Characteristics of Fibrinolytic Drugs Used in the Management of Patients With ST-Segment Elevation Myocardial Infarction

Characteristic	Streptokinase	Alteplase	Reteplase	Tenecteplase
Fibrin specificity[a]	–	++	+	+++
Dose	1.5 million units	100 mg	20 U	30–50 mg
Administration	Infusion over 30–60 min	Bolus 15 mg; then infusion 0.75 mg/kg (maximum, 50 mg) over 30 min, 0.5 mg/kg (maximum, 35 mg) over the next 60 min	Double bolus, 10 U over 2 min; then repeat 10 U bolus after 30 min	Single weight-adjusted bolus, <60 kg = 30 mg, 60–69 kg = 35 mg, 70–79 kg = 40 mg, 80–89 kg = 45 mg, ≥90 kg = 50 mg
Half-life (min)	18–23	3–4	18	20
Adjunctive antiplatelet therapy[b]	Aspirin	Aspirin	Aspirin	Aspirin
Adjunctive anticoagulant therapy	Heparin in patients at high risk of thromboembolism[c]	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/h (maximum, 1000 U/h)	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/h (maximum, 1000 U/h)	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/h (maximum, 1000 U/h)

[a] Less fibrin specificity is associated with more systemic fibrinogen depletion.

[b] Fibrinolytic drugs were evaluated on a background of aspirin, but the addition of clopidogrel to aspirin was subsequently shown to provide incremental benefit.

[c] High-risk patients include those with large or anterior myocardial infarction, atrial fibrillation, known left ventricular thrombus, or previous thromboembolism.

circulating level of fibrinogen, is an important potential advantage of fibrin-specific drugs because this can be expected to be associated with a lower risk of bleeding complications.

Initial trials with streptokinase established the efficacy of fibrinolytic therapy for reduction in the risk of MI and death; subsequent trials compared the efficacy and safety of newer fibrinolytic drugs with those of streptokinase or alteplase.

Streptokinase

Streptokinase is a single-chain polypeptide derived from β-hemolytic *Streptococcus* cultures. After intravenous (IV) administration, streptokinase binds to plasminogen, and the resulting streptokinase–plasminogen enzymatic complex converts plasminogen to plasmin. Because plasmin nonspecifically degrades circulating fibrinogen as well as fibrin, streptokinase produces a systemic lytic state. Streptokinase induces the formation of anti-streptokinase antibodies and can cause allergic reactions, particularly with repeated administration. Severe reactions are rare, but rash, shivering, pyrexia, and mild hypotension occur in up to 10% of patients. It is uncertain whether neutralizing antibodies reduce the efficacy of streptokinase.

The GISSI-1 (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico 1) trial, which was conducted in 11,806 patients with STEMI, demonstrated that compared with no lytic therapy, streptokinase (1.5 million units over 1 hour) significantly reduced 21-day in-hospital mortality (10.7% vs. 13.0%; $P = .0002$). A similar reduction in mortality was seen when the same dose of streptokinase was compared with no lytic therapy in 17,187 patients with suspected MI in the ISIS-2 (International Studies of Infarct Survival 2) trial (9.2% vs. 12.0%; $P < .00001$).

Alteplase

Alteplase is a recombinant tissue-type plasminogen activator that directly converts plasminogen to plasmin. Although more fibrin-specific than streptokinase, alteplase still induces a systemic lytic state. It has a short circulating half-life of 3 to 4 minutes, which necessitates its administration by a bolus followed by a continuous IV infusion.

The ISIS-3 ($n = 41{,}299$) and GISSI-2 ($n = 20{,}891$) trials found no benefit of alteplase over streptokinase; findings possibly explained by the suboptimal use of heparin in conjunction with a short-acting fibrinolytic agent (heparin was given subcutaneously after a delay of 4 to 12 hours) and lack of front-loading of alteplase. The GUSTO-1 (Global Utilization of Streptokinase and Tissue Plasminogen Activator to Treat Occluded Arteries 1) trial ($n = 41{,}021$) demonstrated that front-loaded alteplase (15 mg bolus, followed by 0.75 mg/kg [maximum, 50 mg] as an infusion over 30 minutes and then 0.50 mg/kg [maximum, 35 mg] over 60 minutes [maximum, 100 mg over 90 minutes]) plus IV heparin (5000 U IV bolus, followed by 1000 U/hour as an infusion, with the dose titrated to achieve an activated partial thromboplastin time [aPTT] of 60 to 85 seconds) compared with streptokinase (1.5 million units over 1 hour) with or without IV heparin, reduced 30-day mortality (6.3% vs. 7.3%; $P = .001$). The mortality benefits of alteplase were greatest in patients younger than the age of 75 years and those with anterior MI. Despite its enhanced fibrin specificity, alteplase was not associated with less bleeding than streptokinase.

The greatest benefits of fibrinolytic therapy are seen in patients treated within 1 hour of symptom onset; there is a much smaller benefit or no benefit if treatment is commenced more than 6 hours after symptom onset.[7]

Reteplase

Reteplase is a second-generation non-glycosylated deletion mutant of alteplase. Reteplase is less fibrin-specific than alteplase but has a longer half-life (18 minutes) that enables administration by double-bolus IV injection.

The INJECT trial ($n = 6010$) demonstrated that reteplase and streptokinase were associated with similar 35-day rates of mortality (9.0% vs. 9.5%), in-hospital stroke (1.2% vs. 1.0%), and major bleeding (0.7% vs. 1.0%), although reteplase was associated with a twofold higher rate of intracranial bleeding (0.8% vs. 0.4%). The GUSTO-III trial ($n = 15{,}059$) demonstrated that reteplase (two 10-mg IV bolus injections given 30 minutes apart) and front-loaded alteplase were associated with similar 30-day rates of mortality (7.5% vs. 7.2%) and stroke (1.6% vs. 1.7%).

Tenecteplase

Tenecteplase is a third-generation multiple point mutant of alteplase. Tenecteplase has a half-life of 20 minutes and is given by a single bolus injection. Tenecteplase is the most fibrin-specific fibrinolytic drug approved for clinical use.

The ASSENT-2 (Assessment of the Safety and Efficacy of a New Thrombolytic) study, which enrolled 16,949 STEMI patients, showed that tenecteplase and alteplase were associated with similar 30-day rates of mortality (6.2% vs. 6.2%) and stroke (1.8% vs. 1.7%). Tenecteplase did not reduce the risk of intracerebral bleeding compared with alteplase (1% vs. 1%) but reduced the rate of major noncerebral bleeding (4.7% vs. 5.9%; $P < .0002$), possibly reflecting its enhanced fibrin specificity.

Adjunctive Antithrombotic Therapy in Patients Receiving Fibrinolytic Drugs

A compelling rationale exists to administer adjunctive antithrombotic therapy to STEMI patients treated with fibrinolytic therapy. Platelet-rich thrombi that form after plaque rupture are relatively resistant to degradation, and the use of concomitant antiplatelet and anticoagulant therapy may help to promote clot lysis. Fibrinolytic drugs have an early activating effect on platelets, and the plaque rupture site remains prothrombotic after successful reperfusion therapy. Evidence in support of the efficacy of adjuvant antiplatelet and anticoagulant therapy in patients with STEMI is summarized in the sections on antiplatelet and anticoagulant therapy, respectively.

Intracranial Bleeding

The most important side effect of fibrinolytic therapy is intracranial bleeding, which affects up to 1% of patients and, in the majority of cases, is either fatal or permanently disabling.[8] Risk factors for intracranial bleeding include increasing age (particularly in patients older than 75 years of age), history of prior stroke, uncontrolled blood pressure, female sex, and low body weight. Bolus dose fibrinolytic therapy may be associated with a higher risk of intracranial bleeding than fibrinolytic therapy administered by continuous IV infusion (see Table 145.2 and box on Case 1: Bleeding After Fibrinolytic Therapy).[9]

ANTIPLATELET THERAPY

Aspirin and oral adenosine diphosphate (ADP) receptor antagonists, such as clopidogrel, prasugrel, and ticagrelor are the foundation antiplatelet therapies for the management of ACS. The use of glycoprotein (GP) IIb/IIIa antagonists has decreased since the introduction of the ADP receptor antagonists, but they retain a role in high-risk ACS patients, particularly STEMI patients undergoing primary PCI.[5,6,10] In 2015, the US Food and Drug Administration approved cangrelor, a short-acting parenteral ADP receptor antagonist, for ACS patients undergoing PCI who have not received an oral ADP receptor antagonist and who are not given a GPIIb/IIIa inhibitor. The pharmacologic characteristics of antiplatelet drugs commonly used in the management of ACS are summarized in Table 145.3 (oral drugs) and 145.4 (IV drugs).

Oral Antiplatelet Drugs

Aspirin

Aspirin inhibits platelets by irreversibly blocking the platelet enzyme cyclooxygenase-1, thereby preventing the formation of thromboxane A_2, a potent platelet agonist and vasoconstrictor. Despite having a half-life of only 20 minutes, the antiplatelet effect of aspirin lasts for the lifetime of the platelet (5 to 10 days) because platelets are anucleate and lack the machinery to synthesize new enzymes.[11]

TABLE 145.2 Management of Major Bleeding in Patients With ST-Segment Elevation Myocardial Infarction Treated With Fibrinolytic Therapy

Steps	Approach	Considerations
Stop treatment	Stop fibrinolytic drug	Recovery of fibrinogen levels can take 24–48 h after stopping streptokinase
	Stop antiplatelet drugs	Antiplatelet effects of aspirin and clopidogrel last for the life span of platelets (5–10 days)
	Stop anticoagulant	Heparin has a half-life of about 40 min; LMWH has a half-life of 3-6 h
Local measures	Local pressure	Sustained local pressure (e.g., for 30 min) may be required
	Endoscopy and local injection[a]	Can be used for upper or distal lower GI bleeding
	Embolization[a]	Used in rare situations such as life-threatening pulmonary or intraabdominal bleeding
Laboratory evaluation	Fibrinogen	Levels may be undetectable (<100 mg/dL)
	PT and aPTT	Results are uninterpretable if fibrinogen levels are low (<100 mg/dL)
	Anti-Xa level	PT (INR) and aPTT are elevated with warfarin; aPTT is prolonged with therapeutic doses of heparin but not with LMWH or fondaparinux
	Crossmatch blood	Chromogenic anti-factor Xa assay for LMWH and fondaparinux; this test is unaffected by low fibrinogen levels
		To restore blood volume and maintain hemoglobin
Reversal of fibrinolytic effect	Cryoprecipitate	Recommended initial dose is 10 U; monitored by repeating fibrinogen level
	FFP	The half-life of fibrinogen is about 4 days
		Requires large volumes (e.g., 2 L) to restore fibrinogen levels
Reversal of antiplatelet effect	Platelet transfusion	Increases the number of functional platelets but does not reverse the antiplatelet effects of aspirin and clopidogrel
		Also see text under heading "Antiplatelet Therapy"
Reversal of anticoagulant effect	Protamine sulphate	Protamine reverses heparin and partially reverses LMWH; it has no effect on fondaparinux (also see Table 145.6)

[a] Also requires restoration of adequate hemostasis.

aPTT, Activated partial thromboplastin time; *FFP*, fresh frozen plasma; *GI*, gastrointestinal; *INR*, international normalized ratio; *LMWH*, low-molecular-weight heparin; *PT*, prothrombin time.

CASE 1: BLEEDING AFTER FIBRINOLYTIC THERAPY

A 63-year-old man with a history of hypertension presents to a rural hospital with sudden onset of severe retrosternal chest pain. An electrocardiogram (ECG) performed in the emergency department demonstrates 4-mm ST-segment elevation in the anterior leads. The nearest hospital with a cardiac catheterization laboratory is more than 6 h away. After treatment with aspirin (325 mg loading dose), clopidogrel (300 mg loading dose), and an intravenous (IV) infusion of front-loaded alteplase, he has a rapid resolution of his pain and the ECG reveals normalization of the ST-segment elevation. Toward the end of the alteplase infusion, he complains of abdominal pain, becomes hypotensive, and develops melena. Hemoglobin is 10.2 g/dL, the activated partial thromboplastin time (aPTT) is 89 s, the international normalized ratio (INR) is 1.7, and the fibrinogen level is 80 mg/dL.

Aspirin and clopidogrel are held; the patient receives fibrinogen concentrate and is started on an IV infusion of a proton pump inhibitor. He undergoes urgent upper gastrointestinal tract endoscopy with an injection of a bleeding ulcer. He does not receive platelets because of concerns about the risk of recurrent myocardial infarction (MI). No further bleeding occurs, and after 48 h he resumes aspirin. Clopidogrel is restarted 1 week later after repeat endoscopy demonstrates the healing of the ulcer.

Comment

Fibrinolytic trials in patients with acute MI report a 1%–6% incidence of major bleeding and a 10% incidence of moderate bleeding during the first 30 days. The most common sources of major bleeding are the gastrointestinal tract and procedure-related bleeding. The principles of management of major bleeding in ST-segment elevation MI (STEMI) patients treated with fibrinolytic therapy are summarized in Table 145.2. Steps include (1) stop antithrombotic therapies; (2) use local measures when possible to control bleeding; (3) draw blood to measure fibrinogen, prothrombin time (PT), aPTT, and possibly anti-Xa levels (to measure the anticoagulant effect of low-molecular-weight heparin [LMWH]) and for blood typing and cross-match; and (4) administer therapies to mitigate or reverse the effects of fibrinolytic, antiplatelet, and anticoagulant drugs.

The extent and duration of the systemic lytic state induced by fibrinolytic drugs are determined by their fibrin specificity. Whereas streptokinase produces profound and sustained depletion of fibrinogen (<100 mg/dL) that lasts for up to 24-48 h, alteplase and other more fibrin-specific agents exert less pronounced and more short-lived effects on fibrinogen levels. The aPTT and PT can be markedly prolonged in patients with hypofibrinogenemia. Normal coagulation can be restored by increasing the fibrinogen level to at least 100 mg/dL. This can readily be achieved by infusing fibrinogen concentrate (dose [mg/kg] = [target level (mg/dL) - measured level (mg/dL)] divided by 1.7 or 1.8 [mg/dL per mg/kg body weight]), or 70 mg/kg body weight if fibrinogen level unknown) or cryoprecipitate (recommended dose: 10 units). Although fresh frozen plasma also contains fibrinogen, large volumes are needed to increase the fibrinogen concentration to the desired range.

Platelet dysfunction caused by antiplatelet therapy and fibrinolytic therapy cannot be specifically reversed, but the infusion of donor platelets might help to restore platelet function. Platelet transfusion is generally reserved for patients with life-threatening bleeding because of concerns about the risk of recurrent MI. A single unit of single donor platelets can be expected to increase the platelet count by 50–60 × 10^9/L. Even a small number of functional (non-aspirinated) platelets (e.g., 10%–20%) is sufficient to generate enough thromboxane A_2 to overcome the effects of aspirin, but a much larger number of transfused platelets is needed to overcome the antiplatelet effects of clopidogrel and prasugrel. Platelet infusions are relatively ineffective if given within 24 h of the last dose of ticagrelor. In this case, bleeding was controlled with fibrinogen concentrate and local measures, and platelet transfusion was not required.

Multiple randomized trials have demonstrated the efficacy of aspirin for the prevention of recurrent MI, stroke, or death in patients with ACS.[12] The ISIS-2 investigators evaluated the efficacy and safety of aspirin in 17,187 STEMI patients who were also randomized to receive or not to receive fibrinolytic therapy. Aspirin (162 mg/day), compared with no aspirin, significantly reduced 35-day mortality (9.4% vs. 11.8%; $P < .00001$) as well as nonfatal reinfarction (1.0% vs. 2.0%) and stroke (0.3% vs. 0.6%) without increasing bleeding. The Antithrombotic Trialists' Collaboration (ATTC) pooled the data from 15 randomized trials of antiplatelet therapy (predominantly with aspirin) involving 19,302 acute MI patients who were also treated with fibrinolytic therapy. Compared with placebo or no antiplatelet therapy, antiplatelet therapy given for a mean duration of 1 month significantly reduced the composite outcome of MI, stroke, or death (10.4% vs. 14.2%; $P < .0001$).

At least four randomized controlled trials have demonstrated the efficacy of aspirin in patients with NSTE ACS. Pooled data from four trials that included a combined total of 3096 patients indicate that aspirin compared with placebo or no aspirin significantly reduced the composite endpoint of MI, stroke, or vascular death (6.4% vs. 12.5%; $P = .0005$).

The efficacy and safety of aspirin in combination with dipyridamole have been evaluated in PCI patients in one randomized controlled trial involving 376 patients. Aspirin (300 mg) plus dipyridamole (75 mg given three times daily except during a 24-hour period around the time of the procedure when dipyridamole was given intravenously) reduced the risk of MI by more than half compared with placebo (1.6% vs. 6.9%; $P = .01$). These results led to the adoption of aspirin as standard therapy for patients undergoing PCI.

The CURRENT OASIS-7 (Clopidogrel Optimal Loading Dose Usage to Reduce Recurrent EveNTs/Optimal Antiplatelet Strategy for InterventionS) trial explored the optimal dose of aspirin in 25,086 ACS patients with or without ST-segment elevation on the presenting ECG and included 17,263 patients undergoing early PCI.[13] After an initial aspirin loading dose, patients were randomized to receive aspirin at a dose of 300 to 325 mg/day or 75 to 100 mg/day for 30 days. The two doses were associated with similar rates of MI, stroke, or death at 30 days (4.2% vs. 4.4%), but the higher aspirin dose increased the rate of gastrointestinal bleeding (0.4% vs. 0.2%; $P = .04$). Based on these results, the optimal dose of aspirin for the management of patients with ACS (after an initial loading dose of 160 to 325 mg) appears to be 75 to 100 mg/day.

Clopidogrel

Clopidogrel undergoes metabolic activation in the liver to form the active moiety that irreversibly blocks P2Y12, the major ADP receptor on the platelet surface, as evidenced by a decrease in ADP-induced platelet activation and aggregation. Like aspirin, the antiplatelet effect of clopidogrel lasts for the lifetime of the platelet. Clopidogrel is an effective antiplatelet drug for the prevention of MI and death when used in combination with aspirin but has a slow onset of action and a variable antiplatelet effect, which may limit its effectiveness.

The COMMIT (Clopidogrel and Metoprolol in Myocardial Infarction Trial) trial, which involved 45,582 patients with STEMI, all of whom were treated with aspirin (162 mg/day), demonstrated that compared with placebo, 30 days of treatment with clopidogrel (75 mg/day) reduced the risk of MI, stroke, or death (9.2% vs. 10.1%; $P = .002$) with no increase in major bleeding (0.58% vs. 0.55%).[14] There was no age restriction to enrollment in the COMMIT trial, and clopidogrel was given without a loading dose. In the CLARITY (Clopidogrel as Adjunctive Reperfusion Therapy) trial ($n = 3491$), which was conducted in parallel with COMMIT, clopidogrel was given as a loading dose of 300 mg followed by 75 mg/day for 2 to 8 days was compared with placebo in patients receiving fibrinolysis. Clopidogrel reduced the risk of MI or death (15% vs. 21.7%; $P < .001$). Consistent benefits of clopidogrel were demonstrated in the 1863 patients who underwent PCI after mandated angiography.

The CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial, which included 12,562 patients with NSTE ACS, all of whom were treated with aspirin (recommended dose: 75 to 325 mg/day), demonstrated that compared with placebo, a median of 9 months of treatment with clopidogrel (300 mg loading dose followed by 75 mg/day) reduced the risk of MI, stroke, or death (9.3% vs. 11.4%; $P < .001$) at the cost of an increase in major bleeding (3.7%

TABLE 145.3 **Pharmacologic Characteristics of Oral Antiplatelet Drugs Commonly Used in the Management of Acute Coronary Syndrome**

		ADP Receptor Antagonists		
Characteristic	**Aspirin**	**Clopidogrel**	**Prasugrel**	**Ticagrelor**
Class	COX inhibitor	Thienopyridine (second generation)	Thienopyridine (third generation)	Cyclopentyl triazolopyrimidine
Target	COX-1	P2Y12	P2Y12	P2Y12
Dose	162–325-mg loading dose; 75–325 mg/day maintenance dose	300–600-mg loading dose; 75 mg/day maintenance dose	60-mg loading dose; 10 mg/day maintenance dose	180-mg loading dose; 90 mg bid maintenance dose
Prodrug	No	Yes	Yes	No
Time to effect[a]	<1 h	4–6 h[b]	<1 h	<1 h
Drug half-life	20 min	Minutes	Minutes	12 h
Reversible	No	No	No	Yes

[a] After loading dose.

[b] Increased antithrombotic benefit was seen after the first hour in patients enrolled in the COMMIT trial who did not receive a loading dose, but the maximum effect is not seen until after 4-6 h.

ADP, Adenosine diphosphate; *bid*, twice daily; *COX*, cyclooxygenase.

vs. 2.7%; $P = .001$).[15] Consistent benefits of clopidogrel were seen in the 2,658 patients who underwent PCI regardless of whether or not they underwent coronary stenting.

Prompted by concerns that some patients achieve suboptimal inhibition of platelet function with conventional doses of clopidogrel, the CURRENT-OASIS 7 trial compared the efficacy and safety of a higher loading and maintenance dose of clopidogrel (600-mg loading dose followed by 150 mg/day for 6 days and 75 mg/day for 23 days thereafter) with standard-dose clopidogrel (300-mg loading dose and 75 mg daily thereafter) in 25,086 patients with ACS referred for an invasive management strategy.[13] Both regimens were associated with similar rates of the primary outcome, MI, stroke, or vascular death (4.2% vs. 4.4%), but the higher dose regimen was associated with an increase in major bleeding (2.5% vs. 2.0%; $P = .01$). However, in the 17,263 patients who underwent PCI, the higher dose regimen reduced MI, stroke, or vascular death (3.9% vs. 4.5%; $P = .039$) and stent thrombosis (0.7% vs. 1.3%; $P = .0001$) compared with the lower dose regimen.

Prasugrel

Prasugrel is a third-generation thienopyridine that is more potent than clopidogrel and has a more rapid onset of action. Prasugrel is a prodrug, but unlike clopidogrel, it requires only single-step bioconversion to form the active metabolite that irreversibly blocks the platelet P2Y12 receptor.

The TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel–Thrombolysis In Myocardial Infarction 38) trial evaluated the efficacy and safety of prasugrel in 13,608 ACS patients with or without ST-segment elevation who were undergoing PCI, all of whom were treated with aspirin (recommended dose: 75 to 162 mg/day).[16] Compared with clopidogrel (300 mg followed by 75 mg once daily thereafter), prasugrel (60 mg followed by 10 mg once daily thereafter) continued for a median of 14.5 months reduced the risk of MI, stroke, or cardiovascular death (9.9% vs. 12.1%; $P < .001$) and stent thrombosis (1.1% vs. 2.4%; $P < .001$) but did not reduce mortality and increased noncoronary artery bypass graft (CABG) major bleeding (2.4% vs. 1.8%; $P = .03$) as well as intracranial and fatal bleeding.

The TRILOGY ACS[17] (Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes) trial evaluated the efficacy and safety of prasugrel in 9326 aspirin-treated patients with NSTE ACS who were managed noninvasively. At a median of 17 months of follow-up, prasugrel (30 mg followed by 10 mg once daily in patients less than 75 years or 5 mg once daily for those 75 years or older or who weighed less than 60 kg) and clopidogrel (300 mg followed by 75 mg once daily) were associated with similar rates of MI, stroke or cardiovascular death (13.9% vs. 16.0%; $P = .21$) and similar rates of major bleeding.

Ticagrelor

Ticagrelor is a nonthienopyridine P2Y12 receptor antagonist. Like prasugrel, ticagrelor is more potent and has a more rapid onset of action than clopidogrel, but unlike both clopidogrel and prasugrel, ticagrelor binds reversibly to the P2Y12 receptor.

The PLATO trial evaluated the efficacy and safety of ticagrelor in 18,624ACS patients with or without ST-segment elevation.[18] Compared with clopidogrel (300 or 600 mg loading dose followed by 75 mg once daily), ticagrelor (180 mg loading dose followed by 90 mg twice daily) reduced the risk of MI, stroke, or vascular death by 16% (9.8% vs. 11.7%; $P < .001$) and produced a significant reduction in vascular death (4.0% vs. 5.1%; $P = .001$) and stent thrombosis (1.3% vs. 1.9%; $P = .009$) (see box on Case 2: Stent Thrombosis). There was no increase in major bleeding (11.6% vs. 11.2%) or intracranial or fatal bleeding, but ticagrelor increased non-CABG major bleeding (4.5% vs. 3.8%; $P = .03$).

The ISAR-REACT 5 trial evaluated the relative efficacy and safety of ticagrelor and prasugrel in 4018 patients who presented with ACS and for whom invasive evaluation was planned. Compared with prasugrel (60 mg followed by 10 mg once daily thereafter), ticagrelor (180 mg loading dose followed by 90 mg twice daily) was associated with a significantly higher rate of MI, stroke or death (9.3% vs. 6.9%, $P = .006$) at 1 year, with no significant difference in individual components of this primary outcome, stent thrombosis or major bleeding (5.4% vs. 4.8%, $P = .46$).

Duration of Dual Antiplatelet Therapy

Results of the CURE, TRITON-TIMI 38, and PLATO studies support the recommendation to treat patients with recent ACS with dual antiplatelet for a minimum of 12 months. Building on these results, the PEGASUS-TIMI 54 trial demonstrated in 21,162 post-MI patients who successfully completed 12 months of treatment with dual antiplatelet therapy that extended-duration ticagrelor (60 or 90 mg twice daily; median 1.7 years) compared with placebo on a background of aspirin reduced CV death, MI or stroke (60 mg twice

CASE 2: STENT THROMBOSIS

A 49-year-old man with a history of type 2 diabetes presents with non–ST-segment elevation myocardial infarction and undergoes percutaneous coronary intervention (PCI) with the placement of a drug-eluting stent in the left anterior descending coronary artery. He receives a 325-mg loading dose of aspirin and a 180 mg loading dose of ticagrelor and is discharged on aspirin 81 mg/day and ticagrelor 90 mg twice daily. He presents to the emergency department 3 weeks later with recurrent chest pain and anterior ST-segment elevation on the ECG. He is taken urgently to the cardiac catheterization laboratory where a diagnosis of stent thrombosis is confirmed, and he undergoes repeat PCI with thrombus aspiration.

Further history reveals that he discontinued ticagrelor after leaving the hospital because he felt that he was taking too many pills. He is counselled regarding the importance of adherence to antiplatelet therapy to protect his stent and is discharged on indefinite dual antiplatelet therapy with aspirin and ticagrelor.

Comment

Stent thrombosis is a potentially life-threatening complication of PCI, affecting 1%–2% of patients during the first year and presenting in almost all cases like death or myocardial infarction.[19] Risk factors for stent thrombosis can be categorized as patient-related, technical (procedure, stent, or lesion), or drug-related. The single most important predictor of stent thrombosis is premature discontinuation of antiplatelet therapy. In patients treated with clopidogrel, high on-treatment platelet reactivity during treatment has also emerged as a predictor of stent thrombosis and is affected by clinical (e.g., age, diabetes, renal insufficiency) and genetic factors. Carriers of reduced-function *CYP2C19* alleles have low levels of the active metabolite of clopidogrel, diminished platelet inhibition, and an increased risk of stent thrombosis. Unlike clopidogrel, which undergoes two-step, cytochrome P450 (CYP)-dependent metabolic bioconversion in the liver, prasugrel and ticagrelor are not affected by CYP polymorphisms and consistently produce greater and more consistent inhibition of ADP-induced platelet aggregation than standard doses of clopidogrel. Higher doses of clopidogrel (e.g., 225 or 300 mg/day) in patients heterozygous for *CYP2C19*2* alleles produce levels of platelet inhibition like those seen with standard (75 mg) doses but have not been evaluated in clinical outcome studies.

Concerns regarding the risk of stent thrombosis caused by poor clopidogrel response[20] have been alleviated by the routine use of ticagrelor or prasugrel in preference to clopidogrel. However, the lack of persistence or adherence remains an important cause of stent thrombosis.

daily vs. placebo: 7.77% vs. 9.04%, $P = .004$; 90 mg twice daily vs. placebo: 7.85% vs. 9.04%, $P = .008$). Both doses of ticagrelor increased TIMI major bleeding but not intracranial bleeding. The DAPT trial demonstrated in 9961 stented patients who had successfully completed 12 months of treatment with dual antiplatelet therapy that extended duration clopidogrel or prasugrel (median 18 months) compared with control on a background of aspirin reduced stent thrombosis (0.4% vs. 1.4%, $P < .001$) as well as death, MI, or stroke (4.3% vs. 5.9%, $P < .001$) at the cost of an increase in GUSTO bleeding. The greatest benefits were evident in patients with a history of MI. Accordingly, guidelines recommend extended dual antiplatelet therapy for up to an additional 36 months in patients with recent ACS who were successfully treated for the first year and did not have major bleeding.

Intravenous Antiplatelet Drugs

Glycoprotein IIb/IIIa Inhibitors

Three GPIIb/IIIa inhibitors are available for clinical use (see Table 145.4). Abciximab is a humanized version of a Fab fragment of a murine antibody directed against GPIIb/IIIa; tirofiban is a nonpeptide tyrosine derivative that selectively binds to GPIIb/IIIa, and eptifibatide is a synthetic disulfide-linked cyclic heptapeptide with high specificity for GPIIb/IIIa.

The efficacy and safety of GPIIb/IIIa inhibitors have been extensively evaluated in patients with ACS. A meta-analysis restricted to trials ($n = 6$) involving at least 1000 patients suggests a modest effect of these agents for the prevention of MI, urgent revascularization, or vascular death in patients with NSTE ACS (10.8% vs. 11.8%; $P = .015$).[21] Pooled data from a meta-analysis of 16 randomized trials involving 10,085 STEMI patients undergoing primary PCI demonstrated that adjunctive GPIIb/IIIa blockade did not reduce 30-day mortality (2.8 vs. 2.9%; $P = .75$) or reinfarction (1.5 vs. 1.9%; $P = .22$) and increased major bleeding (4.1 vs. 2.7%; $P = .0004$). However, meta-regression analysis confirmed the impression from individual trials of a mortality benefit of IV GPIIb/IIIa inhibitors in those at highest risk.[22]

Cangrelor

Cangrelor is a rapid-acting IV P2Y12 receptor antagonist that has been compared with clopidogrel or placebo in three randomized trials that included patients with NSTE ACS. An individual patient meta-analysis of the three trials[23] demonstrated that compared with control, cangrelor reduced the risk of ischemia-driven revascularization, stent thrombosis, MI, or death at 48 hours (3.8% vs. 4.7%, $P = .0007$) at the cost of an increase in GUSTO mild bleeding (16.8% vs. 13.0%, $P < .0001$) but no increase in more severe bleeding.

ANTICOAGULANT THERAPY

Anticoagulant therapy is effective for the initial and long-term management of patients with ACS with or without ST-segment elevation.[5,6,10] The pharmacologic characteristics of parenteral anticoagulants used in the management of ACS are summarized in Table 145.5. Early trials demonstrated that heparin and aspirin were similarly effective for the prevention of MI, but aspirin was adopted as the foundation antithrombotic agent because it caused less bleeding than heparin. Subsequent randomized trials demonstrated that the use of heparin on top of aspirin provided additive benefit and that low-molecular-weight heparin (LMWH), fondaparinux, and bivalirudin provided advantages over heparin.

TABLE 145.4 Pharmacologic Characteristics of Intravenous Antiplatelet Drugs Used in the Management of Acute Coronary Syndrome

	GPIIb/IIIa Inhibitors			ADP Receptor Antagonist

[a] The first dose of enoxaparin was given by the intravenous route in the TIMI-11B (Thrombolysis In Myocardial Infarction 11B) and EXTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment, Thrombolysis in Myocardial Infarction 25) studies. The first dose of fondaparinux was given by the intravenous route in the OASIS-6 (Optimal Antiplatelet Strategy for InterventionS 6) trial.

[b] Acute coronary syndrome patients with creatinine up to 265 µmol/L were eligible for inclusion in the OASIS-5 and -6 trials (equivalent to an estimated creatinine clearance of 15–20 mL/min in a 70-kg patient who is 70 years of age).

[c] Fondaparinux is contraindicated in patients with venous thromboembolism who have severe renal impairment.

[d] Monitoring and dose adjustment required in patients with creatinine clearance below 30 mL/min.

ACS, Acute coronary syndromes; *aPTT*, activated partial thromboplastin time; *CrCl*, creatinine clearance; *HIT*, heparin-induced thrombocytopenia; *IV*, intravenous; *SC*, subcutaneous.

The pharmacologic characteristics of oral anticoagulants that have been demonstrated to be effective in the initial and long-term management of ACS are summarized in Table 145.6.[24] Warfarin is effective for the prevention of major cardiovascular events for the long-term management of patients with ACS who are also treated with aspirin, but no adequately powered randomized controlled trials have evaluated the efficacy and safety of warfarin in the context of dual antiplatelet therapy. Two direct oral anticoagulants, rivaroxaban and apixaban, have been evaluated in phase III trials for long-term secondary prevention in ACS patients,[25,26] and rivaroxaban has been approved for this indication in Europe.

Heparin

Heparin is derived from porcine intestinal mucosa and is administered by IV or subcutaneous injection. It inhibits coagulation by binding to antithrombin to induce a conformational change that converts antithrombin from a slow to a rapid inhibitor of thrombin and factor Xa.

Heparin has several limitations, including immune-mediated platelet activation, which leads to heparin-induced thrombocytopenia, and nonspecific protein binding, resulting in a variable anticoagulant response and the need for routine coagulation monitoring. Despite these limitations, heparin remains widely used because it has important advantages over more recently introduced parenteral anticoagulants. First, the anticoagulant effect of heparin can be rapidly and completely reversed with protamine sulfate. Second, heparin is suitable for use in patients with renal failure because it is predominantly cleared via extra-renal routes. Third, unlike LMWH and fondaparinux, heparin is also highly effective for the prevention of contact activation of coagulation induced by guide wires, catheters and stents.[27]

Meta-analysis of four randomized controlled trials involving 1239 STEMI patients treated with aspirin and fibrinolytic therapy demonstrated that short-term IV heparin (given for about 1 week) did not significantly reduce death or reinfarction compared with placebo or no heparin, but increased bleeding.[28] However, these trials were underpowered to demonstrate the benefit of heparin. Definitive data concerning the efficacy of heparin in STEMI patients treated with fibrinolysis come from a meta-analysis of 26 trials involving 73,000 patients, in which heparin, given either intravenously or subcutaneously, reduced mortality and reinfarction compared with placebo or no heparin.[29] Consistent benefits were evident in a subset of five trials in which patients also received aspirin; heparin compared with placebo or no heparin reduced both mortality (8.6% vs. 9.1%; $P = .03$) and reinfarction (3.0% vs. 3.3%; $P = .04$).

Short-term heparin therapy is also beneficial when added to aspirin in patients with NSTE ACS. A meta-analysis of six trials involving 1353 patients demonstrated that compared with placebo or no heparin, up to 7 days of IV heparin reduced death or MI (4.5% vs. 7.4%; $P = .045$) with a nonsignificant excess of major bleeding.[30] Heparin has not been rigorously evaluated in ACS patients undergoing PCI but is routinely used in this setting.

Low-Molecular-Weight Heparin

LMWH is derived from heparin by enzymatic or chemical methods, yielding shorter polysaccharide chains that produce a more predictable anticoagulant effect than heparin and a lower propensity for heparin-induced thrombocytopenia. LMWH is given in fixed weight-adjusted doses without routine coagulation monitoring. The anticoagulant effects of LMWH can be partially reversed with protamine sulfate.

TABLE 145.6 Pharmacological Characteristics of Warfarin and New Oral Anticoagulants Evaluated in Phase III Trials for the Long-Term Management of Acute Coronary Syndrome

Characteristic	Warfarin	Rivaroxaban	Apixaban
Target	VKORC1	Factor Xa	Factor Xa

Antidote	Yes (vitamin K, PCC, FFP)	Yes[d]	Yes[d]
Approved for ACS management	Yes	Yes, in Europe	No

[a] A once-daily regimen was tested in atrial fibrillation.

[b] Half of renally cleared rivaroxaban is cleared as unchanged drug and half as inactive metabolites.

[c] Potent inhibitors of both CYP3A4 and P-glycoprotein include azole antifungals (e.g., ketoconazole, itraconazole, voriconazole, posaconazole) and protease inhibitors, such as ritonavir. Potent inhibitors of CYP3A4 include azole antifungals, macrolide antibiotics (e.g., clarithromycin), and protease inhibitors (e.g., atanazavir).

[d] Andexanet alfa is approved in Europe and United States for use as an antidote for rivaroxaban and apixaban.

The CREATE trial ($n = 15{,}570$) was the largest of four trials that evaluated the efficacy and safety of various LMWH preparations in patients with STEMI also treated with aspirin and fibrinolysis.[31] Approximately half of the patients in the CREATE trial were treated with dual antiplatelet therapy. The pooled data ($n = 16{,}943$) demonstrated that compared with placebo, initial LMWH continued for up to 7 days reduced the risk of reinfarction (1.6% vs. 2.2%; $P < .05$) and death (7.8% vs. 8.7%; $P < .05$) at the cost of an increase in major bleeding (1.1% vs. 0.4%; $P < .05$).

Most of the trials compared LMWH with heparin for the treatment of STEMI tested enoxaparin. Pooled data from eight trials involving 27,758 patients demonstrated that compared with heparin, initial LMWH reduced the risk of MI (2.1% vs. 3.9%; $P < .05$); rates of death were similar (5.3% vs. 5.8%) and there was more major bleeding (2.2% vs. 1.6%).[32] Consistent results were evident at 30 days.

The Fragmin during Instability in Coronary artery disease 1 (FRISC-1) trial evaluated the efficacy and safety of dalteparin in patients with NSTE ACS. Pooled data from FRISC-1 ($n = 1539$) and a second much smaller phase II study demonstrated that compared with placebo or no LMWH, LMWH reduced the risk of MI or death (1.6% vs. 5.2%; $P < .0001$) with no significant increase in major bleeding.

Multiple trials have compared LMWH with heparin in patients with NSTE ACS. A pooled analysis of five trials involving 12,171 patients demonstrated that LMWH and heparin were associated with similar rates of MI or death (2.2% vs. 2.3%) and major bleeding.[30] A subsequent meta-analysis involving 21,946 patients with NSTE ACS demonstrated that compared with heparin, enoxaparin reduced the risk of death or MI (10.1% vs. 11.0%; $P < .05$) with no increase in major bleeding.[31] The latter meta-analysis included some trials that did not involve the use of GPIIb/IIIa inhibitors and others in which they were widely used. The proportion of patients who underwent an invasive management strategy also varied across the trials.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide that contains the essential five-sugar chain that binds antithrombin with high affinity and enhances the rate at which it inhibits factor Xa. Fondaparinux has a half-life of 17 hours, which enables once-daily subcutaneous administration and produces an even more predictable anticoagulant effect than LMWH and does not appear to cause heparin-induced thrombocytopenia. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux.

Fondaparinux has been evaluated in patients with ACS in three large phases III randomized controlled trials. The OASIS-6 trial evaluated fondaparinux in 12,092 STEMI patients treated with single or dual antiplatelet therapy and fibrinolytic therapy.[33] Compared with placebo or heparin, fondaparinux (2.5 mg/day) reduced the risk of reinfarction or death (9.7% vs. 11.2%; $P = .008$) with consistent effects in patients with or without an indication for heparin therapy and in patients who received aspirin alone or the combination of aspirin and clopidogrel. Fondaparinux did not increase major bleeding. However, fondaparinux was associated with no benefit and a trend for harm in patients undergoing primary PCI.

The OASIS-5 trial evaluated fondaparinux in 20,078 patients with NSTE ACS treated with aspirin with or without clopidogrel. Fondaparinux (2.5 mg once daily) and enoxaparin (1 mg/kg twice a day) given for a mean of 6 days were associated with similar rates of the primary outcome of refractory ischemic, MI, or death at 9 days (5.8% vs. 5.7%), but there was a lower rate of major bleeding with fondaparinux (2.2% vs. 4.1%; $P < .001$).[34] At 30 days, fondaparinux was associated with a reduced rate of death compared with enoxaparin (2.9% vs. 3.5%; $P = .02$), which appeared to be explained primarily by the lower rate of bleeding. In 6238 invasively managed patients, fondaparinux and enoxaparin were associated with similar rates of the primary outcome but fondaparinux was associated with a small excess of catheter-related thrombosis (0.9% vs. 0.4%) and a reduction in major bleeding (2.4% vs. 5.1%; $P < .00001$). The risk of catheter thrombosis was largely prevented by the administration of IV heparin at the time of intervention.

The FUTURA OASIS-8 (Fondaparinux Trial With Unfractionated Heparin During Revascularization in Acute Coronary Syndromes) study compared the effect of standard-dose heparin (85 units/kg bolus with additional boluses based on an activated clotting time dosing algorithm) with reduced-dose heparin (50 units/kg without activated clotting time adjustment) on the primary outcome, a composite of bleeding or major vascular site access complications, in 2026 patients with NSTE ACS who were treated with fondaparinux and scheduled to undergo PCI within 72 hours.[35] The incidences of the primary outcome and catheter-related thrombosis were similar in the two heparin dose groups, but death, MI, or target vessel revascularization occurred more often in the low-dose heparin group. These data support the use of standard-dose heparin in patients with NSTE ACS who are treated with fondaparinux and scheduled to undergo PCI.

Bivalirudin

Bivalirudin is an IV direct thrombin inhibitor that binds thrombin and prevents it from interacting with its substrates. Bivalirudin has a half-life of only 25 minutes after IV injection, making the lack of an antidote less problematic than it is for longer-acting anticoagulants. It is about 20% renally cleared, and the half-life is prolonged in patients with renal impairment. Bivalirudin does not cause heparin-induced thrombocytopenia.

The efficacy and safety of direct thrombin inhibitors in ACS patients and those undergoing PCI were examined in the Direct Thrombin Inhibitor Trialists' Collaboration meta-analysis that included data from 11 trials and 35,970 patients.[36] The pooled data indicated a significant benefit of direct thrombin inhibitors (including bivalirudin) compared with heparin for the prevention of MI or death. Clopidogrel and GPIIb/IIIa inhibitors were not used in the trials included in this meta-analysis.

The HORIZONS AMI (Harmonizing Outcomes With Revascularization and Stents in Acute Myocardial Infarction) trial evaluated the use of bivalirudin in 3602 STEMI patients undergoing PCI who were treated with the combination of aspirin and clopidogrel.[37] Compared with heparin plus GPIIb/IIIa, bivalirudin plus provisional GPIIb/IIIa inhibitor was associated with similar rates of the primary outcome, MI, target vessel revascularization, stroke, or death (5.4% vs. 5.5%) at 30 days, but bivalirudin significantly reduced major bleeding (4.9% vs. 8.3%; $P < .0001$).

The EUROMAX (European Ambulance Acute Coronary Syndrome Angiography) trial[38] evaluated the use of prehospital bivalirudin in 2218 participants treated with aspirin and a P2Y12 receptor antagonist (more than 50% received ticagrelor or prasugrel) being transported for primary PCI. Compared with heparin (unfractionated or low-molecular-weight) plus optional GPIIb/IIIa inhibitor, bivalirudin reduced the risk of death or non-CABG major bleeding (5.1% vs. 8.5%; $P = .001$), a difference that was primarily driven by a reduction in major bleeding (2.6% vs. 6.0%; $P < .001$). Bivalirudin was associated with an increase in stent thrombosis within 24 hours (1.1% vs. 0.2%; $P = .007$).

The single-center, open-label HEAT-PPCI (unfractionated heparin versus bivalirudin in primary percutaneous coronary intervention) trial[39] evaluated the use of bivalirudin in 1829 participants treated with aspirin and a P2Y12 receptor antagonist (almost 90% received ticagrelor or prasugrel) undergoing emergency angiography. Compared with heparin (13% also received a GPIIb/IIIa inhibitor), bivalirudin (15% also received a GPIIb/IIIa inhibitor) was associated with an increase in the composite of death, stroke, reinfarction, or unplanned target lesion revascularization (8.7% vs. 5.7%; $P = .01$). The rates of major bleeding were similar (3.5% vs. 3.1%; $P = .59$), but there was more stent thrombosis with bivalirudin (3.4% vs. 0.9%; $P = .001$)

The BRIGHT (Bivalirudin vs. Heparin With or Without Tirofiban) trial[40] evaluated the use of bivalirudin continued for 30 minutes to 4 hours after PCI in 2194 participants with acute MI. Compared with heparin alone or heparin plus a GPIIb/IIIa inhibitor, bivalirudin reduced the risk of death, reinfarction, stroke, ischemia-driven target vessel revascularization, or any bleeding (8.8% vs. 13.2%; $P = .008$, and 8.8% vs. 17%; $P < .001$), primarily driven by a reduction in bleeding (4.1% vs. 7.5% vs. 12.3%; $P < .001$) with similar rates of major adverse cardiac or cerebral events (5.0% vs. 5.8% vs. 4.9%; $P = .74$) and stent thrombosis (0.6% vs. 0.9% vs. 0.7%; $P < .77$). Prolonged bivalirudin therapy after PCI might explain the lack of excess stent thrombosis that was seen in most of the earlier bivalirudin trials.

The ACUITY (Acute Catheterization and Urgent Intervention Triage Strategy) trial evaluated the use of bivalirudin in 13,819 patients with NSTE ACS undergoing PCI who were treated with the combination of aspirin plus clopidogrel as well as a GPIIb/IIIa inhibitor.[41] Bivalirudin was non-inferior to heparin or enoxaparin plus a G IIb/IIIa inhibitor for the prevention of MI, unplanned revascularization, or death at 30 days (7.8% vs. 7.3%) but was associated with a lower rate of major bleeding (3.0% vs. 5.7%; $P < .001$).

A meta-analysis of 16 trials involving 33,958 participants[42] showed that compared with heparin-based treatment regimens, bivalirudin was associated with increased major adverse cardiac events and stent thrombosis and a reduction in major bleeding, with no difference in death.

Oral Anticoagulation

Warfarin is an oral vitamin K antagonist that has been evaluated in the long-term management of patients with ACS who are treated with aspirin but has not been rigorously tested on a background of dual antiplatelet therapy. Furthermore, the efficacy and safety of the combination of aspirin plus warfarin have not been compared with those of dual antiplatelet therapy.

The results from a meta-analysis of 14 trials involving 25,307 patients demonstrated that compared with placebo or no warfarin, long-term warfarin (target INR, 2.0 to 3.0) reduced the risk of MI, ischemic stroke or death (9.4% vs. 12.3%; $P < .0001$) at the cost of a twofold increase in major bleeding (2.6% vs. 1.1%; $P < .00001$).[43]

Rivaroxaban and apixaban are oral direct factor Xa inhibitors that have undergone evaluation in phase III trials for the long-term management of patients with ACS. The ATLAS TIMI-51 trial compared rivaroxaban (2.5 or 5 mg twice a day) with placebo in 15,526 ACS patients, the majority of whom were also treated with dual antiplatelet therapy with aspirin plus clopidogrel.[25] Treatment was started a median of 4.7 days after onset of symptoms and was continued for a mean of 13 months. Rivaroxaban significantly reduced the risk of MI, stroke, or cardiovascular death (8.9% vs. 10.7%; $P = .008$) at the cost of an increase in non-CABG major bleeding (2.1% vs. 0.6%; $P < .001$) and intracranial bleeding (0.6% vs. 0.2%; $P = .009$).

The COMPASS trial evaluated the same doses of rivaroxaban shown to be effective in the ATLAS TIMI 51 trial for long term management in 27,395 patients with chronic coronary artery disease (CAD) or peripheral artery disease (PAD). During a mean of 23 months of follow up, the combination of rivaroxaban plus aspirin compared with aspirin alone reduced CV death, stroke or MI (4.1% vs. 5.4%, $P < .001$), and mortality (3.4% vs. 4.1%, $P = .01$) at the cost of an increase in major bleeding (3.1% vs. 1.9%, $P < .001$).

Based on the results of the ATLAS and COMPASS trials, rivaroxaban (2.5 mg twice daily) has been approved in Europe for post ACS patients, and in North America, Europe, and elsewhere for the long term management of patients with chronic CAD or PAD.

The APPRAISE trial compared apixaban (5 mg twice daily; 2.5 mg twice daily in selected patients) with placebo in patients with ACS. The trial was stopped early because of an excess of bleeding with no significant reduction in ischemic events.[26]

The oral direct thrombin inhibitor dabigatran etexilate has been tested in a phase II trial in ACS patients but has not undergone evaluation in a phase III trial (see Table 145.7 and box on Case 3: Coronary Artery Stenting in a Patient Who Requires Anticoagulant Therapy).

CONCLUSIONS AND FUTURE DIRECTIONS

Antiplatelet and anticoagulant drugs are effective for the prevention of MI and death across the spectrum of patients with ACS, including STEMI patients treated with fibrinolytic therapy and those undergoing PCI. Aggressive antithrombotic treatment regimens involving multiple antiplatelet drugs given in combination with an anticoagulant during the acute phase have substantially reduced the risk of early and late recurrent ischemic events and stent thrombosis in ACS patients but at the cost of an increased risk of bleeding. Clinicians require detailed knowledge of the pharmacology and side effects of antithrombotic therapies used in the management of patients with

ACS to optimize clinical outcomes. Comparative effectiveness studies are required to better identify the combinations of antithrombotic drugs that maximize the net clinical benefit for patients with ACS by minimizing the risk of both thrombotic and bleeding events.

TABLE 145.7 Strategies Aimed at Minimizing the Risk of Bleeding in Patients Treated With Combinations of Antiplatelet and Anticoagulant Therapies

Proposed Approach	Rationale
Aspirin maintenance dose ≤100 mg/day	Higher aspirin maintenance doses increase bleeding, and there is no evidence that they improve efficacy
PPI with a preference for agents that interfere less with CYP 2C19 (e.g., pantoprazole)	Much of the excess bleeding is from the GI tract. The use of acid-suppressive agents that interfere less with CYP 2C19 minimizes the potential for a negative interaction with clopidogrel
Preference for a direct oral anticoagulant	All direct oral anticoagulants are associated with lower rates of life-threatening bleeding than warfarin
Manage warfarin in a specialized anticoagulation clinic	Compared with usual care, specialist clinics achieve a greater time in the therapeutic range of the INR
Avoid NSAIDs	NSAIDs are a common cause of upper GI bleeding
Avoid prasugrel and ticagrelor	Prasugrel and ticagrelor are more potent than clopidogrel and cause more bleeding

CYP, Cytochrome P450; *GI*, gastrointestinal; *INR*, international normalized ratio; *NSAID*, nonsteroidal antiinflammatory drug; *PPI*, proton pump inhibitor.

CASE 3: CORONARY STENTING IN PATIENTS WHO REQUIRE ANTICOAGULANT THERAPY

A 55-year-old woman with a recent anterior myocardial infarction who underwent primary PCI with implantation of a drug-eluting stent in the left anterior descending coronary artery is found to have a left ventricular thrombus on transthoracic echocardiogram. She is taking aspirin and ticagrelor. She is switched from ticagrelor to clopidogrel and is started on intravenous heparin, which is overlapped with warfarin until an international normalized ratio of 2 is achieved. At the time of discharge from the hospital, aspirin is stopped and she continues on dual antithrombotic therapy with clopidogrel and warfarin.

Comment

Anticoagulation is indicated for the management of left ventricular thrombosis, and dual antiplatelet therapy is indicated for the management of patients with drug-eluting stents. The combination of an anticoagulant with dual antiplatelet therapy (i.e., triple therapy) is associated with a 2%–3% incidence of major bleeding during the first 30 days and a 4%–12% incidence during the first year.[44] Randomized trials have demonstrated that dual antithrombotic therapy with the combination of dabigatran etexilate (110 or 150 mg twice daily), apixaban (2.5 or 5.0 mg twice daily), rivaroxaban (15 or 20 mg once daily) or edoxaban (60 or 30 mg once daily), and clopidogrel substantially reduce bleeding compared with triple therapy in patients who have an indication for both anticoagulation and antiplatelet therapy after coronary artery stenting.[45–48]

CHAPTER 146

PERIPHERAL ARTERY DISEASE

Stanislav Henkin and Mark A. Creager

Peripheral artery disease (PAD) is an important manifestation of systemic atherosclerosis with significant morbidity and mortality.PAD affects the lower extremities and is defined as a stenosis or occlusion in the aorta or the arteries supplying blood to the legs, including the iliac, femoral, popliteal, or infrapopliteal vessels (peroneal, posterior tibial, and anterior tibial arteries). Stenosis is typically caused by atherosclerosis. Nonatherosclerotic causes of vascular disease also can obstruct the peripheral arteries (see later discussion). There are two major clinical consequences of PAD. First, PAD can cause leg symptoms that include intermittent claudication, which impairs walking ability and diminishes the quality of life, and rest pain, which occurs when there is critical limb ischemia (CLI). Second, as an atherosclerotic disorder, PAD is associated with as much as a four- to six-fold increased risk of cardiovascular death, myocardial infarction (MI), and stroke. This chapter reviews the epidemiology, pathophysiology, and management of PAD.

EPIDEMIOLOGY

Prevalence and Incidence

The prevalence of PAD has been determined from several epidemiologic studies. Early studies determined the prevalence of PAD from the presence of symptoms, such as intermittent claudication, or a history of peripheral revascularization. Many patients with PAD are asymptomatic, and the use of noninvasive diagnostic testing, specifically the measurement of the ankle-brachial index (ABI), has provided further clarification of the overall prevalence of the disease.[1–3] In most of these studies, an ABI of 0.90 or less was used to define PAD. The prevalence of PAD in adults 40 years of age or older is estimated to be 7.2%, accounting for approximately 8.5 million adults in the United States alone.[4] In addition, PAD is estimated to affect as many as 202 million individuals worldwide, with increasing prevalence in both high and low-middle income countries.[4,5] There is a sharp increase in the prevalence of PAD with increasing age, approximating 16.8% of women and 19.8% of men older than age 65 years in the German Epidemiological Trial on ABI (GetABI study).[6] There is a similar trend in the US, as ~20% of adults older than 70 years have PAD, with a higher prevalence among those with a history of diabetes or smoking. Recent studies have also shown higher PAD prevalence in populations of lower socioeconomic status, including lower education and lower income levels, as well as a disproportionate burden among some race/ethnicity groups, particularly blacks, as compared with Hispanic or non-Hispanic white populations.[7,8]

The incidence of PAD, which is largely based on the development of symptomatic disease, is less well established. Data from the Framingham Heart Study show an incidence rate of intermittent claudication of less than 0.4 per 1000 per year in younger men (35 to 45 years) and a rate as high as 6 per 1000 per year in older men (older than 65 years). The incidence of symptomatic PAD is lower in women in most age groups, although the estimates are more comparable in the oldest age group. Estimates of the incidence of PAD based on ABI are less commonly reported. One such study reports an incidence of 1.7 per 1000 person-years for ages 40 to 54 years, 1.5 per 1000 person-years for ages 55 to 64 years, and 17.8 per 1000 person-years for ages 65 years and older. When the diagnosis of PAD is based on ABI alone, the differences in incidence between men and women are less evident. In the Cardiovascular Health Study, for example, there are no gender differences in the incidence of PAD based on ABI after adjusting for cardiovascular risk factors. At the other end of the spectrum, CLI represents approximately 11% of the patients with PAD.[9] The incidence of CLI is estimated to be approximately 2% per year in the US or 400 to 1000 per million individuals per year.[3,9]

Risk Factors

Atherosclerotic risk factors, including smoking, diabetes, hypertension, hyperlipidemia, renal insufficiency, and inflammation, contribute to the development of PAD (see Chapter 142).

In virtually all population-based studies, smoking has been one of the strongest risk factors for PAD. The risk is highest for current smokers compared with nonsmokers, with two to four times increased odds of PAD and the risk of PAD increases in a dose-dependent manner relative to the number of cigarettes smoked and the duration of tobacco use. In the Women's Health Study, smoking more than 15 cigarettes per day increased the risk of incident PAD approximately 17-fold, and the risk was lower in former smokers than in active smokers.[10] In the Edinburgh Artery Study, smoking was two to three times more likely to cause lower extremity PAD compared with coronary artery disease (CAD).[11]

Diabetes is also a potent risk factor for PAD and increases the risk of PAD by two- to four-fold. Data from the Rotterdam study and the San Luis Valley Diabetes study reveal that upwards of 12% to 20% of individuals with PAD have coexisting diabetes.[12,13] Moreover, the risk of PAD increases depending on the duration and severity of diabetes. In the Strong Heart Study, individuals with PAD had a more than two-fold higher prevalence of diabetes compared with those without PAD, and diabetes tended to be of longer duration and associated with higher glycosylated hemoglobin levels.[14] Patients with PAD who have concomitant diabetes are also more likely to develop intermittent claudication and ischemic ulceration and to require major amputation compared with those without diabetes.

Hypertension is a more modest risk factor for the development of PAD compared with its importance as a risk factor for coronary and cerebrovascular disease.[1] Although evidence suggests that hypertension increases the prevalence of PAD by 1.5- to 2.2-fold, the association of hypertension with an incident or symptomatic PAD is less clear. Among Native Americans in the Strong Heart Study, those with PAD had a higher mean systolic blood pressure, and the prevalence of PAD was significantly higher in those with established hypertension.[14] In the Framingham Heart Study, hypertension increased the risk of developing intermittent claudication.[15] In the Women's Health study, the risk of incident PAD increased by 43% with every 10 mm Hg increase in systolic blood pressure.[16] In the Atherosclerosis Risk in Communities (subjects with diabetes) study, individuals with systolic blood pressure greater than 130 mm Hg were significantly more likely to develop PAD.[17] In the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial, both low (<120 mm Hg) and high (>160 mm Hg) systolic blood pressures were associated with PAD events (PAD-related hospitalization, PAD-related procedure, outpatient PAD medical therapy, or PAD-related death).[18]

Dyslipidemia, specifically elevated total cholesterol, low-density lipoprotein (LDL) cholesterol and triglycerides, and reduced high-density lipoprotein (HDL) cholesterol, is associated with PAD. Epidemiologic studies, such as the Cardiovascular Health Study and the Framingham Heart Study, have shown that a 10-mg/dL increase in total cholesterol increases the risk of PAD by 5% to 10%. In the Strong Heart study, individuals with PAD had significantly higher levels of total cholesterol, triglycerides, and LDL cholesterol than those without. The Whitehall study also demonstrated that an elevated total cholesterol level was associated with symptoms of intermittent claudication.[19]

Chronic renal insufficiency has been recognized to be significantly associated with PAD in several studies. In the NHANES, renal insufficiency (defined as a glomerular filtration rate <60 mL/min) was associated with a 2.5-fold higher odds of PAD even after adjustment for other cardiovascular risk factors.[20] In the Heart and Estrogen/Progesterone Replacement (HERS) study, renal insufficiency was also associated with an increased risk of incident peripheral vascular events, including revascularization and amputation.[21] In The Chronic Renal Insufficiency Cohort study (CRIC), women less than 70 years old were 50% more likely than men to develop PAD.[22] Moreover, renal insufficiency or albuminuria increases the mortality risk in patients with PAD irrespective of other risk factors, including diabetes.

Several nontraditional factors have been associated with PAD. Markers of systemic inflammation, such as C-reactive protein (CRP), are elevated in patients with PAD. In the Physicians' Health Study, the risk of developing symptomatic PAD was approximately two-fold higher in those in the highest CRP quartile compared with those in the lowest quartile.[23] Although several markers of inflammation, such as soluble intercellular adhesion molecule 1, chemokine ligand 2, galactin-3, and others have been studied in patients with PAD, none are routinely measured in clinical practice. Insulin resistance is associated with both prevalent PAD as shown in data from the NHANES study and with incident PAD as demonstrated in the Cardiovascular Health Study.

PATHOBIOLOGY

Atherosclerosis is a progressive vascular disease characterized by lipid accumulation and the formation of plaque in the arterial walls (see Chapter 145). The pathophysiology of atherosclerosis includes endothelial dysfunction, vascular inflammation, and cellular proliferation. Early in the atherogenic process, recruitment of inflammatory cells and accumulation of lipids promote the development of a lipid-rich atheroma. Inflammation promotes the elaboration of proteases that weaken the vessel wall and allow positive remodeling with the outward expansion of the arterial wall to accommodate the intimal expansion that occurs as a result of plaque formation. Although positive remodeling initially preserves the arterial lumen, continued plaque growth results in progressive narrowing of the lumen, which then limits blood flow and oxygen supply to target organs. This process may be enhanced by biomechanical factors, such as turbulent blood flow, particularly in areas of altered shear stress. This phenomenon is of particular significance at branch points along the arterial tree, which is predisposed to atherosclerotic plaque formation.

Pathologic studies primarily involving coronary arteries have shown that atherosclerotic plaque formation is a dynamic biologic process that exhibits marked heterogeneity; some plaques remain "stable," while others have a more "unstable" pathophysiology. Stable atherosclerotic plaques may be asymptomatic, or symptoms can occur with exertion if demand exceeds supply. On the other hand, "vulnerable" or unstable plaques are prone to acute rupture, and superimposed thrombi may cause sudden arterial insufficiency, and cause events such as MI, or theoretically acute limb ischemia (see Chapters 142 and 145). Whereas atherosclerotic plaque contributes importantly to PAD, recent pathologic studies have demonstrated an important role of thrombosis detected in amputated limbs of patients with CLI.[24] Specifically, in almost 75% of patients with CLI, thrombosis contributed to luminal stenosis. Significant atherosclerosis, often with associated thrombus, was found in most lesions in the femoral-popliteal arteries, whereas thrombus without significant atherosclerosis was found in the majority of infrapopliteal arteries, indicative of embolism from a more proximal site, or thrombosis in situ. It is notable that a recent genome-wide association study showed an association between PAD and Factor V Leiden (FVL; F5 p.R506Q), further highlighting the potential pathophysiologic role of thrombosis in PAD.[25]

Although PAD is mostly caused by atherosclerosis, other causes include thromboembolism, vasculitides (e.g., thromboangiitis obliterans, giant cell arteritis, Takayasu arteritis), trauma, popliteal artery entrapment, cystic adventitial disease, fibromuscular dysplasia, and endofibrosis of the iliac artery (Table 146.1). Nonvascular causes of leg pain should also be considered in the differential diagnosis, including lumbosacral spine disease (causing pseudoclaudication), venous diseases, hip, knee, or ankle osteoarthritis, chronic compartment syndrome, myositis, and others (Table 146.2).

TABLE 146.1 Nonatherosclerotic Causes of Peripheral Artery Disease

- Lumbar radiculopathy
- Spinal stenosis
- Hip or knee osteoarthritis
- Myositis
- Venous claudication

CLINICAL MANIFESTATIONS

Most patients with PAD are asymptomatic at presentation. Typical claudication symptoms are present in only 10% to 35% of patients and CLI in approximately 11%.[1] The classic symptoms of PAD include intermittent claudication and rest pain, the latter occurring in patients with CLI. Intermittent claudication is defined as exertional discomfort in the muscles of the lower extremities that is variably described as pain, aching, burning, fatigue, or heaviness. Symptoms arise with leg exercise, typically walking, and are relieved after a predictable duration of rest (usually <10 minutes). Intermittent claudication occurs with effort and not at rest, and symptoms do not abate until activity ceases; a change in position is unnecessary. Although many patients with PAD report atypical symptoms, most have impaired walking ability exemplified by reduced walking speed or distance. CLI arises when there is inadequate perfusion to meet the resting metabolic demands of the tissues. Patients with CLI have pain at rest, typically affecting the toes, feet, or both; they may have accompanying tissue loss with nonhealing ulcers, tissue necrosis, or gangrene (Fig. 146.1).

DIAGNOSIS

The diagnosis of PAD is often evident from the history and physical examination. An important diagnostic feature is diminished or absent pulses in the legs. The examiner should palpate the femoral,

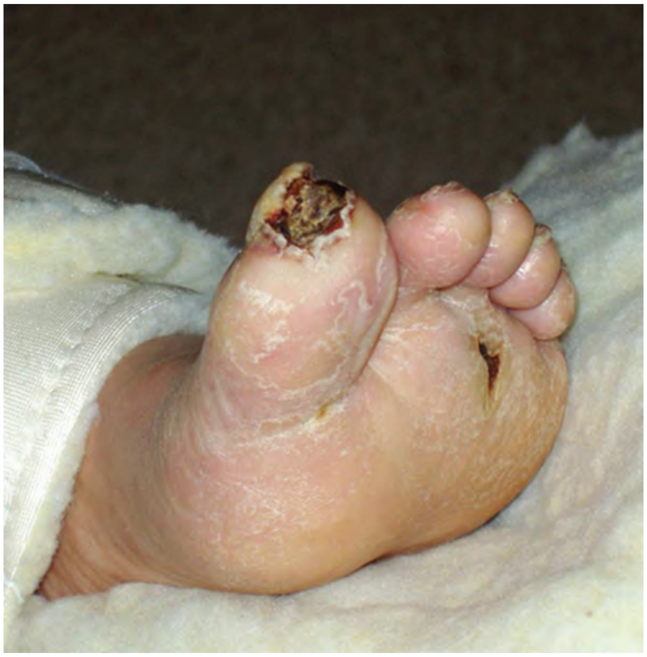

Figure 146.1 Ulceration and gangrene of the foot representative of critical limb ischemia in a patient with peripheral artery disease.

popliteal, dorsalis pedis, and posterior tibial pulses. The absence of selected pulses provides insight into the location of critical stenoses. The groin should be auscultated for femoral artery bruits, which may be indicative of turbulent flow from atherosclerotic plaque. Other findings suggestive of PAD include pallor of the soles of the feet upon leg elevation and the development of rubor when the feet are then placed in the dependent position. Signs of chronic limb ischemia include muscle atrophy; hair loss; thickened nails; and in severe stages, cyanosis, pallor, and coolness of the skin of the feet.

Ankle–Brachial Index

The ABI is a simple, non-invasive test for the diagnosis of PAD.[26] Normally, when measured in the supine position, the systolic blood pressure in the legs is the same as that in the arms. However, pulse wave amplification may yield a higher systolic pressure at the ankle. Therefore, the ratio of the ankle to the brachial systolic pressure, designated as the ABI, should be 1.0 or slightly higher. A diminution of the ankle systolic blood pressure relative to the brachial artery pressure indicates a stenosis or occlusion in the aorta or arteries of the lower extremities.

The ABI is determined by measuring the systolic blood pressure in both arms (brachial arteries) and both ankle arteries (dorsalis pedis and posterior tibial arteries) after the patient has been in the supine position for at least 5 to 10 minutes.[1] To measure these pressures, sphygmomanometric cuffs are sequentially inflated at each location to suprasystolic pressures. The onset of systole with subsequent cuff deflation is determined with a Doppler device that is placed over the artery. The ABI for each leg is calculated by dividing the higher of the two ankle pressures by the higher of the two arm pressures. Considering the intrinsic variability in blood pressure over time, an ABI of 0.90 or less is indicative of PAD. At this threshold, the ABI has excellent sensitivity (90%) and specificity (>95%) compared with angiography. An ABI of 0.91 to 1.0 is considered borderline.[1,2] Vascular calcification, as often occurs in patients with diabetes or renal insufficiency, may preclude accurate determination of systolic blood pressure at the ankle. For this reason, an ABI that is markedly elevated (e.g., >1.4) is considered inaccurate and indicative of vascular calcification. In this circumstance, other simple noninvasive diagnostic tests, such as assessment of the toe–brachial index, pulse volume recording (PVR), or continuous wave Doppler may be useful to detect PAD. In some cases of PAD, the ABI is normal at rest. This is particularly common in patients who have a proximal disease, such as iliac artery stenosis, and an extensive collateral circulation. In such cases, measurement of the ABI after walking will detect a decrease in the ankle systolic pressure relative to brachial artery systolic pressure, thereby revealing the presence of PAD.

Noninvasive Testing and Imaging for Diagnosis of Peripheral Artery Disease

Several other noninvasive tests may help in the diagnosis of PAD and the identification of sites of stenosis. These tests include segmental pressures with PVR or continuous wave Doppler, duplex ultrasonography, computed tomography angiography (CTA), magnetic resonance angiography (MRA), and conventional contrast angiography. When measuring segmental leg pressures, systolic blood pressure measurements are obtained at multiple levels in the leg, typically in the upper thigh, lower thigh, upper calf, ankle, and across the metatarsal region of the foot. Systolic blood pressures in these sites are then compared with the higher of the arm systolic blood pressures. A significant drop in blood pressure (>20 mm Hg) from one level to the next can localize arterial stenosis with a high degree of precision. An upper thigh pressure that is lower than the arm pressure indicates stenosis in the distal aorta or the iliac or femoral arteries (or both). PVRs, using a plethysmographic instrument that records the change in volume with each arterial pulsation, or continuous wave Doppler with a hand-held Doppler instrument can be obtained at each level. A normal PVR waveform resembles an arterial waveform with a brisk upstroke and a prominent dicrotic notch in the downstroke (Fig. 146.2). Abnormal waveforms, which appear distal to a hemodynamically significant stenosis, have a parvus et tardus appearance with a blunted upstroke and decreased pulse amplitude. The normal Doppler waveform is made up of three components, including rapid antegrade flow during systole, transient reversal of flow during early diastole, and slow antegrade flow during late diastole.

Duplex ultrasonography is used both for the diagnosis of PAD and for the surveillance of bypass grafts or stents after revascularization procedures. Color Doppler can identify abnormal flow with turbulence and Doppler aliasing suggesting an area of stenosis (Fig. 146.3). Pulse-Doppler sampling can then confirm flow acceleration in a diseased segment. A peak systolic velocity (PSV) in a diseased segment that is more than twice the PSV in the proximal segment indicates a hemodynamically significant stenosis of at least 50%. Duplex ultrasonography has been shown to be up to 95% accurate and reproducible with sensitivity and specificity of 88% to 92% and 79% to 97%, respectively, compared with angiography.[27,28] However, duplex ultrasonography is a time-consuming and operator-dependent procedure.

The most used imaging modalities for diagnosis of PAD are MRA and CTA. The two tests have comparable diagnostic accuracy for identification of arterial stenosis. MRA has been shown to have a sensitivity of 95% and specificity of 97% to detect stenosis greater than 50%, and CTA was shown to have a sensitivity of 91% and specificity of 91%.[29]

MRA takes advantage of the inherent magnetic properties of human tissue. Pulsed magnetic sequences cause protons within cells to spin and align, generating a frequency of energy that can be detected by the scanner. Various tissues have different frequencies that allow delineation of the structures and tissues within the body. The addition of the paramagnetic contrast agent gadolinium allows selective imaging of moving blood (Fig. 146.4). This flow-related enhancement of the vasculature produces angiographic images. Although MRA has the advantage of using nonionizing radiation, it has several limitations. For example, MRA cannot be performed in patients with some implanted cardiac devices or other metal objects. Although MRA can be used in patients with vascular stents, ferromagnetic metals in the stents may produce artifacts that limit the assessment of the stented vessel. Claustrophobia may also preclude MRA.

Figure 146.2 SEGMENTAL LEG PRESSURE MEASUREMENTS AND PULSE VOLUME RECORDINGS. The ankle–brachial index (ABI) is normal in the right leg. The greater than 20-mm Hg drop in systolic blood pressure between the lower thigh and the calf in the left leg suggests stenosis involving the distal left superficial femoral artery, popliteal artery, or both. There is also evidence of blunting of the pulse volume recording with a parvus et tardus waveform. The significant difference in brachial artery systolic blood pressure is suggestive of left subclavian artery stenosis. *Amp*, Amplitude; *DP*, dorsalis pedis; *PT*, posterior tibial; *PVR*, pulse volume recordings; *Spd*, speed.

Like MRA, CTA also has excellent specificity and sensitivity for detection of arterial stenosis. The advent of large-volume imaging with multidetector scanners enables rapid image acquisition and high resolution. Advantages of CTA include the capacity to rapidly visualize the entire arterial tree and to delineate vascular calcification and intraluminal thrombus. Limitations of the test include the exposure to ionizing radiation and the need for iodinated contrast agents, which is problematic in patients with renal impairment. In addition, extensive arterial calcification may prevent accurate determination of the degree of stenosis.

MRA and CTA have largely supplanted conventional catheter-based angiography for PAD diagnosis. Nonetheless, invasive contrast angiography remains the gold standard for the diagnosis of PAD. Catheter-based angiography is most useful in situations in which concurrent endovascular interventions are planned or in preparation for surgical revascularization. Limitations to catheter-based angiography include the invasive nature of the procedure, the need to administer iodinated contrast, and the radiation exposure. Potential complications include arteriovenous fistula or pseudoaneurysm formation at the access site, atheroembolism, dissection, and contrast-induced renal insufficiency. Alternatives to iodine-based contrast agents, such as carbon dioxide and gadolinium, can be used when administration of iodinated contrast is contraindicated.

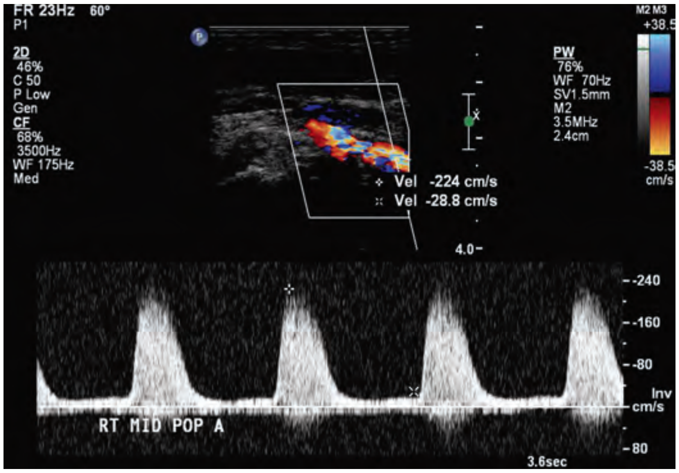

Figure 146.3 DUPLEX ARTERIAL ULTRASOUND DEMONSTRATING DOPPLER INTERROGATION OF THE POPLITEAL ARTERY. Turbulence of color Doppler flow indicates possible stenosis, confirmed by elevated peak systolic velocity, monophasic waveform, and spectral broadening.

PROGNOSIS

Prognostic considerations are broadly divided into limb outcomes and overall cardiovascular outcomes. Limb prognosis is dependent on the severity of symptoms at initial presentation; concurrent risk factors, such as cigarette smoking and diabetes; and the likelihood of successful revascularization in those with threatened limb viability. Among patients with claudication symptoms, leg discomfort remains stable in the majority (≈70% to 80%), worsens in about 10% to 20%, and progresses to CLI in less than 1%.[1,9] Data from the Reduction of Atherothrombosis for Continued Health (REACH) registry, which enrolled patients with established PAD on the basis of clinical symptoms, revealed that patients with abnormal ABI and prior revascularization had a 23.6% rate of new adverse limb events over 4 years including new revascularization procedures and ischemic amputations.[30] These data are consistent with findings from the TRA2 P-TIMI 50 trial, which evaluated the impact of vorapaxar (see Chapter 142) in patients with PAD, where the rate of peripheral artery revascularization in the placebo-treated group was 22.2% over a median period of 3 years.[31] Prognosis is the worst for those with CLI, where mean amputation-free survival at 1 year is only 50%. Outcomes are worse for patients with PAD who continue to smoke or have coexisting comorbidities (diabetes, renal insufficiency, CAD); such patients have even higher rates of ischemic ulceration and amputation.

Given the high risk of concomitant coronary and cerebral artery disease, individuals with PAD are also at increased risk of MI, stroke, and cardiovascular death (see Chapters 144 and 145). The mortality rate is increased two- to four-fold in patients with PAD (ABI <0.9) compared with those without PAD, as confirmed in a meta-analysis of 16 cohort studies from the ABI collaboration.[32] Furthermore, a graded association has been noted with lower ABI associated with increased mortality.[32] Also, individuals with high ABI (≥1.4) but without baseline cardiovascular disease are three times as likely to die from cardiovascular disease compared with those with normal ABI.[33] In patients with PAD, the risk of MI is increased by 20% to 60%, and the risk of stroke is increased by 40%. In the TRA 2°P-TIMI 50 trial, the 3-year event rate for the composite of cardiovascular death, MI, or stroke was 7.6% in individuals with PAD alone, and 12.8% in individuals with concomitant PAD and CAD.[34] In the COMPASS trial, the adverse cardiovascular event rate in the PAD group for the same composite outcome was 7% over a median of 21 months.[35]

THERAPY

The major goals in the management of patients with PAD are to (1) reduce the risk of cardiovascular morbidity and mortality and (2) improve lower extremity symptoms and preserve limb viability. Aggressive cardiovascular risk factor modification is indicated for all patients with PAD. This includes treatment of dyslipidemia, hypertension, and diabetes (including regular foot care) and the use of antiplatelet therapy. Encouragement of healthy lifestyle habits remains a cornerstone of the management of individuals with PAD; these include smoking cessation, a diet enriched in fruits and vegetables and limited in saturated fats, and regular physical activity.[1]

Dyslipidemia

Treatment of dyslipidemia with statins decreases major cardiovascular events in patients with all manifestations of atherosclerosis (see Chapter 142). The 4S study (Scandinavian Simvastatin Survival Study) was one of the first to demonstrate a clear benefit of lipid-lowering therapy for secondary prevention in patients with atherosclerosis and dyslipidemia.[36] Subsequently, the Heart Protection Study demonstrated that statin therapy was associated with a 22% relative risk (RR) reduction in adverse cardiovascular events in patients with vascular disease, including PAD.[37] Recent practice guidelines recommend the use of high-intensity statin therapy, such as atorvastatin 80 mg daily or rosuvastatin 20 mg daily, for individuals with established atherosclerotic vascular disease, including those with PAD to lower cholesterol (LDL <70 mg/dL) and to reduce the risk of atherosclerotic events in this population. Statin use is not only associated with lower cardiovascular event rates, but also with approximately 18% lower rates of adverse limb outcomes, including worsening symptoms, peripheral revascularization, and amputations. Individuals with recurrent atherosclerotic events or LDL ≥70 mg/dL may benefit from ezetimibe or a PCSK9 inhibitor in addition to a maximally tolerated statin.[38] In the Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER) trial, the PCSK9 inhibitor evolocumab reduced the composite outcome of cardiovascular death, MI, stroke, unstable angina, or coronary revascularization by 21% in individuals with PAD. Importantly, individuals with PAD had a larger absolute risk reduction in key outcomes compared to those without PAD.[39]

The appropriate management of non-LDL cholesterol (HDL and triglycerides) is less clear. Although reduced HDL levels are a risk factor for atherosclerosis, studies with medications that increase HDL levels and lower triglyceride levels have yielded conflicting results (see Chapter 142). The VA-HIT study (Veterans Affairs High-Density Lipoprotein Intervention Trial) showed that gemfibrozil reduced the risk of fatal coronary disease or nonfatal MI by 22% over a median of 5.1 years in patients with known CAD.[40] However, in a study of patients with PAD, bezafibrate did not affect the rate of coronary events or stroke.[41] In addition, in the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study, fenofibrate did not reduce coronary events in diabetics, although its use was associated with fewer nonfatal MIs and revascularization procedures.[42] Although niacin also reduces lipid levels, its efficacy for reducing cardiovascular events has been called into question based on recent studies showing no added benefit in patients with established atherosclerotic vascular disease.[43] Subgroup analyses showed no meaningful differences in the subset of patients with established PAD.

Hypertension

Treatment of hypertension is a critical component of the management of patients with atherosclerotic PAD. Such treatment reduces the risk of stroke, MI, and congestive heart failure. Management of hypertension should follow current guidelines.[44] Although there is concern that lower systemic blood pressure may exacerbate symptoms of claudication or CLI, the majority of patients experience no change in their symptoms. Several studies have found that antihypertensive drugs reduce cardiovascular events in patients with PAD. The HOPE (Heart Outcomes Prevention) study demonstrated a 22% reduction in cardiovascular events with ramipril in patients with atherosclerotic disease, including those with PAD.[45] ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial) demonstrated that telmisartan and ramipril produced similar reductions in cardiovascular death, MI, stroke, or hospitalization for heart failure (16.7% and 16.5%, respectively; RR, 1.01; 95% confidence interval, 0.94 to 1.09), albeit at the cost of greater risk of hypotension, syncope, and renal insufficiency when the combination of telmisartan and ramipril was used.[46] In a substudy of the Appropriate Blood Pressure Control in Diabetes (ABCD) trial, intensive blood pressure lowering in patients with PAD was associated with a 65% relative reduction in the risk of MI, stroke, or cardiovascular death compared with modest blood pressure-lowering therapy.[47] The INVEST study (International Verapamil-SR/Trandolapril Study) demonstrated that a calcium channel blocker-based antihypertensive strategy was comparable to a beta-blocker-based strategy in patients with concomitant PAD.[48] The ALLHAT trial (Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial) noted a J-shaped relationship between systolic blood pressure and peripheral vascular events, with best outcomes in individuals with systolic blood pressure between 120 and 129 mm Hg.[18]

Diabetes

In patients with PAD with concomitant diabetes, the goals of diabetes care include control of hyperglycemia and attention to diabetic foot care. Not only is diabetes associated with adverse limb outcomes (increased risk of ischemic ulceration and amputation in patients with PAD), but it also is associated with increased mortality. Aggressive glycemic control reduces both macrovascular events (MI, stroke, and death) and microvascular events (nephropathy, neuropathy, and retinopathy) in patients with type I diabetes. Although aggressive glycemic control reduces microvascular events in individuals with type II diabetes, reductions in macrovascular events have not been shown. Several studies, such as the ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicron Modified Release Controlled Evaluation),[49] Action to Control Cardiovascular Risk in Diabetes[50] and Veterans Affairs Diabetes trials,[51] have failed to show a reduction in cardiovascular events with aggressive treatments aimed at lowering the hemoglobin A1c to 6%. Likewise in patients with type II diabetes who were at risk for cardiovascular events, the PROactive study (Prospective Pioglitazone Clinical Trial in Macrovascular Events) failed to show a reduction in the primary composite endpoint of cardiovascular or limb outcomes (lower rates of extremity revascularization or amputation) with pioglitazone. However, the study did show a significant 16% reduction in the secondary endpoint, a composite of total mortality, nonfatal MI, or stroke, with pioglitazone.[52] Several recent studies have evaluated the cardiovascular effects of newer classes of glucose-lowering agents including the glucagon-like peptide-1 (GLP-1) analogues, such as semaglutide and liraglutide; dipeptidyl peptidase-4 inhibitors (DPP-4), such as saxagliptin; and sodium-glucose co-transporter-2 (SGLT-2) agents, such as empagliflozin, canagliflozin, and dapagliflozin. These studies, as well as meta-analyses, have suggested that SGLT-2 inhibitors and GLP-1 agonists have beneficial effects in lowering cardiovascular mortality and major adverse cardiac events, while DPP-4 inhibitors do not have a significant effect on these outcomes.[53–57] Although the optimal glycemic control required to reduce macrovascular complications in patients with type II diabetes remains unclear, guidelines recommend treatments that maintain the level of hemoglobin A1c below 7%.

Foot care is a critical component of diabetes management, particularly in those with PAD. Diabetes increases the risk of foot injury because of the associated peripheral neuropathy and decreased sensation, thereby increasing the risk of ulcer formation. Resting limb ischemia and amputation are more frequent in patients with PAD with diabetes than in those without diabetes. Therefore careful attention to foot care is imperative to prevent skin breakdown, infections, ulceration, and amputation.

Antiplatelet Therapy

Antiplatelet therapy is recommended for patients with atherosclerosis, including patients with symptomatic PAD.[1] The Antiplatelet Trialists' Collaboration meta-analysis showed that antiplatelet therapy produces a 22% to 32% reduction in the RR of stroke, MI, or vascular death in patients with high-risk vascular disease, including prior stroke or transient ischemic attack or MI.[58] In a subset of patients with evidence of PAD based on symptoms of claudication or prior lower extremity bypass or angioplasty, antiplatelet therapy also produced a 22% RR reduction. The meta-analysis included studies that evaluated a variety of antiplatelet agents, such as aspirin, dipyridamole, picotamide, and ticlopidine. However, the benefits of aspirin have been called into question with a recent meta-analysis showing no significant effect of aspirin on cardiovascular events and a higher risk of major bleeding in patients with PAD, especially in asymptomatic patients.[59] The POPADAD (Prevention Of Progression of Arterial Disease and Diabetes) study,[60] which randomized patients with ABI below 0.99 and no known cardiovascular disease to 100 mg of aspirin or placebo, showed no significant difference between the groups. The Aspirin for Asymptomatic Atherosclerosis (AAA) trial explored whether aspirin (100 mg/day) was of benefit in asymptomatic individuals with PAD diagnosed solely on the basis of an abnormal ABI.[61] Compared with placebo, aspirin had no effect on the composite endpoint of fatal or nonfatal MI, stroke, or revascularization.

When clopidogrel was compared with aspirin in the CAPRIE trial, clopidogrel was associated with an 8% RR reduction in cardiovascular events for the entire study population of patients with recent MI, ischemic stroke, and PAD, and an even higher 24% RR reduction in

PAD subgroup.[62] The CHARISMA study showed no benefit of dual antiplatelet therapy with aspirin plus clopidogrel in a population of patients with established CAD, cerebrovascular disease, or PAD or those with risk factors for these disorders.[63] In a post-hoc analysis that focused on patients with symptomatic or asymptomatic PAD, there also was no benefit of dual antiplatelet therapy for the primary endpoint. However, the risk of MI and repeat hospitalization for ischemic events was lower with dual antiplatelet therapy (HR, 0.63; 95% CI, 0.42 to 0.96 and HR, 0.81; 95% CI, 0.68 to 0.95, respectively).[64]

Newer antiplatelet agents have also been evaluated in patients with PAD. The TRA2P-TIMI 50 study found that the addition of vorapaxar, a protease-activated receptor-1 antagonist, significantly reduced the composite endpoint of cardiovascular death, MI, or stroke by 13% in patients with established atherosclerosis manifesting as a prior MI, ischemic stroke, or established PAD.[65] Among the subset of patients with PAD, vorapaxar did not significantly affect the composite endpoint but did reduce the risk of hospitalization for acute limb ischemia by 42% ($P = .006$) and peripheral artery revascularization by 16% ($P = .017$), albeit with an increased risk of bleeding (HR 1.62, $P = .001$).[31] More recently, the EUCLID study compared ticagrelor (90 mg twice daily) with clopidogrel in patients with symptomatic PAD. There was no statistically significant difference between the two therapies in reducing a composite endpoint including cardiovascular death, MI, or ischemic stroke (HR 1.02, $P = .65$), and no difference in rates of acute limb ischemia (HR 1.03, $P = .85$). Additionally, there was no difference bleeding risk between clopidogrel and ticagrelor.[66] The PEGASUS-TIMI 54 study also demonstrated the benefit of ticagrelor in reducing major cardiovascular events among patient with PAD.[67]

Anticoagulant Therapy

A combination of anticoagulant therapy with warfarin and aspirin was initially evaluated in the Warfarin Antiplatelet Vascular Evaluation (WAVE) trial, which randomized patients to antiplatelet agent alone versus a combination of warfarin (target international normalized ratio 2.0 to 3.0) and antiplatelet therapy in patients with PAD. There was no difference in major adverse cardiac events between groups, with a significantly higher risk of life-threatening bleeding in the warfarin arm. Thus, full-dose anticoagulation is not recommended for treatment of PAD.[68] More recently, the combination of low-dose rivaroxaban (2.5 mg twice daily) in addition to aspirin in patients with the stable atherosclerotic vascular disease was examined in the COMPASS trial. Individuals receiving rivaroxaban and aspirin, compared with aspirin alone, had a 24% RR reduction in cardiovascular death, stroke, or MI, albeit at a significantly higher risk of major bleeding (HR 1.7, 95% CI 1.4 to 2.05).[69] A similar trend was seen in the PAD subgroup, including a significant reduction in major adverse limb events, including limb revascularization or amputation.[70] The VOYAGER PAD (Vascular Outcomes Study of ASA Along with Rivaroxaban in Endovascular or Surgical Limb Revascularization for PAD) trial, low-dose rivaroxaban in addition to aspirin also reduced major adverse cardiac and limb events after lower extremity revascularization, but with a higher risk of bleeding.[71] Based on these data, low-dose rivaroxaban may be considered in patients at a high risk of vascular events and low risk of bleeding. A small trial compared edoxaban with clopidogrel after endovascular therapy for PAD; there was no difference in rates of restenosis or reocclusion between the two groups.[72] There are no published trials that have evaluated either dabigatran or apixaban in patients with PAD. Thus, the results of COMPASS and VOYAGER PAD with rivaroxaban cannot be extrapolated to other direct oral anticoagulants.

Treatment of Lower Extremity Symptoms

Treatments that target the symptoms and signs of PAD are implemented to improve function and mobility and preserve limb viability. Established treatments can be broadly categorized into supervised exercise therapy, pharmacotherapy, and revascularization. Therapeutic angiogenesis has also been explored as a potential therapeutic option.

Exercise Therapy

Supervised exercise therapy improves walking distance by as much as 100% to 150% in patients with PAD. Patients are recommended to walk on a treadmill or track three to five times per week for a duration of at least 45 minutes per session for 3 to 6 months. Exercise should continue until patients develop moderate to severe claudication; after a rest period, they should resume walking with the cycle repeated until the session is over. As patients improve, walking speed and treadmill grade can be increased. Studies have shown that home-based exercise therapy is also effective when home activities are monitored and quantified[73] or when paired with periodic and facilitated group behavioral training.[74] The CLEVER (Claudication: Exercise Versus Endoluminal Revascularization) trial showed that a 6-month supervised exercise training program in patients with aortoiliac disease and claudication produced a greater improvement in walking time than optimal medical therapy alone or stenting.[75] In contrast, in the IRONIC (Invasive Revascularization or Not in Intermittent Claudication) study, improvement in disease-specific quality-of-life measures was greater for stenting than supervised exercise therapy in patients with life-limiting claudication at 1 year after intervention,[76] but not at 5 years after intervention.[77] While prior studies had evaluated the benefits of supervised exercise therapy in comparison to revascularization, the ERASE study assessed the impact of exercise therapy in addition to endovascular revascularization. The study showed that combination treatment resulted in greater walking distance and quality of life at 1 year than supervised exercise therapy alone.[78] That the combination of supervised exercise and endovascular intervention improves quality of life has been confirmed in a meta-analysis, while no difference in either the quality of life or future revascularization or amputation was seen between supervised exercise alone versus endovascular intervention.[79] It remains clear that physical activity should be recommended as a part of a multifaceted approach to improving symptoms in patients with PAD.

The mechanisms responsible for the benefits of exercise remain unclear. Potential mechanisms include collateral blood vessel development because of upregulation of angiogenic growth factors, endothelium-dependent vasodilation because of enhanced nitric oxide bioavailability, more efficient walking biomechanics, and improved skeletal muscle metabolism.

Pharmacologic Therapies

Although many medications have been evaluated, few have improved the symptoms of claudication in patients with PAD. Only two medications are approved by the Food and Drugs Administration: cilostazol and pentoxifylline. Cilostazol is a phosphodiesterase 3 (PDE3) inhibitor with both vasodilator and antiplatelet properties. The precise mechanism by which cilostazol confers a benefit in patients with PAD is unknown. Several randomized trials have shown that compared with placebo, cilostazol produces an approximately 50% increase in walking time and improves the perceived quality of life.[80] Because other PDE3 inhibitors (e.g., milrinone) have been linked to increased mortality in patients with congestive heart failure, cilostazol should not be used in this subpopulation of patients with PAD. However, cilostazol has not been associated with an increase in mortality. Evidence for the efficacy of pentoxifylline, a hemorheological agent, is less robust than that for cilostazol, and pentoxifylline is less likely to be of clinical benefit.

Statins have also been explored for the treatment of claudication to exploit their pleiotropic effects, such as attenuation of inflammation. One study showed an improvement in pain-free walking time with atorvastatin but no significant increase in maximal walking time.[81] Other studies revealed an increase in walking time with simvastatin.[82,83] Another study, however, showed no benefit of niacin plus lovastatin on walking times compared with placebo.[84]

Revascularization

Lower extremity revascularization is reserved for patients with CLI or lifestyle-limiting claudication symptoms despite maximal medical therapy. For those with CLI, prompt revascularization is necessary. Revascularization in such patients may alleviate resting limb pain, accelerate the healing of ulcers, and reduce infection. In patients with claudication, revascularization, in addition to supervised exercise and medical therapy, can lessen leg discomfort and improve the quality of life. Options for revascularization include endovascular (percutaneous) intervention or open surgical revascularization.

Endovascular intervention, which includes percutaneous transluminal balloon angioplasty (PTA) and endovascular stenting, is increasingly being used as a less invasive option for revascularization in patients with PAD (Fig. 146.5). The advances in the technology of balloon-expandable and self-expanding stents have widened the population of patients with suitable anatomic lesions that stand to benefit from these procedures. Eligible patients include those with severe or disabling symptoms of claudication and those with limb-threatening ischemia. Clinical outcomes for endovascular revascularization depend on the type and length of the lesions. Treatment of stenoses is more likely to be successful than treatment of total occlusions, and success is influenced by a variety of morphologic characteristics, as delineated in the TransAtlantic Inter-Society Consensus (TASC) Working Group classification for iliac and femoropopliteal lesions.[3] Durability and patency are greatest for iliac artery lesions; the likelihood of long-term patency with endovascular interventions is lower with the disease in more distal arteries. Patency rates decrease with increasing lesion length, the presence of diffuse disease or multiple lesions, and poor run-off, as well as other adverse patient characteristics, such as diabetes, active smoking, and renal failure.[1]

For aortoiliac interventions, endovascular treatment affords excellent long-term patency, especially when combined with stenting. Five-year patency rates are approximately 94% and are comparable to rates achieved with surgical intervention. Results are less durable for femoropopliteal PTA with studies showing a variable benefit of standard nitinol stents in the femoropopliteal arteries depending on lesion length and other factors.[85] Compared with bare-metal stents, drug-eluting stents (DES) have shown promise for femoral artery revascularization with improved survival free of major vascular events (death, amputation, or revascularization) with paclitaxel-eluting DES.[86] There are also studies showing benefits of the drug-eluting balloon over standard (uncoated) balloon angioplasty for femoropopliteal artery revascularization resulting in reduced rates of restenosis and target vessel revascularization with comparable safety.[87] However, recent meta-analyses has called into question the safety of paclitaxel-coated balloons and stents, suggesting a higher risk of all-cause mortality, though other analyses have not identified this risk.[88–91] Thus, the operator must weigh the decision between improved vascular outcomes but possible higher all-cause mortality with DES; in this case, a detailed risk/benefit discussion with the patient is of utmost importance.

Endovascular treatment of infrapopliteal artery stenosis is typically reserved for patients with limb ischemia. In the PARADISE (Preventing Amputations Using Drug Eluting Stents) study, a prospective, nonrandomized study of 106 patients, the 3-year amputation-free survival rate after DES implantation for treatment of limb ischemia involving the infrapopliteal vessels was 68%.[92] In the IN.PACT DEEP study, infrapopliteal artery revascularization with a drug-eluting balloon was non-inferior to standard balloon angioplasty with respect to the primary endpoints of target lesion revascularization and late lumen loss at 5 years; importantly the safety of paclitaxel-coated balloon angioplasty was similar to PTA.[93]

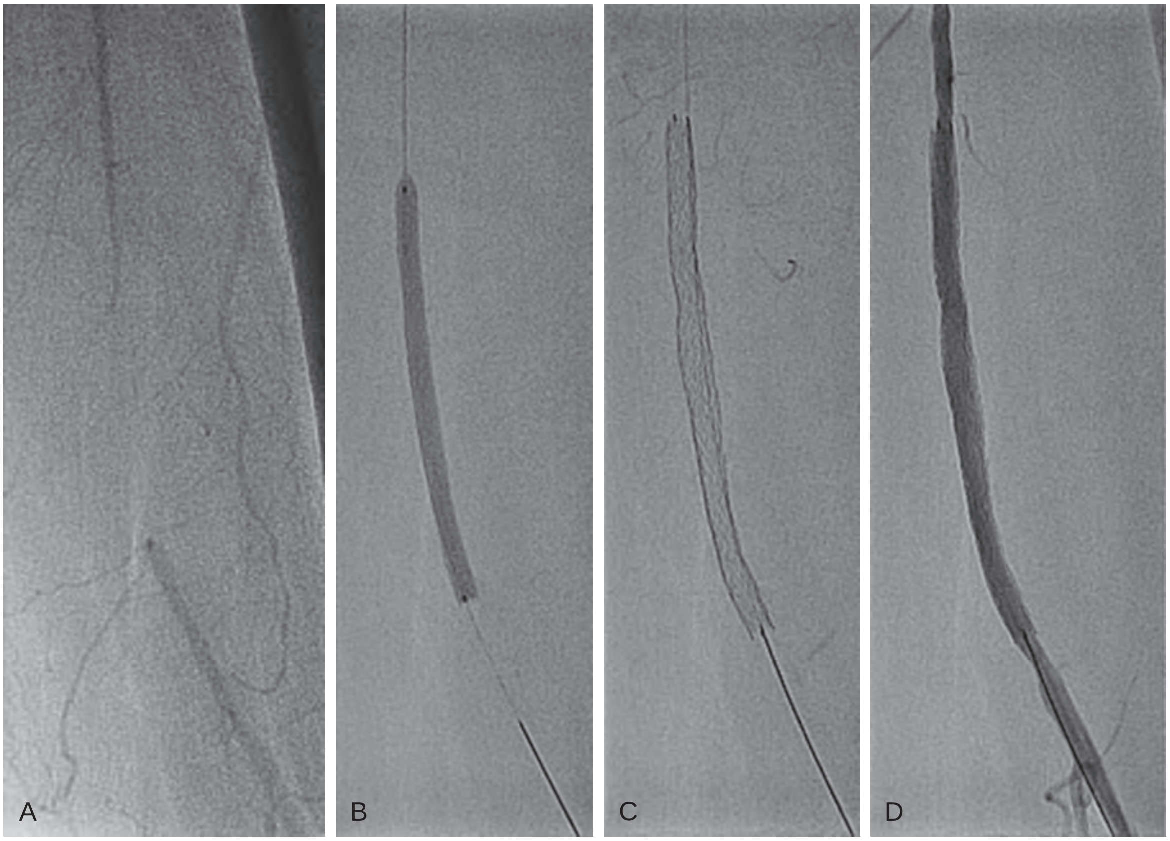

Figure 146.5 CONVENTIONAL CONTRAST ANGIOGRAPHY ILLUSTRATING USE OF A SELF-EXPANDING NITINOL STENT TREATMENT OF AN OCCLUSION OF THE SUPERFICIAL FEMORAL ARTERY. (A) Occlusion in the mid-superficial femoral artery. (B) Balloon angioplasty. (C) Stent deployment in the lesion. (D) Angiogram after stent deployment. *(From Thukkani AK, Kinlay S. Endovascular intervention for peripheral artery disease. Circ Res. 2015;116(9):1599–1613.)*

Surgical revascularization remains the gold standard for peripheral revascularization with the choice of operation depending on the location of the stenosis. Options include (1) aortoiliac or aortofemoral reconstruction for proximal disease involving the aorta or iliofemoral vessels, (2) femoral-popliteal bypass (either above- or below-knee popliteal) for superficial femoral artery or popliteal artery disease, and (3) femoral-distal (tibial or peroneal) bypass for distal arterial stenosis. Aortobiiliac or aortobifemoral bypass graft surgery for aortoiliac occlusive disease ("inflow") produces excellent long-term results with 5-year patency rates ranging from 85% to 90%. Surgical treatment of infrainguinal disease ("outflow") also produces durable results, although outcomes depend on the type of bypass conduit used. Vein grafts are the most durable; femoral-popliteal vein bypass grafts have an expected 5-year patency rate of approximately 66%. The 5-year patency rate for prosthetic grafts, such as polytetrafluoroethylene (PTFE), is lower, about 47%.[1] Limitations of surgical interventions include the need for general anesthesia and the attendant risk of cardiovascular events and death associated with major noncardiac surgery in patients with atherosclerosis. Given the potential for coexistent cardiovascular disease, preoperative assessment is important to identify and limit the risk of cardiovascular events in vascular surgery patients.[94]

Whereas revascularization is indicated for most patients with CLI to preserve limb viability, the comparative efficacy and safety of endovascular revascularization and surgical reconstruction for CLI are not known. A contemporary registry has sought to evaluate the comparative safety and effectiveness of surgical and endovascular interventions in patients with symptomatic PAD.[95] The BEST-CLI Trial (Best Endovascular versus Best Surgical Therapy in Patients with Critical Limb Ischemia) is an ongoing trial that is comparing the relative benefits of surgical versus endovascular treatment in this population.[96]

FUTURE DIRECTIONS

A better understanding of the factors that contribute to intermittent claudication and CLI is needed to craft innovative and durable therapeutic interventions for the management of the limb complications of PAD. In addition, greater knowledge is needed about the unique contributors to atherogenesis and thrombosis in the lower extremities compared with other arterial beds. Further understanding of the downstream effects of compromised blood flow, such as changes in skeletal muscle energetics and impaired neural function, will inform the design and development of novel pharmacotherapies for individuals with PAD. Finally, more comparative efficacy studies are needed to clarify ongoing debates with respect to the relative benefits of exercise training versus invasive therapies; endovascular versus surgical revascularization; and the impact of therapeutic angiogenesis and cell-based therapies in the treatment of PAD. Greater knowledge dissemination regarding PAD diagnosis and risks associated with PAD remains key to early detection and implementation of risk factor modification therapies to improve the care of this high-risk population.

CHAPTER 147

ATRIAL FIBRILLATION

Monika Kozieł Siołkowska, Tatjana S. Potpara, and Gregory Y. H. Lip

Atrial fibrillation (AF) is the most prevalent sustained cardiac arrhythmia, affecting approximately 3% of adults worldwide.[1] Its prevalence and incidence are rising continuously with the increasingly aging population. AF is associated with impaired prognosis, increased risk of all-cause mortality, stroke, heart failure, and hospital admissions, in addition to poor quality of life.

Importantly, AF should not be considered in isolation regarding the process of prevention, detection, and management. Rather, a more holistic approach and integrated care is needed to consider underlying comorbidities and cross-disease sequelae of AF.

In this chapter, we present a brief overview of the overall aspects of AF, with particular focus on the issues relating to stroke and systemic embolism (SSE).

EPIDEMIOLOGY

There have been progressive increases in the incidence and prevalence of AF, and the burden of this condition is estimated to increase further. This increase seems to be associated with an aging population, conditions predisposing to AF, and better detection of silent AF. AF is commonly accompanied by conditions, such as hypertension, heart failure, coronary artery disease (CAD), valvular heart disease, diabetes mellitus, obesity, or chronic kidney disease (CKD).[2] Given that AF is a growing epidemic, the societal impact and cost of this disease will continue to increase.

Pathobiology and Classification of Atrial Fibrillation

AF can be classified based on etiology, depending on whether it is present in patients without structural heart disease or occurs in association with other conditions. AF is defined as paroxysmal if it is self-terminating within 7 days, persistent if it is continuous greater than 7 days or permanent if it is chronic and accepted by the patient and physician. In case of permanent AF, rhythm control strategy is not a management option.

The pathogenesis of AF involves progressive structural changes in the atria, including atrial fibrosis, hypocontractility, fatty infiltration, inflammation, ischemia, vascular remodeling, ion channel dysfunction, and Ca^{2+} instability.

Although there is an overlap, pulmonary vein triggers seem to play a dominant role in younger patients with relatively normal hearts and short episodes of AF, and an abnormal atrial tissue substrate may play a more important role in patients with structural heart disease and persistent/permanent AF. After a period of continuous AF, electrical remodeling occurs, further facilitating the continuance of AF ("AF begets AF"). These changes are initially reversible if sinus rhythm is restored but may become permanent and related to structural changes if AF continues (left atrial dilatation, cardiac fibrosis, and impairment of systolic/diastolic function). Of note is that AF, especially if early-onset, may have a genetic component, independent of cardiovascular comorbidities.

CLINICAL MANIFESTATIONS

Symptoms

Patients with AF experience worse quality of life than healthy controls. AF is associated with symptoms including lethargy, dyspnea, palpitations, chest tightness, sleeping disorders, and psychosocial distress. However, these symptoms may reflect other concomitant diseases. The arrhythmia may be symptomatic or asymptomatic ("silent AF"), and AF patients may have both symptomatic and asymptomatic episodes. Importantly, silent AF is common, with severe consequences, such as stroke and/or death.

The modified European Heart Rhythm Association (EHRA) symptom scale has been proposed to assess symptom severity in patients with AF (Table 147.1).

Stroke and Thromboembolism

Patients with AF have an elevated risk of stroke (a four- to five-fold increase), but this risk is not homogeneous and is dependent upon stroke risk factors (see Chapter 143). Ischemic strokes associated with AF usually result from cardioembolism to a large cerebral artery, and, therefore, AF-related strokes tend to be larger and more often fatal or result in greater disability, worse functional outcomes, and greater mortality compared with strokes from other causes.[3] The arrhythmia is also associated with greater cognitive decline and increased risk of vascular dementia. Cognitive disturbances may occur in the absence of a clinically overt stroke because of multiple asymptomatic cerebral emboli.

In patients with AF, thrombi commonly form within the LAA due to stagnant flow and decreased emptying of this blind-ended structure. Most atrial thrombi in nonvalvular AF (approximately 90%) are formed within the LAA, which explains why, on the background of anticoagulant therapy, surgical occlusion of the LAA at the time of cardiac surgery reduced the risk of stroke by 33% compared with no occlusion.[5] Thrombus formation in AF is consistent with the fulfilment of the Virchow triad of thrombogenesis, including intra-atrial stasis, endothelial dysfunction, and a prothrombotic or hypercoagulable state, due to elevated levels of D-dimer, P-selectin, and von Willebrand factor.[6]

Heart Failure, Other Consequences and Death

Heart failure and AF coexist in many patients, and they can cause and exacerbate each other. Rapid ventricular rate in AF may precipitate signs and symptoms of acute heart failure in patients with an underlying heart failure with preserved LVEF. Poorly controlled ventricular rate in AF may also result in development of heart failure with reduced LVEF in individuals with previously normal left ventricular function (so-called tachycardiomyopathy), with or without clinically overt symptoms and signs of heart failure. Patients with AF and heart failure (with either preserved or reduced LVEF) have

CASE 1: CONCOMITANT ATRIAL FIBRILLATION AND RISK OF STROKE

A 76-year-old woman with chronic heart failure and coronary artery disease who was taking warfarin for stroke prevention because of a history of paroxysmal AF was referred to cardiology because of a history of palpitations and progressive exertional breathlessness. Decompensation of chronic heart failure was diagnosed. Laboratory tests showed poor quality of anticoagulation control (the time in therapeutic range [TTR] of the international normalized ratio was 50%). The electrocardiogram (ECG) confirmed AF with mean ventricular rate of 130 beats/min. On transthoracic echocardiography (TTE), the left ventricular ejection fraction (LVEF) was reduced (30%), no significant valvular disease was revealed, and the left atrium was enlarged (46 mm). Intravenous diuretics were administered to improve the patient's clinical status. Coronary angiography revealed no critical stenoses in coronary arteries. Transesophageal echocardiography (TEE) showed a thrombus in the left atrial appendage (LAA) measuring 2 cm. Warfarin was stopped and a non-vitamin K antagonist oral anticoagulant (NOAC) was initiated. After one month, a follow-up TEE showed disappearance of the LAA thrombus and a successful electrical cardioversion (ECV) was performed. Optimal pharmacological therapy was implemented. Three months later, the LVEF increased to 40%. Multiple ECGs confirmed sinus rhythm.

Comment

In the context of other cardiovascular comorbidities, identifying symptoms of AF may be challenging, since AF commonly complicates other conditions, especially those that have a structural impact on the heart, such as heart failure, hypertension, or valvular disease. The need for early identification of AF and its appropriate management according to guidelines should be emphasized to reduce adverse outcomes. Paroxysmal AF with a rapid ventricular rate has been associated with clinical deterioration of heart failure. Thrombus in the LAA was related to poor quality of anticoagulation with warfarin. Thus, NOACs were started due to their better efficacy/safety ratio, convenience of use, predictable anticoagulant effects without the need for routine coagulation monitoring, and fewer food and drug interactions compared with vitamin K antagonists (VKAs).[4]

worse symptoms, poorer prognosis, and increased mortality compared with individuals with AF without heart failure.[7] Regardless of the development of heart failure, AF is associated with a twofold increased risk of all-cause mortality in women and a 1.5-fold increase in men.

DIAGNOSIS

Advances in diagnostic technologies facilitate the development of more precise therapeutic approaches. The diagnosis of AF is based on ECG showing the absence of P waves, fibrillatory waves between QRS complexes, and irregular R-R intervals. Importantly, prolonged ECG monitoring may increase the probability of detecting undiagnosed, silent AF.

Cardiac electronic implantable devices with an atrial lead enable detection of atrial high-rate episodes (AHRE). An increasing body of evidence shows that AHRE are associated with an elevated risk of AF and AF-related thromboembolism.[8] Thus, individuals with AHRE require further assessment for AF with regular ECG monitoring.[9] In stroke survivors, additional non-invasive ECG monitoring or implantable loop-recorders should be considered to detect silent AF.

Key Investigations

Cardiac ultrasound in AF provides important information on risk stratification, cardiac function, complications, prognosis, and management of associated conditions. Whereas TTE is useful in all patients with AF, TEE allows evaluation of LAA thrombus in individuals being considered for cardioversion or catheter ablation. Intracardiac echocardiography, computed tomography, or magnetic resonance complement TEE and play additional roles in the management of patients with AF.

TABLE 147.1 Symptom Scoring in Atrial Fibrillation

mEHRA Score	Symptoms	Description
1	None	No symptoms related to AF
2a	Mild	Normal daily activity not affected by symptoms associated with AF
2b	Moderate	Normal daily activity not affected, but patient troubled by symptoms
3	Severe	Normal daily activity affected
4	Disabling	Normal daily activity discontinued

AF, Atrial fibrillation.

Blood tests may be useful in initial assessment of patients with AF, and they should include tests for renal, thyroid, and hepatic function, in addition to serum electrolytes, full blood count, and tests of coagulation, such as prothrombin time/INR and activated partial thromboplastin time.

Numerous biomarkers have been associated with the risk of stroke and bleeding in AF and have contributed to our understanding of pathophysiological mechanisms involved in complications of AF. Moreover, many biomarkers are non-specifically related to multiple outcomes, both cardiovascular and non-cardiovascular. Thus, they may be better used to rule out (rather than rule in) in relation to management decision-making.

Differential Diagnoses

Other atrial rhythms may be similar to AF on an ECG, but these can often be distinguished by the presence of discrete P waves (e.g., atrial tachycardias). Atrial flutter, in its typical form, is defined by a sawtooth pattern of regular atrial activation, visible as flutter waves in leads II, III, aVF, and V1. Atrial flutter commonly appears with 2:1 atrioventricular block, resulting in a ventricular rate of approximately 150 beats/min (unless rate control medications have been used). It should be emphasized that atrial flutter is also associated with SSE, and the requirements for anticoagulation are the same as those for AF. Supraventricular tachycardias can be easily distinguished from other narrow complex tachycardias (and often effectively treated) using intravenous adenosine. A regular wide QRS complex tachycardia should be medicated urgently as ventricular tachycardia, unless a high probability of a bundle-branch block pattern or ventricular pre-excitation is assumed.

An Integrated Approach to Atrial Fibrillation Management

The Atrial fibrillation Better Care (ABC) pathway for integrated management is a simple strategy (A–avoid stroke, B–better symptom management, C–cardiovascular and comorbidity risk reduction) that improves detection and reminds clinicians of the simple decision-making steps for treatment of AF in a holistic manner ("Easy as ABC …") (Fig. 147.1).[10]

"A" Avoid Stroke/Anticoagulation

Stroke prevention is a fundamental part of the management of patients with AF. The first step is to identify low-risk patients (those with CHA_2DS_2-VASc [congestive heart failure, hypertension, age ≥75 years, diabetes, stroke/transient ischemic attack, vascular disease, age 65 to 74 years, sex category] score of 0 in men or 1 in women), in whom antithrombotic therapy is not indicated (Table 147.2).[11] The subsequent step is to offer stroke prevention to patients with one or more non-sex CHA_2DS_2-VASc stroke risk factors, and stroke prevention means oral anticoagulation, either a well-managed VKA or a non-vitamin K antagonist oral anticoagulant (NOAC) (see later sections).

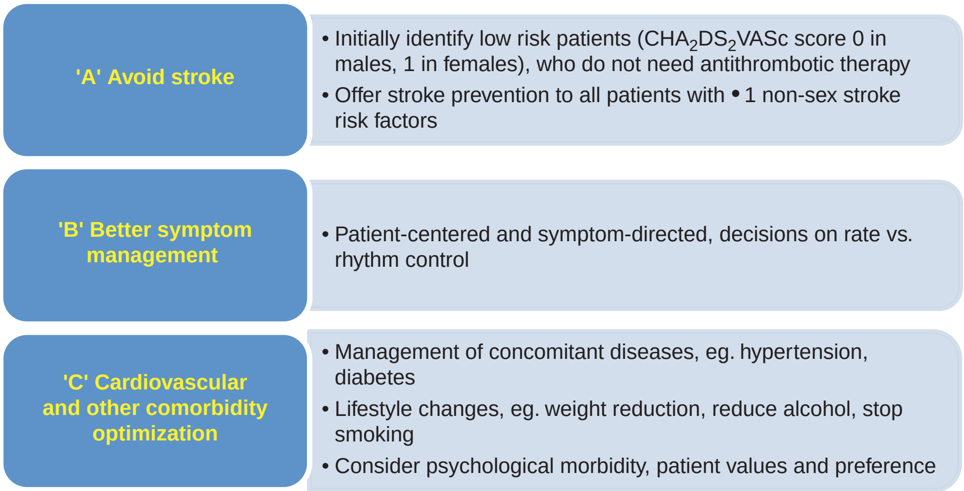
Evaluation of bleeding risk should be performed in all patients. The HAS-BLED (hypertension, abnormal renal/liver function, stroke, bleeding history or predisposition, labile INR, elderly, drugs or alcohol concomitantly) score was originally derived and proposed for bleeding risk assessment in patients with AF (Table 147.3).[12] The HAS-BLED score should be used to draw attention to modifiable bleeding risk factors (e.g., uncontrolled blood pressure, concomitant use of nonsteroidal anti-inflammatory drugs [NSAIDs] or antiplatelet agents in an anticoagulated patient, labile INRs), and to flag "high risk" patients for early follow-up review (e.g., 4 weeks rather than 4 to 6 months) (Fig. 147.2). Such a proactive strategy with appropriate use of dynamic bleeding risk assessment and follow-up was associated with lower risk of bleeding events and improved anticoagulation uptake, compared with usual care.[13]

"B" Better Symptom Control

The next aspect of AF management is patient-centered, symptom directed decision on rate or rhythm control. In general, there is little difference in AF-related clinical outcomes between rate or rhythm control.

"C" Cardiovascular Risk Factor and Comorbidity Management

Multiple cardiovascular risk factors and comorbidities commonly coexist with AF. As part of integrated holistic AF care, comorbidities should be addressed, for example, management of heart failure,



'A' Avoid stroke
'B' Better symptom management
'C' Cardiovascular and other comorbidity optimization

- Initially identify low risk patients (CHA_2DS_2VASc score 0 in males, 1 in females), who do not need antithrombotic therapy
- Offer stroke prevention to all patients with • 1 non-sex stroke risk factors

- Patient-centered and symptom-directed, decisions on rate vs. rhythm control

- Management of concomitant diseases, eg. hypertension, diabetes
- Lifestyle changes, eg. weight reduction, reduce alcohol, stop smoking
- Consider psychological morbidity, patient values and preference

Figure 147.1 THE ABC PATHWAY FOR INTEGRATED CARE MANAGEMENT OF ATRIAL FIBRILLATION.

TABLE 147.2 **Risk Stratification for Stroke and Systemic Thromboembolism**

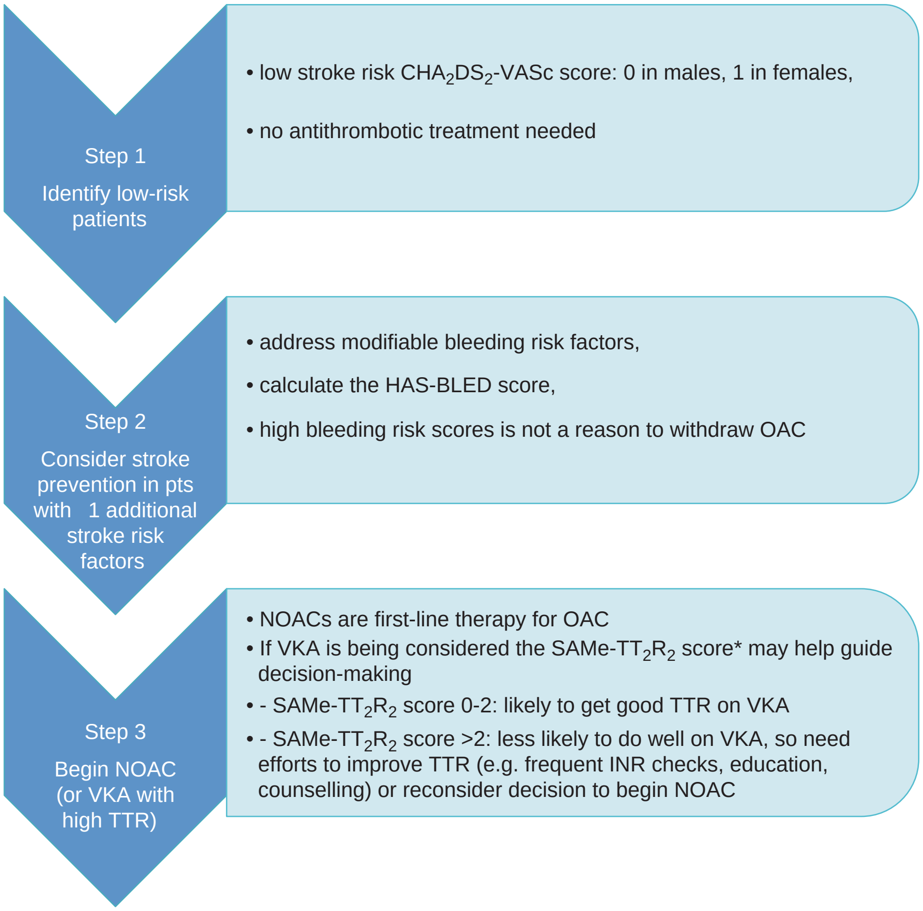
CHA_2DS_2-VASc Score	
Clinical Characteristic	**Points**
CHF or LVEF ≤40%	1
Hypertension	1
Age ≥75 years	2
Diabetes	1
Stroke/TIA	2
Vascular disease	1
Age 65–74 years	1
Sex category (female)	1
Cumulative score	Range 0–9

For the CHA2DS2-VASc score, estimated stroke and thromboembolism event rates at 1 year follow-up are 0.78% (0 points), 2.01% (1 point), 3.71% (2 points), 5.92% (3 points), 9.27% (4 points), 15.26% (5 points), 19.74% (6 points), 21.50% (7 points), 22.38% (8 points), 23.64% (9 points); see Olesen JB, Lip GY, Hansen ML et al. Validation of risk stratification schemes for predicting stroke and thromboembolism in patients with atrial fibrillation: nationwide cohort study. *Br Med J.* 2011;342:d124.
Vascular disease = prior myocardial infarction, peripheral artery disease, and/or aortic plaque.
CHF, Congestive heart failure; *LVEF*, left ventricular ejection fraction; *TIA*, transient ischemic attack.

TABLE 147.3 **Risk Stratification for Bleeding: The HAS-BLED Score**

HAS-BLED Score	
Clinical Characteristic	**Points**
Hypertension	1
Abnormal renal/liver function	1 or 2
Stroke	1
Bleeding	1
Labile INRs	1
Elderly (age >65 years)	1
Drugs or alcohol	1 or 2
Cumulative score	Range 0–9

Hypertension = systolic blood pressure >160 mm Hg; abnormal renal function = dialysis, transplant, creatinine >2.6 mg/dL or >200 µmol/L; abnormal liver function = cirrhosis or bilirubin >2x normal with AST/ALT/AP >3x normal; labile INR = unstable/high INRs, time in therapeutic range <60%; drugs = antiplatelet agents, nonsteroidal anti-inflammatory drugs; alcohol = eight or more drinks/week.
ALT, Alanine aminotransferase; *AP*, alanine phosphatase; *AST*, aspartate aminotransferase; *INR*, international normalized ratio.



Step 1
Identify low-risk patients
• low stroke risk CHA$_2$DS$_2$-VASc score: 0 in males, 1 in females,
• no antithrombotic treatment needed
Step 2
Consider stroke prevention in pts with 1 additional stroke risk factors
• address modifiable bleeding risk factors,
• calculate the HAS-BLED score,
• high bleeding risk scores is not a reason to withdraw OAC
Step 3
Begin NOAC (or VKA with high TTR)
• NOACs are first-line therapy for OAC
• If VKA is being considered the SAMe-TT$_2$R$_2$ score* may help guide decision-making
• - SAMe-TT$_2$R$_2$ score 0-2: likely to get good TTR on VKA
• - SAMe-TT$_2$R$_2$ score >2: less likely to do well on VKA, so need efforts to improve TTR (e.g. frequent INR checks, education, counselling) or reconsider decision to begin NOAC

Figure 147.2 STRATEGIES FOR STROKE PREVENTION. *SAMe-TT$_2$R$_2$ (sex [female], age [<60 years]), medical history (≥2 from: hypertension, diabetes mellitus, coronary artery disease/ myocardial infarction, peripheral artery disease, congestive heart failure, previous stroke, pulmonary disease, and hepatic or renal disease), treatment (interacting drugs, e.g., amiodarone), tobacco use (within 2 years), race (non-White).

hypertension, diabetes mellitus, sleep apnea, and underlying cardiac ischemia. Lifestyle changes, including weight reduction, regular exercise, and limitation of alcohol and stimulant use, should be pursued. If possible, education and counseling should be implemented.

Hypertension is common in AF patients. Hypertension has an impact on the pathogenesis, management, and prognosis of AF. As a modifiable risk factor, control of hypertension carries a potential for AF prevention, lowering of AF recurrence rates, and avoiding the devastating complications, such as stroke. Thus, optimal blood pressure control should be an integral part of the management of AF patients. In case of rate control strategy, beta-blockers or non-dihydropyridine calcium channel blockers should be considered. Stroke prevention with OAC is recommended in AF individuals with hypertension. Importantly, hypertension substantially elevates the risk of intracerebral hemorrhage in AF patients on OAC. Thus, efforts should be made towards achieving a target blood pressure of less than 130/80 mm Hg in patients receiving OAC.[14]

Management compliant with the ABC approach has been associated with a reduced rate of cardiovascular events and lower healthcare costs when compared with noncompliance with the ABC pathway.[15] The prospective cluster randomized mAFA II trial randomized AF patients to the mAFA intervention arm (based on the ABC pathway) versus a usual care arm.[11,16] The intervention arm was associated with significantly reduced risks of rehospitalization (1.2% vs. 4.5%; hazard ratio [HR]: 0.32; 95% confidence interval [CI]: 0.17 to 0.60; $P < .001$) and composite of stroke/thromboembolism, all-cause death and rehospitalization (1.9% vs. usual care, 6.0%; HR: 0.39; 95% CI: 0.22 to 0.67; $P < .001$).[17]

Rate Control

Rate control is usually adequate to improve symptoms related to AF, although the evidence for the optimal type and intensity of rate control is scarce. Pharmacological agents for maintaining acute or long-term rate control include digoxin, beta-blockers, diltiazem or verapamil, or combination therapy.

Patients with acute, new-onset AF often require heart rate control with a preference for beta-blockers or rate-limiting calcium antagonists, such as diltiazem or verapamil. In sedentary individuals, digoxin may be considered. Diltiazem or verapamil is contraindicated in patients with left ventricular systolic dysfunction, where beta blockers and/or digoxin may be considered. However, beta-blockers do not decrease all-cause mortality in individuals with AF and heart failure when compared with placebo.[18] Conventional approaches to maintain a strict heart rate (<80 beats/min) have not proved to be better than a more lenient approach, for both prognosis and symptom control.

Rhythm Control

Clinical trials that compared rhythm control with rate control alone have not shown superiority of one strategy over another for clinical outcomes.[19] Thus, a rhythm control strategy is recommended to improve AF-related symptoms in patients who remain symptomatic on optimal rate control therapy. Cardioversion, catheter/surgical ablation, or combination therapy is frequently effective when antiarrhythmic drugs have failed. All antiarrhythmic agents have possible side effects (for example, thyroid dysfunction, corneal microdeposits, and pulmonary fibrosis with amiodarone use; proarrhythmic effects of Class I antiarrhythmics). The initial choice of antiarrhythmic drug should be preceded by evaluation of the safety of antiarrhythmic therapy.[19]

As a non-drug option, electrical cardioversion (ECV) is a common method of converting AF to sinus rhythm, especially in hemodynamically unstable patients with AF. Pre-treatment with antiarrhythmic drugs may increase the efficacy of ECV. Catheter ablation of AF involves radiofrequency ablation or cryoablation to the endocardium, typically including isolation of the pulmonary veins. This rhythm control approach is a second-line treatment in patients with AF and failure of or intolerance to antiarrhythmic drug therapy. In selected patients, catheter ablation in AF patients with heart failure significantly reduces recurrent AF.

Surgical ablation (targeting the pulmonary veins or Cox-Maze approach) is usually performed in patients undergoing cardiac surgery for other reasons (e.g., coronary artery bypass grafting or valve surgery), often in combination with surgical left atrial appendage exclusion. Each method of rhythm control strategy is associated with recurrence of AF, which can be often asymptomatic. Due to risk of recurrent AF, long-term anticoagulation should not be stopped in patients with risk factors for stroke.

PREVENTION OF STROKE AND THROMBOEMBOLISM

Thromboembolic risk is not homogeneous among AF patients, and it depends on the presence of various stroke risk factors, such as prior stroke or transient ischemic attack, hypertension, age, structural heart disease, and diabetes mellitus.[11] The more common and validated stroke risk factors have been used to formulate various stroke risk stratification schema, and the CHA$_2$DS$_2$-VASc score is the most used (see Table 147.2). The default should be to offer stroke prevention, unless the patient is low risk, and no antithrombotic therapy is required. Thus, the CHA$_2$DS$_2$-VASc score should be used to initially identify patients with "low stroke risk" (CHA$_2$DS$_2$-VASc score 0 in men, or 1 in women) who do not require antithrombotic therapy. The subsequent step is to offer stroke prevention to AF patients with one or more non-sex CHA$_2$DS$_2$-VASc stroke risk factors (CHA$_2$DS$_2$-VASc score ≥ 1 in a male, ≥ 2 in a female). In most cases of AF associated with valvular heart disease (such as mitral stenosis), there are rarely any reasons not to offer antithrombotic therapy to patients due to the high baseline risk of SSE, regardless of other patient characteristics.[20]

Oral Anticoagulation

Adjusted-dose warfarin is associated with a 64% relative risk (RR) reduction in stroke and a 26% reduction in all-cause mortality, compared with placebo or control.[21] Aspirin was associated with a nonsignificant reduction (19%) in stroke. A target INR range of 2.0 to 3.0 is recommended, and the average TTR should be less than 70%. There is no evidence that lower INR range targets are beneficial, despite such practice being common in Asian countries.[22]

We are now in the era of the NOACs, which offer relative efficacy, safety, and convenience compared with VKAs. In the meta-analysis by Ruff et al.,[23] NOACs were compared with warfarin using data from the Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY), Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in AF (ROCKET-AF), Apixaban for the Prevention of Stroke in Subjects With AF (ARISTOTLE), and the Effective Anticoagulation with Factor Xa Next Generation in AF–Thrombolysis in Myocardial Infarction 48 (ENGAGE AF-TIMI 48) clinical trials; NOACs were shown to have a better risk-benefit profile, with significant decreases in stroke or systemic embolic events (RR 0.81, 95% CI 0.73–0.91, $P < .0001$), intracranial hemorrhage (RR 0.49, 95% CI 0.38–0.64, $P < .0001$), and all-cause mortality (RR 0.90, 95% CI 0.85–0.95, $P = .0003$) compared with warfarin. The rate of major bleeding with NOACs was similar to that with warfarin, but gastrointestinal bleeding (GIB) was more frequent with NOACs than with warfarin.

CASE 2: INTERVENTIONAL APPROACH TO ATRIAL FIBRILLATION

A 68-year-old man with hypertension and paroxysmal AF was referred to cardiology with a 4-month history of palpitations and impaired exercise tolerance. He had been admitted to his local emergency department three times due to AF with rapid ventricular response that had required cardioversion. Treatment with a beta-blocker and propafenone had not decreased the frequency of symptoms and the patient complained of profound lethargy associated with higher doses of beta-blocker. The patient was prescribed dabigatran 150 mg twice daily for stroke prevention (see Chapter 142). Blood tests were within reference range. On TTE, LVEF was impaired (45%), no significant valvular disease was revealed, and the left atrium was enlarged (44 mm). After discussing available management options and the procedural risk, cryoballoon ablation of AF was performed. Dabigatran was continued without interruption. The procedure was uncomplicated, and the patient was discharged the following day. At 3 months, the patient remained asymptomatic. His CHA$_2$DS$_2$-VASc score was 2, and the patient continued using dabigatran post-ablation.

Comment

In some patients, symptomatic AF may significantly impair the quality of life, and rhythm control may be a preferred treatment choice. With failure of pharmacological rhythm control therapy, the patient was offered catheter ablation. Catheter ablation of AF performed in experienced centers is usually more effective than antiarrhythmic drug therapy, especially for symptom relief and quality of life improvement. There is no high-quality evidence confirming that AF catheter ablation prevents major cardiovascular outcomes. Thus, in selected patients with symptomatic, paroxysmal AF who prefer an interventional strategy, catheter ablation may be considered as first-line therapy. A higher probability of sinus rhythm maintenance and lower procedure-related complications can be expected in younger patients without structural heart disease, with a short history of AF, and frequent, short episodes of AF. Complication rates are low in experienced centers (1 in 100 risk of cardiac tamponade and 1 in 500 risk of stroke), and 1-year freedom from AF ranges from 50% to 80% in experienced centers.

Regardless of the apparently successful maintenance of sinus rhythm, oral anticoagulation should be continued in patients with two or more CHA$_2$DS$_2$-VASc risk factors, equivalent to an estimated stroke rate of over 3%–4% per year.

The randomized trial data are also complemented by effectiveness and safety data from large "real world" observational cohorts.[24,25] In the largest analysis, ARISTOPHANES (Anticoagulants for Reduction in Stroke: Observational Pooled Analysis on Health Outcomes and Experience in Patients) NOACs were associated with reduced rates of SSE compared with warfarin (HR 0.64, 95% CI 0.58 to 0.70 for apixaban; HR 0.82, 95% CI 0.71 to 0.95 for dabigatran; HR 0.79, 95% CI 0.73 to 0.85 for rivaroxaban) and similar rates of major bleeding (HR 0.60, 95% CI 0.56 to 0.63 for apixaban; HR 0.71, 95% CI 0.65 to 0.78 for dabigatran; HR 1.06, 95% CI 1.02 to 1.10 for rivaroxaban).[24] The FDA-sponsored analysis, by Graham et al.,[26] showed a reduced risk of thromboembolic stroke, intracranial hemorrhage, and mortality among patients on standard doses of NOACs compared with warfarin. Dabigatran and apixaban were associated with a better benefit-harm profile than warfarin.

Compared with warfarin, NOACs have a rapid onset/offset of action, fewer drug interactions, and no effect of dietary vitamin K intake on their activity. The predictable dose-related anticoagulant effect of NOACs enable their use in fixed doses without the need for routine coagulation monitoring, thus simplifying the therapy (Table 147.4). In NOAC-eligible AF patients, international AF guidelines recommend NOACs in preference to VKAs.[11] Patients with nonvalvular AF given VKAs should have the dose adjusted to maintain the INR within the range of 2.0 to 3.0, with a TTR of $\geq 70\%$. The TTR is influenced by various clinical factors, and the more common ones have been used to formulate the SAMe-TT$_2$R$_2$ score, where a score of greater than 2 is associated with a likelihood of having a poor TTR,[27,28] whereby interventions to improve TTR

TABLE 147.4 Characteristics of NOACs

	Dabigatran	Apixaban	Edoxaban	Rivaroxaban
Mechanism	Oral direct thrombin inhibitor	Oral direct factor Xa inhibitor	Oral direct factor Xa inhibitor	Oral direct factor Xa inhibitor
Prodrug	Yes	No	No	No
Standard dose	150 mg twice daily	5 mg twice daily	60 mg once daily	20 mg once daily
Reduced dose	110 mg twice daily; 75 mg twice daily in United States	2.5 mg twice daily	30 mg once daily	15 mg once daily
Bioavailability	3%–7%	50%	62%	66% without food, 80%–100% with food
Renal clearance of absorbed dose	80%	27%	50%	35%
Plasma protein binding	35%	87%	55%	95%
Dialyzability	50%–60%	14%	Not available	Not available
Liver metabolism: CYP3A4 involved	No	Yes (25%)	Minimal (<4% of elimination)	Yes (18%)
Absorption with food	No effect	No effect	6%–22%	≥39%
Elimination half-life	12–17 h	12 h	10–14 h	5–9 h (young), 11–13 h (elderly)

should be implemented (e.g., more frequent INR checks or frequent follow up), or, more ideally, switching to a NOAC should be considered. Efforts to improve prescription of OAC include avoiding under-dosing, which requires education of health care providers; implementation of local guidelines; interdisciplinary medical care programs educating both care providers and patients; and persuasive interventions utilizing peer-group experts.[29]

Of note is that VKAs are currently the only therapy with established safety in patients with AF and rheumatic mitral valve disease and/or mechanical heart valves.[20]

Secondary Stroke Prevention

The highest risk of recurrent stroke occurs in the early phase after a first stroke or TIA (see Chapter 143). Data on the optimal timing of OAC (re)initiation after an AF-related stroke are scarce and conflicting. In AF patients with acute ischemic stroke, OAC should be usually started within 2 weeks of acute ischemic stroke, but the optimal timing within this period is not established. Patients with AF and acute ischemic stroke without contraindications to OAC should be managed with long-term oral anticoagulation.

Prevention of recurrent stroke with OAC is effective but requires a multidisciplinary approach, including stroke physicians and cardiologists, to carefully select appropriate patients and minimize the risk of hemorrhagic transformation. All NOACs are associated with a lower risk of intracranial hemorrhage than VKAs; hence, if a patient had a stroke while on warfarin, clinicians may consider switching to a NOAC. Such patients also require assessment of other causes of stroke, such as uncontrolled blood pressure or significant carotid disease. If on warfarin, we should ensure that the TTR is greater than 70% and, if on a NOAC, whether they were on the label-adherent dose and there was good persistence and adherence to therapy.[30]

Nonpharmacologic Strategies for Stroke Prevention

Several non pharmacological options are available for stroke prevention in AF in patients with history of bleeding who have absolute contraindications OAC. These include LAA occlusion, surgical LAA occlusion, or permanent carotid filters.

Surgical LAA occlusion may be performed during cardiac surgery undertaken for other indications. Among AF patients after cardiac surgery, the majority of whom continued to receive ongoing OAC, the risk of ischemic stroke or systemic embolism was lower with LAA occlusion during the surgery than without it.[5]

Occlusion of the LAA may be considered for stroke prevention in AF patients with absolute contraindications for long-term OAC.[31] A candidate for LAA occlusion should ideally have no contraindications to dual antiplatelet therapy (DAPT) for at least several weeks, followed by permanent single antiplatelet therapy (SAPT). In patients with contraindications to antiplatelet therapy, percutaneous endocardial/epicardial or minimally invasive surgical epicardial LAA occlusion may be considered. In randomized trials,[32] LAA occlusion was non-inferior to VKA for stroke prevention in individuals with AF and moderate stroke risk, with a likelihood of lower bleeding rates during follow-up. In AF patients undergoing cardiac surgery, surgical LAA occlusion or exclusion may be considered for stroke prevention. However, residual LAA flow or incomplete LAA exclusion can contribute to higher risk of stroke. A novel approach using permanent, bilateral common carotid artery (CCA) filters has been proposed to capture emboli and prevent major cerebral stroke in patients with contraindications to OAC.

Periprocedural Anticoagulation

Interruption of anticoagulation temporarily increases the thromboembolic risk, whereas non-interrupted anticoagulation increases the risk of bleeding associated with surgical procedures.[33] Individuals scheduled for low bleeding risk procedures (e.g., dental and cutaneous procedures) can continue oral anticoagulation (warfarin within the target INR range and probably NOACs, as well),[34] whereas AF patients at high or moderate thromboembolic risk should limit the period without anticoagulation to the shortest possible interval with or without bridging with low-molecular-weight heparin (LMWH) in case of procedures requiring a temporary OAC interruption. When interruption of OAC is required, bridging does not appear to be beneficial, except in patients with mechanical heart valves.

ANTICOAGULANT-RELATED BLEEDING

There are various risk factors for bleeding, and the more common risk factors have been used to formulate bleeding risk scores. Of the various bleeding risk stratification schema, the HAS-BLED is a user-friendly tool for clinicians, which stratifies patients into two categories of risk: high, low-intermediate (see Table 147.3).[35] Due to the dynamic nature of bleeding, bleeding risk evaluation needs to be repeated regularly.

Many studies have reported less intracranial hemorrhage and life-threatening bleeding with NOACs than with warfarin. Patients who suffered a major bleeding event on NOACs had a more favorable outcome than those on VKAs.[36,37]

In the 2018 EHRA Practical Guide on the use of NOACs in patients with AF,[4] recommended management of bleeding in individuals treated with NOACs depends on the following factors: the type of bleeding (minor, major non-life threatening, or major life threatening), timing of the last NOAC intake, dosing regimen, renal function, concomitant medication, and other aspects influencing hemostasis.

In AF patients with severe acute bleeding, it is recommended to withhold OAC until the underlying cause is identified and managed. Each case will require an individualized approach and decision to restart OAC therapy after consideration of the risks, benefits, alternatives, and patient's values. Notably, the re-initiation of OACs after a major bleeding in patients with AF has been associated with a positive clinical benefit in comparison to withholding OACs.[38]

Resumption of OAC after bleeding should be considered in all eligible patients by a multidisciplinary AF team. Complex decisions concerning the discontinuation and re-initiation of OAC should also be discussed by a multidisciplinary team, analysing the risk of recurrent stroke and bleeding, and taking into consideration different prevention options.[9] In case of bleeding due to secondary or reversible causes, OAC can be safely reinitiated once the cause of the bleed has been corrected. The risks for recurrent ICH or recurrent GIB are often similar between OAC restarters and non-restarters.[39]

Reversal of Anticoagulation

The management of bleeding remains a clinical challenge in the setting of anticoagulation. The most important aspect is to eliminate the source of bleeding. In patients on VKAs, physicians have many years of experience with reversing the agent with several therapies, such as intravenous vitamin K, fresh frozen plasma (FFP), and prothrombin complex concentrate (PCC). When rapid reversal is required, PCC is preferred over FFP; recombinant factor VIIa is not recommended (see Chapter 142).

Idarucizumab can be useful in case of life-threatening bleeds with dabigatran. Andexanet alfa is an option for reversal of oral factor Xa inhibitors.[40] PCC may also support hemostasis in such patients.[41]

Given their short half-lives, time appears to be the most important factor in bleeding associated with NOACs. This emphasizes the significance of asking patients about the exact time of the last NOAC intake and ascertaining factors affecting plasma concentrations and hemostasis (e.g., age, comorbidities, and concomitant use of antiplatelet drugs).[4]

FUTURE DIRECTIONS

Current gaps in the evidence on management of AF include screening for AF using patient-operated ECG devices, smartphones, and other technologies, comparison of different rate control therapies, defining the place of rhythm control with hybrid approaches to restore sinus rhythm, and establishing how best to manage patients with AF and concomitant heart failure. Problems, such as optimal stroke prevention in patients with severe renal dysfunction, LAA occlusion for stroke prevention, and anticoagulation in patients after major bleeding, especially ICH or GIB, require further research.

Whereas stroke prevention remains to be a cornerstone of AF management, the risk of death in patients with AF remains unacceptably high. Further attention to these areas is crucial, considering the rapidly increasing incidence and prevalence of AF, as well as the burden that this condition is placing on patients and health care systems.

CHAPTER 148

BLEEDING AND CLOTTING DISORDERS IN PEDIATRICS

Nasrin Samji, Anthony K. C. Chan, and Mihir D. Bhatt

The neonatal and pediatric stages are periods of rapid physiologic changes, some of which affect the hemostatic system. The hemostatic system is a dynamic system that evolves gradually from birth into the mature adult form. Evaluation of bleeding and clotting disorders in children requires an understanding of the evolution of physiologic normal values for age, the congenital disorders that present in early life, and the common clinical settings that affect hemostasis and thrombosis risks in childhood. The rapid evolution of the blood coagulation system after birth leads to a dynamic group of age-dependent reference ranges for the levels of the various components that should be considered physiologically normal. Developmental hemostasis is the term applied to the evolution of the hemostatic and fibrinolytic systems through infancy and childhood into adult age.

DEVELOPMENTAL HEMOSTASIS

The coagulation system in children provides innate protection from thrombosis without an increased risk for bleeding. The hemostatic system evolves throughout childhood and most rapidly during the neonatal period. Changes in the plasma concentrations of proteins involved in blood coagulation result in a dynamic group of reference ranges for preterm and term infants. Although different from adult values, these reference ranges are neither abnormal nor pathologic. The relative rarity of hemorrhagic or thrombotic complications in this population suggests that the neonatal coagulation system is physiologically replete.

Laboratory Evaluation

The pioneering work of the late Dr. Maureen Andrew paved the way for research into developmental hemostasis. The concept of developmental hemostasis is now widely accepted, and her seminal papers describing the reference ranges for healthy premature and full-term neonates and children are still widely quoted.[1–3] Laboratory evaluation of thrombosis or bleeding in neonates and children must take into account the age-related reference ranges, which differ significantly from adult levels. In addition, because coagulation assay results vary depending on the type of analyzer and reagents used, caution is needed when prior publications of defined reference ranges for neonates are used.[4]

Although research has looked into age-specific differences in the quantitative levels of hemostatic proteins,[5] functional assays that are reagent and analyzer-specific are still predominantly used for hemostatic diagnosis in the pediatric population. Changes in functional protein levels correspond with changes in global tests of coagulation. The prothrombin time (PT), expressed in seconds, in full-term and premature neonates is like that in children and adults, despite the fact that neonates have relative deficiencies of the vitamin K-dependent coagulation factors. The activated partial thromboplastin time (aPTT) is prolonged in newborns, which is attributed to relative deficiencies in the contact factors (see Chapter 126). Thromboelastography reaction time is significantly lower in neonates compared with children and adults. The thrombin time in neonates is like that in children and adults when measured in the presence of calcium, which compensates for the unique fetal form of fibrinogen that has increased sialic acid content.

Blood Coagulation Proteins

The synthesis of fetal and neonatal coagulation proteins begins at approximately 10 weeks of gestation, and plasma concentrations of these proteins increase with gestational age. Maternal coagulation proteins cannot cross the placenta; however, maternal drugs, such as warfarin and phenytoin, can affect the synthesis of fetal vitamin K-dependent coagulation proteins.

In the healthy newborn, plasma levels of procoagulant factors, such as factor (F)VII, FIX, FX, and prothrombin (the vitamin K-dependent coagulation factors) and FXI, FXII, prekallikrein, and high-molecular-weight kininogen (HMWK) (the contact factors), are about 50% lower than adult values (Table 148.1).[1,2] The levels rise as the infant ages, and they reach about 80% of normal adult values by 6 months of age but remain decreased throughout childhood.[6] The levels of fibrinogen, FV, FVIII, and FXIII in neonates are similar to those in adults and remain so throughout childhood.[2,6] The level of von Willebrand factor (vWF) in newborns is about two-fold higher than that in adults and the level of vWF gradually decreases over the first 6 months of life.[2] In contrast, the levels of antithrombin (AT) are lower than adult levels in the first 3 months of life and are comparable to the levels seen in patients with heterozygous AT deficiency (see Chapter 138). The physiologic ranges for coagulation factors in healthy newborns who have received intramuscular vitamin K after delivery are shown in Table 148.2.

Regulation of Thrombin

Thrombin regulation in neonatal plasma is like that in plasma from adults who are receiving therapeutic doses of anticoagulants. The concentration of prothrombin is lower in neonates than that in adults. However, the extent of thrombin generation depends on the experimental system; thrombin generation in plasma from neonates has been reported to be comparable to that in adult plasma provided that thrombomodulin is added.[7,8]

Thrombin is inhibited by AT, α_2-macroglobulin, and heparin cofactor II. In neonates, the α_2-macroglobulin concentration is two-fold higher than that in adults. The overall capacity of newborn plasma to inhibit thrombin is like that of adult plasma due in part to the increased binding of thrombin by α_2-macroglobulin. Thrombin inhibition by heparin cofactor II is catalyzed by a dermatan sulfate-like proteoglycan, which is produced by the placenta and is found in both maternal and fetal plasma.

Regulation of thrombin generation is accomplished by upstream inhibition of the clotting proteins in the prothrombinase and tenase complexes (see Chapters 121 and 125). Plasma concentrations of protein C are low at birth and gradually increase to adult levels by 6 months of age. Although the total concentration of protein S is low at birth, the functional activity of protein S is comparable to that in adults because low levels of C4b-binding protein result in more free protein S. The interaction of protein S with activated protein C in neonatal plasma may be limited by the elevated levels of α_2-macroglobulin. Free tissue factor pathway inhibitor levels in neonates are

TABLE 148.1 Common Hematologic Manifestations of COVID-19

Component	Neonatal Versus Adult Level	
Primary hemostasis	↔	Platelet count
	↑	vWF
Coagulation factors	↓	FII, FVII, FIX, FX
	↓	FXI, FXII
	↓ to ↔	FV, FXIII
	↔	Fibrinogen
	↔	FVIII

	↑	α_2M
Fibrinolysis	↓	Plasminogen
	↔ to ↑	PAI

α_2M, α_2-Macroglobulin; *AT*, antithrombin; *F*, factor; *PAI*, plasminogen activator inhibitor; *PC*, protein C; *PS*, protein S; *TFPI*, tissue factor pathway inhibitor; *vWF*, von Willebrand factor.
Modified from Guzzetta NA, Miller BE. Principles of hemostasis in children: models and maturation. *Paediatr Anaesth.* 2011;21:3.

lower than in adults, although total levels of tissue factor pathway inhibitor in neonatal plasma are like those in adult plasma.

The Fibrinolytic System

Although the levels of some components of the fibrinolytic system in neonates and children are different from those in adults, the clinical relevance of this finding is probably minimal. The fibrinolytic system regulates fibrin deposition by generating plasmin, which solubilizes fibrin. At birth, the fibrinolytic system has all the key components, but there are important age-related differences in the quantity and quality of the fibrinolytic proteins and enzymes. Plasma concentrations of plasminogen, tissue plasminogen activator (tPA), and α_2-antiplasmin (α_2AP) are decreased, whereas plasma concentrations of plasminogen activator inhibitor 1 (PAI-1) are increased. Furthermore, plasmin generation and overall fibrinolytic activity are decreased.[9] The capacity to generate plasmin in newborn plasma is generally reduced compared with adult plasma, which likely reflects the decreased plasminogen concentration. Despite lower levels of fibrinolytic components, the newborn fibrinolytic system is still effective.

The euglobulin clot lysis time is a global assay of fibrinolytic activity but reflects only part of the physiologic fibrinolytic potential. Maneuvers that induce the release of endogenous fibrinolytic components, such as venous occlusion, desmopressin infusion, or exercise, provide more sensitive measures of in vivo fibrinolytic activity.[9]

Plasminogen levels are lower in neonates and children than in adults, and fetal plasminogen binds to cellular receptors with lower affinity because of its increased sialic acid and mannose content. Whereas healthy neonates have lower plasmin-generating potential than adults, baseline levels of tPA can increase up to eightfold with illness. Neonates with severe plasminogen deficiency have only a minimally increased risk for thrombosis, and most of their clinical findings are the result of impaired extravascular fibrinolysis. The major plasmin inhibitors circulate at near adult levels in the neonate. In children, plasminogen activator inhibitor (PAI-1) is elevated, which results in fibrinolytic suppression during childhood.

Imbalances in the fibrinolytic system, whether hereditary or acquired, can lead to thrombotic or bleeding complications. Hereditary disorders, although rare, include plasminogen deficiency, PAI-1 deficiency, and α_2AP deficiency. The efficacy and safety of fibrinolytic therapy may be influenced by age-dependent differences in the fibrinolytic system. Data are lacking on the optimal doses of fibrinolytic agents for the pediatric population, especially for neonates. tPA is the agent of choice, with the most common dose and duration of treatment being 0.5 mg/kg/h infused over 6 hours.[10]

Platelets

Platelet production starts around the end of the first trimester of gestation and reaches adult levels in the middle of the third trimester. Therefore, platelet counts in term and premature newborns and children are not different from those in adults. Similarly, mean platelet volume and platelet ultrastructure in neonates and children closely resemble those in adults. Yet, all the main platelet functions are deficient at birth. Neonatal platelets exhibit reduced phospholipid metabolism, calcium mobilization, granule secretion, and aggregation in response to agonists compared with platelets from children or adults.[11] Although thrombocytopenia is common in neonates, thrombocytosis is rare and is associated with prematurity.

There are two proposed theories behind the reduced platelet function at birth. One hypothesis suggests that platelet activation and degranulation at the time of labor and delivery leads to exhausted circulating platelets; the other suggests that intrinsic platelet peculiarities account for the reduced reactivity of neonatal platelets. Studies of platelets from neonates reveal reduced aggregation in response to agonists, such as ADP, epinephrine, collagen, thrombin, and thromboxane analogues. This is especially true when platelets from preterm infants are studied. Flow cytometry studies using labeled monoclonal antibodies against platelet activation markers also reveal that platelets from cord blood or from neonates on the first postnatal day are hyporeactive compared with adult platelets.[11] This decreased responsiveness is transient, and the platelets usually regain normal reactivity 10 to 14 days after delivery.

Despite the reduced platelet reactivity at birth, platelet adhesion may be enhanced because of higher levels of functionally more potent high-molecular-weight vWF multimers in the plasma. Consistent with this concept, the bleeding time and the platelet function analyzer (PFA-100) closure time are shorter in neonates than in children and adults.[11] In healthy neonates, enhanced platelet adhesion immediately after delivery may compensate for the reduced platelet activation in response to agonists. Nonetheless, sick neonates may be at increased risk for bleeding.[11]

The PFA-100 closure time is preferred over the bleeding time as a means of assessing platelet-related hemostasis. Bleeding time is an in vivo screening test that reflects the interaction between platelets and the blood vessel wall, but the results are as variable in neonates as they are in children and adults (see Chapter 127). Although the PFA-100 will not detect mild defects in platelet function, such defects rarely cause serious bleeding in neonates.

The Vessel Wall

Studies in vitro and in neonatal animals suggest that the endothelium in neonates has greater antithrombotic potential than that in adult vessels. In both rabbit venous and aortic models, neonatal endothelium expresses more heparan sulfate proteoglycans than adult endothelium, which results in greater AT-mediated anticoagulant activity in rabbit pups compared with adult rabbits. Circulating levels of endothelial cell adhesion markers vary with age, implying dynamic expression and/or secretion of these proteins as a function of age (see Chapter 122).

BLEEDING DISORDERS IN PEDIATRICS

Significant bleeding in children should prompt clinical evaluation. In sick children, acquired factor deficiencies or thrombocytopenia are frequently to blame, but rare congenital factor deficiencies can also manifest with bleeding. Initial empirical therapy consists of platelet

and/or factor supplementation, which is often administered while diagnostic studies are under way.

Evaluation of the Bleeding Child

Age, gender, presentation, birth and neonatal history, surgical history, family history, and medication use are each important in the evaluation of a child with hemorrhagic complications. Bleeding symptoms, such as epistaxis, occur in healthy children and do not always necessitate evaluation for an underlying bleeding disorder. It is important to consider frequency, duration, and severity of these symptoms to identify which children require testing. Table 148.3 highlights bleeding phenotypes in children that are concerning for an underlying bleeding disorder. Along with personal history, family history, such as bleeding tendencies, parental ethnicity, and history of consanguinity, may help to identify congenital bleeding disorders. A negative family history does not exclude an inherited bleeding disorder, especially X-linked and autosomal recessive disorders. In hemophilia, for example, up to one-third of patients have a negative family history.[12] Pregnancy and delivery history, such as maternal infection, drug use, or immune thrombocytopenia (ITP), can provide important clues in cases of neonatal bleeding.

On physical examination, the location and characteristics of the bleeding (e.g., procedural, mucosal, cutaneous, intracranial, visceral), whether diffuse or localized, and the general appearance of the child as sick or well, may help to identify the underlying etiology of the hemorrhage. In ill-appearing children, disseminated intravascular

TABLE 148.3 **Bleeding Phenotypes Concerning for an Underlying Bleeding Disorder**

Umbilical stump bleeding in a newborn
Greater than expected bleeding post-circumcision
Mucocutaneous bleeding lasting >30 min or requiring surgical intervention (ex. cauterization)
Greater than expected bleeding after surgery or minor procedures (e.g., dental extraction)

Spontaneous intracranial hemorrhage
Spontaneous gastrointestinal bleeding
Spontaneous joint, muscle or soft tissue bleeding
Heavy menstrual bleeding in a female with prior history of mucocutaneous bleeding

coagulation (DIC) or liver disease may result in acquired factor deficiencies (see Chapter 137). These disorders tend to present with diffuse bleeding. Well-appearing children are more likely to have localized bleeding or ecchymoses because of thrombocytopenia, von Willebrand disease, platelet function defects, or a rare inherited factor deficiency.

Laboratory evaluation of bleeding in children should include sepsis evaluation and determination of the platelet count, PT/international normalized ratio (INR), aPTT, thrombin time, and fibrinogen concentration (Table 148.4). If the test results are normal, children with a history of bleeding should have levels of FXIII, α_2AP, and PAI-1 activity determined because deficiencies of these proteins are not detected with routine screening. The approach to laboratory screening in neonates is summarized in Fig. 148.1, which has been modified from Blanchette and Rand.[13] Platelet function should be evaluated when primary hemostatic defects are suspected.[14] In children with a family history of hemophilia or when hemophilia is suspected, the levels of FVIII and FIX should be determined regardless of the extent of aPTT prolongation.

Thrombocytopenia

The following factors are important to consider when evaluating children with thrombocytopenia: congenital or acquired, sick or well, maternal antibody or drug (in case of neonates), and platelet size. Thrombocytopenia is defined as a platelet count less than 150 × 10^9/L.[15] Causes of thrombocytopenia in children include decreased platelet production, increased platelet consumption, and/or hypersplenism (Table 148.5). Other contributing factors include infection, placental insufficiency, genetic disorders, medications, DIC, or immune deficiency. Rare causes of decreased platelet production in children include primary congenital platelet or marrow disorders and infiltrative disorders.

Neonatal Thrombocytopenia

Platelet counts in the range of 100 to 150 × 10^9/L are common in healthy neonates; these mostly reflect transient thrombocytopenia and require no further investigation unless there is an ongoing decrease in the count. More severe thrombocytopenia (platelet count <50 × 10^9/L) in neonates rarely manifests with bleeding, particularly in the absence of maternal antiplatelet antibodies (see Chapter 129). The estimated prevalence of thrombocytopenia is in the range of 1% to 5% of all newborns. The prevalence of thrombocytopenia increases to 22% to 35% in neonates admitted to the neonatal intensive care unit (NICU), with the rates increasing with decreasing gestational age. With severe thrombocytopenia, platelet transfusion may be necessary to treat or decrease the risk of bleeding.

APTT, Activated partial thromboplastin time; *HMWK*, high-molecular-weight kininogen; *INR*, international normalized ratio; *PT*, prothrombin time; *vWD*, von Willebrand disease.

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia is the platelet equivalent of hemolytic disease of the newborn. It affects approximately 1 in 2000 pregnancies. When fetal platelets express paternal antigens (HPA) that the mother lacks, transplacental passage of maternal immunoglobulin G directed against fetal platelets can occur and usually results in severe neonatal thrombocytopenia (platelet count <30 × 10^9/L). This may result in major bleeding, particularly ICH, which can occur in 10% to 20% of untreated pregnancies.[15] Incompatibilities for HPA-1a account for the majority of cases of neonatal alloimmune thrombocytopenia in populations of European ancestry. About half of the cases of neonatal alloimmune thrombocytopenia occur in the first pregnancy because fetal platelets pass into the maternal circulation early in the pregnancy. Treatment options include transfusion of antigen-negative platelets if available (HPA-1a ± 5b). Although large, randomized studies are lacking, the threshold count for platelet transfusion in most studies is 30 × 10^9/L. High-dose intravenous immunoglobulin and/or a trial of random donor platelets can be given if compatible platelets are unavailable. The recommended total dose of intravenous immunoglobulin is 1 to 2 g/kg administered either at a dose of 0.4 g/kg daily for 3 to 5 days or at a dose of 1 g/kg daily for 1 or 2 days.[16]

Immune Thrombocytopenia

ITP is a common cause of symptomatic thrombocytopenia in children with an annual incidence of 1 to 6.4 per 100,000.[17] Although ITP can occur at any age, its incidence peaks in children 2 to 5 years of age (see Chapter 129). ITP is classified as newly diagnosed (<3 months), persistent (3 to 12 months), or chronic (>12 months) based on the duration of symptoms and the thrombocytopenia.[18] ITP generally presents in an otherwise healthy child, who may have a history of preceding viral illness with a sudden onset of petechial rash, bruising, and/or bleeding. While bleeding symptoms are variable, the majority of children have mucosal bleeding (40%), and only 3% have serious bleeding requiring blood transfusion and/or hospitalization. Intracranial hemorrhage (ICH) is rare and occurs in less than 1% of children with ITP.[19] The diagnosis of ITP is based on typical presentation, isolated thrombocytopenia (platelets <100,000 × 10^9/L), and an absence of features suggestive of an alternate diagnosis

(e.g., signs and symptoms of malignancy or autoimmune conditions, abnormal white count or hemoglobin on CBC, and abnormal peripheral blood smear among others). The management of newly diagnosed ITP patients is based on severity of bleeding symptoms, degree of thrombocytopenia, and medical and social history. Options include observation alone or one of glucocorticoids, IVIG, or anti-D immune globulin. All patients should be advised to restrict high-risk activities and to avoid antiplatelet and anticoagulant medications. Most children with ITP recover within 3 to 6 months, while 10% to 20% go on to have chronic ITP. Risk factors for chronic ITP include older age, lack of preceding infection, and less severe thrombocytopenia. Options for managing chronic ITP include rituximab, thrombopoietin receptor agonists (romiplostim, eltrombopag), splenectomy, and other immunosuppressive medications (see Chapter 129).

Platelet Function Disorders

Qualitative platelet disorders are rarely associated with overt bleeding in young age. Patients presenting with bleeding who have normal coagulation test results and platelet counts require further investigation. Bleeding may be from mucocutaneous sites, sites of blood sampling and procedures, or may present as cephalohematoma and umbilical stump bleeding in neonates. Platelet function disorders range from defects in several structures and signaling pathway as outlined in Table 148.6. Only the most severe genetic disorders of platelet function present in the neonatal period. These include Glanzmann thrombasthenia and Bernard-Soulier syndrome (see Chapter 124).

Platelet function is affected by commonly used medications, such as aspirin and non-steroidal anti-inflammatory drugs (e.g., ibuprofen, naproxen). Herbal medicines, such as ginkgo biloba, are also known to alter platelet function and can cause bleeding symptoms. In neonates, common medications, such as nitric oxide, prostaglandin E_2, and indomethacin, can affect platelet function (see Chapter 128).

It is challenging to diagnose platelet function disorders in neonates and young children because of the technical limitations of platelet function assays and the need for large volumes of blood for testing (see Chapter 127). Initial screening for suspected platelet function disorders can be performed using the PFA-100 analyzer, followed by evaluation of platelet morphology and platelet aggregation responses using light transmission aggregometry. Flow cytometry can be used to evaluate specific surface glycoproteins and electron microscopy studies can be used to assess platelet granule morphology (see Chapter 124). Absent platelet aggregation in response to all agonists and deficiency of αIIbβ3 on flow cytometry are diagnostic for Glanzmann thrombasthenia (see Chapter 124). Flow cytometry also provides definitive diagnostic information about Bernard-Soulier syndrome, dense granule deficiency, and Scott syndrome.

Platelet transfusions are often given if the patient is bleeding. However, the potential risk of HLA allosensitization if normal platelets are given to patients with congenital deficiency of platelet surface antigens must be weighed against the severity of bleeding when functional defects are suspected. It is recommended that platelet transfusion be restricted to patients with Glanzmann thrombasthenia. Recombinant activated FVII (rFVIIa) has been used to manage serious bleeding and avoid the need for platelet transfusion. Other adjunctive local measures include topical thrombin, fibrin sealants, and antifibrinolytic medications, such as tranexamic acid.

TABLE 148.5 Classification of Thrombocytopenia

Inherited Coagulation Disorders

Isolated Prolonged Prothrombin Time/INR

Isolated prolonged PT/INR can be secondary to factor VII deficiency or vitamin K antagonists (e.g., warfarin). Inherited FVII deficiency is a rare, autosomal recessive condition with a strong gene dosage effect (see Chapter 135). Neonatal bleeding can occur in severe cases (i.e., homozygosity or compound heterozygosity for two mutations in the FVII gene). FVII deficiency can be associated with microcephaly or midline defects because disruption of chromosome 13q can lead to loss of adjacent genes. As a vitamin K-dependent protein, FVII deficiency can occur in association with deficiencies of the other vitamin K-dependent clotting proteins with abnormalities of the vitamin K pathways. Low doses of rFVIIa can be used for treatment of isolated FVII deficiency; FFP and/or vitamin K can be used for management of combined deficiencies.

Isolated Prolonged Activated Partial Thromboplastin Time

Isolated prolonged aPTT can be secondary to deficiencies of factors VIII, IX, XI, XII, HMWK, or prekallikrein and specific or nonspecific antibodies (e.g., lupus anticoagulant) affecting these factors (see Chapters 127 and 139). Evaluation for FVIII, FIX, and FXI deficiencies should be undertaken immediately in any child with bleeding symptoms and isolated prolongation of the aPTT or a positive family history. Deficiencies of FXII, HMWK, and prekallikrein are associated with prolonged aPTT but do not contribute to bleeding symptoms (see Chapter 135). Neonates have a physiologically prolonged aPTT compared with older children and adults; hence, age-appropriate reference ranges must be utilized (see Table 159.2).[1,2]

Prolonged Prothrombin Time/INR and Activated Partial Thromboplastin Time

The association of bleeding with prolongation of both the PT/INR and the aPTT in otherwise healthy children may indicate vitamin K deficiency or congenital deficiencies of prothrombin, FV or FX, as well as rare combined deficiencies (see Chapters 127 and 135). Routine prophylactic administration of vitamin K to newborns can complicate the diagnosis of neonatal bleeding related to vitamin K deficiency.[20] More commonly, combined PT and aPTT prolongation occurs in sick children with DIC or severe hepatic disease. Combined factor deficiencies are rare but must be considered when the laboratory findings or clinical course is confusing. Autosomal recessive mutations in LMAN1 (ERGIC-53) or MCFD2 can lead to combined FV and FVIII deficiency because of defective intracellular processing of the factors (see Chapter 135). Mutations in γ-glutamyl carboxylase are associated with inherited combined deficiencies of all the vitamin K-dependent proteins. FVII deficiency has rarely been reported in combination with FV, FVIII, FIX, FX, FXI, and protein C defects, as reviewed by Girolami et al.[21]

Hemophilia

Hemophilia is one of the most common inherited coagulation disorders, as discussed in detail in Chapter 134. Hemophilia A is caused by FVIII deficiency and hemophilia B is caused by FIX deficiency. In newborns with a family history, cord blood samples can be used for diagnosis of hemophilia A, thereby avoiding the need for peripheral venipuncture. In term and preterm infants, FVIII levels are within the normal adult range despite physiologic differences in the hemostatic system. Thus, confirmation of hemophilia A is possible in the neonatal period. However, because the levels of the vitamin K-dependent clotting factors, including FIX, are reduced at

TABLE 148.6 Inherited Disorders of Platelet Function

Defects in Receptors for Adhesive Proteins

Abnormalities of Membrane Phospholipids
Scott syndrome
Stormorken syndrome

Modified from Israels SJ, El-Ekiaby M, Quiroga T, et al. Inherited disorders of platelet function and challenges to diagnosis of mucocutaneous bleeding. *Haemophilia.* 2010;16:152.

[a] Can manifest in neonatal period.

birth (and even lower in preterm infants), diagnosis of hemophilia B is difficult until older age.

The reported incidence of hemophilia A and B are 1/5000 males and 1/20,000 males, respectively.[12] Hemophilia is more common in males than females, given the location of both the FVIII and FIX gene on the X chromosome. However, severe FVIII or FIX deficiency can, albeit rarely, present in females, such as in Turner syndrome or with extreme Lyonization. Approximately one-third of cases of hemophilia are the result of spontaneous mutations; consequently, a family history may be lacking. Evaluation of hemophilia carrier status in mothers of unknown status (e.g., single prior affected child or positive history in maternal grandfather) can be performed genetically because factor levels in carriers are variable and can overlap with normal levels. The bleeding phenotype in hemophilia patients can vary from mucocutaneous bleeding to spontaneous joint and muscle bleeding. Most bleeding episodes in newborn males occur after circumcision or umbilical stump separation, although ICH is reported in approximately 3.5% of newborns with hemophilia,[22] and cephalhematoma is common. Joint bleeding is unusual in infancy until the child starts to bear weight. Children with hemophilia A or B are treated with recombinant FVIII or FIX concentrates, respectively. Routine prophylaxis is rarely indicated in infancy unless there is significant bleeding. Children generally start prophylactic treatment around 1 year of age. For further details of hemophilia treatment and prognosis, see Chapter 134.

von Willebrand Disease

vWD is the most common inherited bleeding diathesis with an estimated prevalence of 1%. It is described in detail in Chapter 133. There are three types of vWD: type 1 is a partial quantitative defect, type 2 is a qualitative defect, and type 3 is a complete quantitative defect. Children with vWD most commonly present with mucocutaneous bleeding or bleeding after dental/surgical procedures. vWD is rarely associated with neonatal bleeding. In a case series that included 55 newborns with vWD, there were no bleeding complications, although cases of scalp hematomas and bleeding after vitamin K injection or umbilical stump detachment were reported. A family history of vWD, especially type 2 vWD, should prompt vWD evaluation in children before circumcision and possibly before intramuscular injections. The laboratory testing for vWD includes vWF antigen, vWF activity, factor VIII assay, and vWF multimer distribution (if required). The diagnosis of vWD may be difficult in infancy because vWF concentrations are high at birth, and there is a large proportion of high-molecular-weight vWF multimers (see Chapter 127). Children with a diagnosis of type 3 vWD should be tested for mutations that predispose them to inhibitory alloantibody formation before aggressive replacement with exogenous vWF.[23] Treatment of children with severe vWD involves administration of plasma-derived concentrates that contain vWF (e.g., Humate-P or Alphanate), dosed initially at 40 to 60 ristocetin cofactor units/kg.

FXIII Deficiency

FXIII is a transglutaminase that cross-links fibrin, thereby rendering it resistant to lysis. FXIII deficiency is inherited in an autosomal recessive manner, and the prevalence of FXIII deficiency is estimated to be 1 in 3 to 5 million (see Chapter 135). Homozygotes usually have FXIII levels of less than 1% and have a severe bleeding diathesis. Patients with heterozygous FXIII deficiency are usually asymptomatic but have reduced levels of FXIII.[24] Children with FXIII deficiency may present with umbilical bleeding a few days after birth, a frequent finding that occurs in 80% of cases. More severe bleeding, including ICH, occurs in 25% to 30% of patients, a frequency higher than that in patients with hemophilia. ICH is the major cause of death and disability in children with FXIII deficiency, and ICH in a child with no other risk factors should prompt a search for FXIII deficiency. FXIII deficiency is not detected with screening PT, aPTT, or thrombin time assays. Specific assays for FXIII or urea clot solubility testing are used for diagnosis (see Chapter 127). The clot solubility test is sensitive to very low levels of FXIII (<1%) but is normal if FXIII levels are in the 1% to 3% range. Consequently, FXIII immunoassays are perferable.[24] Treatment of FXIII deficiency includes FFP, cryoprecipitate, or FXIII concentrates. Recombinant FXIII concentrate contains the alpha subunit only, whereas plasma-derived FXIII concentrate contains both alpha and beta subunits. Most patients have alpha subunit deficiency and can, therefore, be treated with either. However, patients with beta subunit–related FXIII deficiency require plasma derived FXIII concentrate. Prognosis is excellent, but affected patients face a lifelong risk for bleeding and those with severe deficiency require prophylaxis. In 2013, the US Food and Drug Administration approved a new recombinant FXIII A subunit for use for routine prophylaxis in patients with FXIII deficiency.

Other Rare Inherited Factor Deficiencies

Autosomal recessive deficiencies, in either homozygous or compound heterozygous state, are grouped as rare coagulation disorders that can manifest as severe bleeding diatheses. Severe deficiencies of fibrinogen, FV, FVII, FX, and FXIII (isolated or in combination) are the most likely disorders to present with bleeding conditions. One common feature of these disorders is the association with ICH.[25] Deficiency of fibrinogen can manifest with bleeding in the soft tissues, bleeding after circumcision, or bleeding after umbilical stump detachment. The diagnosis can be established with fibrinogen assays, and treatment involves replacement with cryoprecipitate or, if available, fibrinogen concentrate (see box on Recommended Dosing for Transfusion in Neonatal Hemorrhage). Severe FXI deficiency is more prevalent in Ashkenazi Jews and can present with bleeding in newborns after hemostatic challenges, such as circumcision. FV and prothrombin deficiencies are the other rare autosomal recessive homozygous deficiencies that can cause hemorrhagic symptoms.[14] Autosomal recessive deficiencies of α_2AP and PAI-1 have also been associated with bleeding in childhood and adult age. Not all deficiencies result in a bleeding diathesis.

RECOMMENDED DOSING FOR TRANSFUSION IN NEONATAL HEMORRHAGE

PRBC: 10–15 mL/kg single-donor PRBC infused over 4 h
Platelets[a]: 10 mL/kg raises platelet count by 75,000 (goal >50,000 if bleeding, >20,000 if not bleeding)
FFP: 10–20 mL/kg every 6–12 h for purpura fulminans
Cryoprecipitate: 0.15 units/kg raises fibrinogen about 100 mg/dL (goal >150 mg/dL if bleeding, >50 mg/dL if not bleeding)
vWF: 40–60 ristocetin cofactor units/kg of plasma-derived FVIII/vWF preparations
Factor VIII: for hemophilia A—50 units/kg load, then 25 units/kg every 12 h; recombinant factor preferred (monitor FVIII)
Factor IX: for hemophilia B—80–100 units/kg daily; recombinant factor preferred (monitor FIX)
Factor VIIa: for severe factor VII deficiency—20–30 mcg/kg every 6–12 h

[a] Volume limits transfusion of platelets by the "unit" in small neonates. Practices vary—follow institutional guidelines for volume dosing or volume reduction.
FFP, Fresh frozen plasma; *PRBC*, packed red blood cells; *vWF*, von Willebrand factor.

Liver Disease

Liver disease in children may be caused by viral hepatitis, parenteral nutrition, cholestasis, hypoxic injury, or metabolic disease. Rare disorders that cause liver failure include hereditary tyrosinemia, neonatal hemochromatosis, and hemophagocytic lymphohistiocytosis. Liver dysfunction can affect the hemostatic balance resulting in activation of the coagulation and fibrinolytic systems, reduced synthesis of coagulation factors, poor clearance of activated hemostatic components, thrombocytopenia, platelet dysfunction, loss of coagulation proteins into ascites fluid, and failure to utilize vitamin K.[26]

Due to reduced synthesis of multiple coagulation proteins, laboratory workup typically reveals a prolonged PT and aPTT. Acute liver disease also results in elevated liver enzyme levels, direct hyperbilirubinemia, and elevated ammonia concentrations. The platelet count may be reduced, especially if hypersplenism is present, and platelet dysfunction is common. Hypofibrinogenemia is a late manifestation of liver disease, and elevated levels of fibrin degradation products and D-dimer mainly reflect delayed hepatic clearance. Assays of FV, FVII, and FVIII can help distinguish between liver disease, vitamin K deficiency, and consumptive coagulopathy (e.g., DIC). FV and FVIII are not vitamin K-dependent clotting factors. FV is synthesized in the liver, whereas FVIII is synthesized in multiple cell types, and the levels of both in children are similar to those in adults. Deficiency of all three implies consumption, whereas decreased levels of FV and FVII with a normal FVIII level suggest liver disease (see Chapter 137).

Treatment should include replacement with FFP and/or cryoprecipitate, as well as platelet transfusion. Fibrinogen concentrate has been used as an alternative to cryoprecipitate. Patients with biliary atresia or other cholestatic liver failure syndromes may also benefit from parenteral vitamin K. The outcome is dependent on treatment of the underlying cause of liver disease.

Vitamin K Deficiency and Bleeding in Neonates and Infants

Vitamin K is an essential cofactor for γ-glutamyl carboxylase, the enzyme required for posttranslational carboxylation of prothrombin, FVII, FIX, and FX, and proteins C, S, and Z. Many newborns are deficient in vitamin K. Risk factors for bleeding with vitamin K deficiency include maternal malabsorption, maternal intake of drugs that impair vitamin K metabolism, exclusive breastfeeding, and neonatal malabsorption. Classification is based on the time of presentation. Early vitamin K deficiency–associated bleeding occurs in the first 24 to 48 hours of life and is associated with maternal intake of drugs (e.g., phenytoin, barbiturates, antibiotics), which cross the placenta and impair vitamin K synthesis. Classical vitamin K deficiency–associated bleeding manifests from days 2 to 7 of life and is related to low placental transfer of vitamin K, low concentrations of vitamin K in breast milk, lack of gastrointestinal bacterial flora, and poor oral intake. Gastrointestinal bleeding is the most common presentation, but procedural bleeding, bruising, or ICH can occur. Late-onset vitamin K deficiency–related bleeding can occur at up to 12 weeks of age, usually in association with exclusive breastfeeding or with neonatal fat malabsorption, and often manifests as catastrophic bleeding, including ICH. Congenital vitamin K deficiency is an autosomal recessive disorder that occurs because of mutations in the genes encoding γ-glutamyl carboxylase or the vitamin K2,3–epoxide reductase complex. Neonates with this disorder often have severe bleeding, including ICH. Genotype analysis is necessary to confirm the defects.[27]

Prophylaxis with a single dose of vitamin K (0.5 to 1 mg) in the delivery room prevents early- and classic-onset bleeding. Although oral dosing may be effective, because of the potential for impaired absorption, regurgitation, or noncompliance, parenteral administration by the intramuscular, subcutaneous, or intravenous route is preferred. Additional doses of oral vitamin K should be given at days 7 and 28 in breastfed infants. Vitamin K–induced coagulopathy should be treated with vitamin K, which can be given by slow intravenous infusion or by subcutaneous injection (to minimize anaphylactoid reactions). If there is bleeding, fresh frozen plasma (FFP) at a dose of 10 to 15 mL/kg body weight can be given. The overall prognosis of vitamin K–deficiency bleeding is good.

Intraventricular Hemorrhage in Neonates

Intraventricular hemorrhage (IVH) is associated with significant morbidity and mortality in the newborn period, particularly in premature infants. In the United States, it is estimated that approximately 12,000 premature infants and 20% to 25% of very low-birth-weight infants develop IVH each year. With improvements in neonatal care, the incidence of IVH is decreasing.

The etiology of IVH is multifactorial and includes prematurity of the cerebral vasculature and ischemia-reperfusion injury related to ventilatory support, blood pressure lability, and extracorporeal membrane oxygenation (ECMO). Other risk factors for IVH include vaginal delivery, severe respiratory distress syndrome (RDS), low Apgar scores, pneumothorax, hypoxia, hypercapnia, seizures, patent ductus arteriosus, and infection. Many of these risk factors induce IVH by altering cerebral blood flow. Coagulopathy and thrombocytopenia can contribute to IVH, but their role in the pathogenesis of IVH is uncertain. One study reported hypofibrinogenemia, thrombocytopenia, or prolonged clotting times in 11 of 15 neonates with IVH and in only 5 of 35 unaffected newborns. Hemorrhage complicating cerebral vein thrombosis may explain some cases of IVH (especially in full-term infants), and heterozygosity for the FV Leiden mutation was reported in 18% of neonates with grade 2 to 4 IVH compared with 3% of controls. Cerebellar hemorrhage should raise suspicion of organic acidemia, such as methylmalonic, propionic, or isovaleric acidemia.

Vitamin K, indomethacin, AT, FFP, FXIII, tranexamic acid, and ethamsylate has been evaluated for prevention of IVH with mixed results. rFVIIa may be useful for treatment of IVH, but additional studies are needed to determine its efficacy and safety.

CLOTTING DISORDERS IN PEDIATRICS

The incidence of thromboembolism (TE) has a bi-modal peak in children, with an increased occurrence in newborns and adolescents. Initial registry data from Canada and Denmark estimated the incidence of neonatal TE to be 2.4 per 1000 admissions to neonatal intensive care and 4.1 per 100,000 live births, respectively.[28,29] In the contemporary era, it is reported to be as high as 15 per 1000 neonatal intensive care admissions.[30] Pediatric TE is uncommon with a reported incidence of 0.07 to 0.14 per 10,000 for venous TE,[29,31] the majority of which are provoked.[32] Due to improved diagnostic modalities, increased awareness, greater use of central venous lines (CVLs), the incidence is reportedly rising.[32–34] Pediatric TE is more common in hospitalized children (venous TE incidence: 30 to 58 per 10,000 hospital admissions).[33,35] Idiopathic venous TE is rare with an incidence of 3% to 4% and is frequently recognized in older age groups, post-pubescence, and in the presence of at least two prothrombotic risk factors.[29,31]

Important risk factors for the development of TE include vascular catheterization, infection, surgery, immobilization, thrombophilia, and co-morbidities, such as congenital heart disease, nephrotic syndrome, necrotizing enterocolitis, and asphyxia.[4] Laboratory workup often reveals a hypercoagulable state, such as decreased levels of AT, protein C, or protein S; defective fibrinolysis; hyperactive platelets; elevated levels of clotting factors (i.e., fibrinogen, FVII, FVIII); and the presence of antiphospholipid antibodies or thrombophilic defects, such as FV Leiden or the prothrombin gene mutation.[1,2,4] A family history of TE or miscarriages may indicate a hereditary thrombophilia.

Consensus guidelines have been developed for the management of TE.[10] Heparin, either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), remains the mainstay of treatment in newborns and children. Direct oral anticoagulants (DOACs) are now being increasingly utilized in children. Dabigatran and rivaroxaban are now approved in the USA and Canada, respectively, for the treatment of venous TE (VTE) in children. If the thrombus is limb- or life-threatening, thrombolytic therapy may be considered. Long-term sequelae of TE in children include incomplete thrombus resolution, post-thrombotic syndrome, pulmonary insufficiency, pulmonary hypertension, recurrence, organ dysfunction, paradoxical embolism, and mortality.[36] Duration of anticoagulation depends on the individuals age, persistence of risk factors, thrombus resolution, and location of the thrombus. Most children are treated between 6 weeks to 6 months with anticoagulation. Provoked VTE in children is treated for 3 months like in adults. However, the practice will likely change in the near future with the recent publication of a randomized controlled trial showing non-inferior outcomes with shorter duration of treatment (6 weeks) in children with provoked VTE and no history of severe anticoagulant deficiencies or prior thrombosis.[37] Recurrence ranges from 3% in neonates to 12% in older children, although this number is as high as 21% in children diagnosed with first unprovoked venous TE.[38]

Risk Factors for Pediatric Thrombosis

Virchow's triad of endothelial damage, hypercoagulability, and venous stasis are the cornerstones of development of TE in childhood. Risk factors can be inherited or acquired and may be patient-, disease-, or treatment-related (Table 148.7). Unlike adults, most childhood TEs are associated with multiple risk factors. A registry in the Netherlands reported at least two risk factors were present in 81% of children diagnosed with VTE between 1 month and 18 years of age.[29] Acquired risk factors include central venous access devices, malignancy, trauma, prematurity, severe infection, inflammatory disease, dehydration, and reduced mobility (see Table 148.7). Acquired thrombophilia often reflects chronic diseases states or treatments, which result in high levels of inflammatory cytokines, release or increased expression of tissue factor, diminished fibrinolysis, and imbalance of natural anticoagulants and procoagulants.[39]

Indwelling Catheters

Central venous and arterial access is essential for the advanced care of neonates, infants, and children. CVLs are the single most important acquired risk factor for developing TE in childhood, and are responsible for approximately one-third of all cases of deep vein thrombosis (DVT) in children, mostly in the upper extremites.[31] Indwelling vascular catheters are also the most common acquired thrombotic risk factor in neonates. In a literature review by Park et al.,[40] the incidence of TE in neonates with central venous catheters was 9.2%. Duration of catheter implantation, infusion of blood products and malposition of umbilical venous catheters were found to be important risk factors. The most frequently reported sites of thrombosis in neonates are hepatic veins, right atrium, and inferior vena cava.[41] During childhood, CVL-related thrombosis is frequently diagnosed in the superior vena cava and in the femoral and iliac veins.[29]

The incidence of catheter-associated DVT is influenced by the method of detection. When catheters are used for total parenteral nutrition, it is estimated that DVT is diagnosed in 1% on clinical grounds, in 35% by echocardiography, and in 75% by venography. While contrast venography is regarded as the reference standard for the diagnosis of thrombosis in neonates and children with central venous catheters, ultrasonography is more commonly used because it is noninvasive, easy to perform at the bedside, and it does not expose patients to ionizing radiation.

DVT often causes pain, swelling, and discoloration of the affected limb. Loss of catheter patency, evidence of collateral circulation, and/or unexplained thrombocytopenia should raise the suspicion of DVT. Prospective imaging studies performed before central access catheter removal demonstrate thrombi in up to 86% of patients.[29] Treatment often begins with removal of the catheter, although consideration of anticoagulation before catheter removal is warranted, especially in children with right-to-left intracardiac or intrapulmonary shunting. Small catheter-associated thrombi may resolve without specific therapy. Larger thrombi or those in locations associated with greater morbidity (e.g., sinovenous, renal, portal) may warrant short courses of heparin or thrombolytic agents.[10] Platelets should never be administered through arterial catheters because of the potential risk for TE.

Hereditary Thrombophilia

Inherited thrombophilia plays an important role in development of TE in childhood. It is associated with first onset pediatric venous TE with odds ratios between 2.63 and 8.73.[38,42] The most common inherited thrombophilias include deficiencies of AT, protein C, protein S, Factor V Leiden, and prothrombin gene mutation.[42] Other inherited thrombophilic conditions include elevated lipoprotein(a), maternal anticardiolipin antibodies, and nonspecific inhibitors (see Chapter 138). Studies have shown an increased risk of recurrent VTE in children with thrombophilia, particularly in individuals with two or more genetic abnormalities.[38] However, most individuals diagnosed with thrombosis and thrombophilia have at least one clinical predisposing risk factor, demonstrating that thrombophilia alone may be insufficient to trigger thrombosis in this population.[42]

Hereditary thrombophilia should be suspected in patients with spontaneous and extensive TE, ischemic skin lesions, or purpura fulminans within the neonatal period. Suspicion should be highest in children with a family history of thrombosis, particularly unprovoked VTE.[39] The Subcommittee for Perinatal and Pediatric Thrombosis

TABLE 148.7 Risk Factors for Thrombosis in Neonates and Children

Patient-Related	
Age (<1 year old and ≥11)	
Post-pubertal	
Obesity (BMI > 95th percentile)	
Smoking	
Pregnancy	
Post-partum	
Anatomic anomalies (May-Thurner or thoracic outlet syndrome)	
Prematurity	
Inherited	
Thrombophilia	
• Antithrombin deficiency	
• Prothrombin gene mutation	
• Protein C deficiency	
• Protein S deficiency	
• Factor V Leiden	
Family history of VTE	
Disease-Related	
Malignancy (highest risk in leukemia, lymphoma, sarcoma)	
Inflammatory bowel disease	
Nephrotic syndrome	
Severe infection	
Congenital heart disease	
Trauma requiring ICU admission	
Altered/immobility (>72 h)	
Antiphospholipid antibodies	
Dehydration	
Treatment-Related	
Central venous/arterial catheters	
Orthopedic procedures	
ICU admission	
Surgery	
Total parenteral nutrition	
Medication	
• Chemotherapy (asparaginase, cisplatin, doxorubicin)	
• Steroids	
• Combined oral contraception	
Perinatal Risk Factors	
Maternal-associated conditions:	Neonatal risk factors:
Maternal infection	Central venous catheter
Placental disease	Sepsis
Maternal diabetes	Dehydration
Antiphospholipid antibody syndrome	Perinatal asphyxia
Hypertension	Congenital heart disease
Metabolic syndrome	Prematurity
C-section delivery	
Inherited thrombophilia	
Premature rupture of membranes	

of the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis recommended that pediatric patients with spontaneous TE be tested for a full panel of genetic and acquired thrombophilic defects.[43] However, because of the difficulty in obtaining a large volume of blood from neonates, one can consider performing these tests in stages unless the result of the testing has immediate impact on patient management. On initial presentation of TE, DNA-based assays can be performed. Testing for levels of natural coagulation inhibitors should be delayed until 6 months of age, when the levels approach those in adults, and until anticoagulant treatment is discontinued.

Diagnosis

Thrombosis can be asymptomatic or symptomatic with clinical manifestations dependent on the location. For example, cerebral vein thrombosis can present with headache, vomiting, focal neurologic deficits, or seizures. Patients with pulmonary embolism (PE) may present with shortness of breath and chest pain, while extremity DVT usually present with edema of the affected limb, pain, and skin discoloration.[29] Noninvasive tests are used to diagnose DVT, although historically, venography was the gold standard. Compression doppler ultrasonography is the most widely used noninvasive imagining modality, and it can be performed at the bedside of critically ill children. However, inability to compress the vessels of the upper central venous system, apart from the jugular veins, reduces the utility of this imaging modality. Cross-sectional imagining, such as magnetic resonance angiography/venography and computed tomography angiography/venography, are the primary imaging tools for assessment of veins and arteries in the brain, chest, and abdomen. Additionally, these imaging modalities are useful in assessing the clot burden or identifying anatomic abnormalities that may predispose patients to thrombosis, such as May-Thurner or thoracic outlet syndrome (TOS). The utility of biomarkers, such as D-dimer, which is useful in adults, requires further research in pediatrics.

Specific Neonatal Thrombotic Syndromes

Renal Vein Thrombosis

The renal vein is one of the most common sites of neonatal thrombosis. The incidence of renal vein thrombosis (RVT) is estimated to be 0.5 per 1000 NICU admissions and 2.2 to 2.6 per 100,000 live births.[28,41,44] RVT is more common in males than in females and in the left renal vein, although 28% to 44% occur bilaterally. Two-thirds of neonates with RVT presents within 3 days postnatally, and 7% of neonates can present with RVT in utero.[43] Most common clinical manifestations of RVT include hematuria, palpable flank mass, and thrombocytopenia. Neonates may also have co-existing hypertension, proteinuria, renal failure, adrenal hemorrhage, and anemia. RVT is associated with prematurity, umbilical venous catheters, diabetic mothers, asphyxia, and infections. Although FV Leiden, the prothrombin gene mutation, and elevated lipoprotein(a) have been associated with RVT, they are unlikely to be causal in most cases. Most infants with RVT will experience complete, cortical, or segmental infarction of the affected kidney and/or hypertension.[26] It is estimated that neonatal RVT increase risk of chronic kidney disease, hypertension, or death by 15.5-fold.[44]

Diagnosis is reliably confirmed by Doppler ultrasound examination. There are no evidence-based treatment guidelines, and most cases of RVT result in loss of renal tissue regardless of the treatment.[45] Neonates with RVT should be followed for persistent hypertension and progressive renal insufficiency. Unilateral RVT without uremia or clot extension into the inferior vena cava can be managed with heparin or LMWH. Treatment should be given for at least 3 months if there is extension into the inferior vena cava. Bilateral RVT with renal failure should be treated with thrombolytic therapy, followed by heparin or LMWH.[10] There is an ongoing registry by International Pediatric Thrombosis Network on neonatal RVT that shall help to derive more information on this entity.

Portal Vein Thrombosis

The true incidence of portal vein thrombosis (PVT) is unknown, but it is estimated to range from 1% to 43% of neonates with umbilical venous catheters or 36 per 1000 NICU admissions.[46,47] The wide variation in incidence reflects differences in imaging protocols. Major risk factors for PVT include umbilical venous catheters and sepsis/omphalitis. The role of inherited thrombophilia in PVT is controversial. There are multiple studies reporting on the association of inhibitor protein deficiencies (protein C, protein S, and AT) with PVT; however, it is difficult to ascertain whether the deficiencies are genetic or acquired because the testing is done after the diagnosis of PVT has been established.[46] Long-term complications of PVT include lobar atrophy of the liver and portal hypertension with associated gastrointestinal bleeding. Complications are more frequent with ectopic umbilical venous catheter placement (below or in the liver) or when thrombi are occlusive. Ultrasonography may reveal evidence of prior PVT with cavernous transformation of the portal vein and subsequent splenomegaly and reversal of portal flow.[48] Spontaneous resolution of PVT is common, but detection of PVT is important, even in asymptomatic patients, because PVT can lead to portal hypertension, which may manifest up to 10 years later.[48] Neonates with umbilical venous catheters should be monitored by ultrasonography, and catheter removal and/or anticoagulation therapy should be considered for PVT.

Cerebral Sinovenous Thrombosis

Based on data from the Canadian Pediatric Ischemic Stroke Registry, the prevalence of cerebral sinovenous thrombosis (CSVT) is 0.67 per 100,000 children, with 43% occurring in the neonatal period.[49] The clinical presentation may be relatively silent, or patients may manifest with diffuse neurologic changes, seizures, and IVH. The most frequently involved vessels are the superior and lateral sinuses, and up to one-third of cases have associated venous infarction and subsequent hemorrhage.[26] Up to 31% of full-term neonates with IVH have associated CSVT, suggesting that the pathophysiology of IVH in full-term neonates is different from that in premature infants.

Risk factors for neonatal CSVT include perinatal asphyxia, diffuse hypoxic injury, dehydration, infection, congenital heart disease, and severe illness, with ECMO now recognized as a specific risk factor. The frequency of hereditary thrombophilia in neonates with CSVT ranges from 20% to 40%, with FV Leiden and MTHFR C677T occurring most often. In contrast to purpura fulminans, no cases of congenital deficiencies of protein C, protein S, nor AT have been reported in association with CSVT. Multiple risk factors (maternal, neonatal, perinatal, or prothrombotic) are found in over half of neonates with CSVT.[10] Although the diagnosis of CSVT in neonates is often made by transcranial ultrasonography, magnetic resonance venography is the most sensitive diagnostic test. Based on data from the Canadian Pediatric Ischemic Stroke Registry, neonatal CSVT is associated with cerebral parenchymal infarcts in 42% of cases, and 83% of these are hemorrhagic infarcts.[49]

Aside from treatment of the underlying conditions, when relevant, there are no standard treatment guidelines. Nonetheless, good results have been obtained with anticoagulant therapy, and UFH or LMWH is given if there is no significant ICH. Extended treatment with LMWH or a vitamin K antagonist is recommended for a minimum of 6 weeks and no longer than 3 months.[10] The goal of anticoagulation is not to prevent recurrence; rather to prevent progression and minimize neurologic sequelae. In a study by Kenet et al.,[50] none of the 75 neonates with CSVT had a recurrence after a median follow-up of 36 months. For those with significant hemorrhage, radiologic monitoring in 5 to 7 days is recommended, and anticoagulation should be initiated if there is evidence of thrombus propagation.[10] Anticoagulation is associated with a high rate of hemorrhage, so treatment plans should be individualized. In older patients, punctate hemorrhage behind a cerebral venous infarct is not an absolute contraindication to anticoagulation, but studies in neonates are lacking. Nevertheless, in the Canadian registry, 36% of neonates were treated with UFH or LMWH, mostly for 3 months, and no cases of death or neurologic compromise from hemorrhage were reported.[49] Overall, neurologic impairment was reported in up to two-thirds of cases, and approximately 2% died.

Purpura Fulminans

Purpura fulminans is characterized by disseminated purpuric lesions often associated with bullae and necrosis. The histopathology of these lesions reveals diffuse cutaneous microthrombi with surrounding hemorrhage. Diffuse thrombosis, including stroke, retinal infarcts, limb gangrene, and DIC, can occur in purpura fulminans. Causes include severe protein C, protein S, or AT deficiency, either acquired as a complication of sepsis or inherited as homozygous or compound heterozygous conditions. Some infants with severe protein C deficiency do not develop TE until adulthood, suggesting that additional factors influence the neonatal presentation. Treatment with heparin and replacement with protein C concentrate or FFP are indicated. Long-term anticoagulation is often needed.[51]

Ischemic Stroke

Perinatal acute ischemic stroke (AIS) is an important cause of cerebral palsy, epilepsy, and cognitive impairment. Perinatal AIS mostly occurs in full-term neonates with a prevalence of 29 to 93 cases per 100,000 live births. Presenting features include seizures and lethargy. In the neonatal period, AIS often presents with focal or generalized seizures, although pathologic hand preference before 1 year of age is most common if the stroke was asymptomatic in the newborn period. Ischemic injury is usually detected by magnetic resonance angiography, and unilateral lesions favor the left hemisphere. Diffusion-weighted magnetic resonance imaging is superior to cranial ultrasonography or computed tomography scanning.[10]

Risk factors for perinatal AIS are different from TE risk factors in older infants and children because maternal and placental factors play a more important role, and some events even occur in utero.[52] The most common acquired risk factors for perinatal AIS are perinatal asphyxia, fetal distress, chorioamnionitis or other infections, preeclampsia, congenital heart disease, and dehydration. The contribution of congenital thrombophilia to perinatal AIS risk is unclear, although maternal anticardiolipin antibodies may be present for a brief period. In most cases of perinatal AIS, a hypercoagulable state is not detected. One potential mechanism of stroke is embolism of placental thrombi via the umbilical vein and through the patent foramen ovale of the fetus or neonate. Evaluation of placental pathologic conditions is important because demonstration of placental thrombi or abruption may be indicative of a maternal prothrombotic state. Furthermore, if placental thrombi are seen on histological examination, the risk for recurrent events is especially low. Long-term developmental outcomes depend on the extent of the stroke and location of the lesion; strokes involving Broca and Wernicke areas, the internal capsule, or the basal ganglia have a poor outcome.

Treatment depends on whether the stroke is embolic or nonembolic in origin. For nonembolic AIS, current guidelines recommend against anticoagulation or aspirin for neonates with first AIS, especially if the infarct is large or there is evidence of hemorrhage. Anticoagulant or aspirin therapy is recommended for neonates with recurrent AIS.[10] In a patient with a documented cardioembolic stroke, anticoagulant therapy is suggested.

Specific Pediatric Thrombotic Syndromes

Pulmonary Embolism

PE in children is rare, with an incidence of 0.1 to 0.9 per 100,000 overall[29] and 9 to 57 per 100,000 hospitalization children.[31] The epidemiology and pathophysiology are significantly different from that of the adult population. Most PE occurs in neonates. In adolescents, females may have a higher predilection possibly due pregnancy and hormonal therapy. Additionally, Black children have a twofold higher risk compared with White children. PE is associated with DVT in 30% to 60% of cases. Unprovoked PE in the pediatric population is rare, with more than 95% of children have an underlying condition that places them at risk of VTE.[53]

Severe PE can present with symptoms, such as pleuritic chest pain, dyspnea, hemoptysis, persistent tachycardia, hypoxemia, and fever. Massive PE causes complete obstruction of pulmonary flow and can present with concomitant hemodynamic instability or sudden death. Delayed diagnosis is not uncommon as symptoms are non-specific resulting in preliminary investigation of more common childhood illnesses.[53] Computed tomography pulmonary angiography (CTPA) is the diagnostic imaging modality of choice; however, diagnostic work-up should also assess clinical severity to guide management. Traditionally, ventilation perfusion (V/Q) lung scanning was used for the diagnosis of PE. However, such scans require cooperation of the child, and abnormalities may not be specific for PE.[53–55]

Treatment of PE is adapted from adult data and smaller pediatric studies. Pharmacologic treatment includes anticoagulation with either UFH or LMWH, followed by LMWH, vitamin K antagonist, or a DOAC. LMWH is the preferred agent in children without a significant bleeding risk. Thrombolysis, thrombectomy, or embolectomy is indicated in the setting of massive PE with associated hemodynamic instability. Thrombolysis can be catheter-directed or systemic. CHEST guidelines recommend anticoagulation for at least 3 months, or until resolution of precipitating risk factor for secondary PE.[10]

Anatomic Abnormality–Associated Thrombotic Syndromes

Anatomic abnormalities within the pediatric population increase the risk of DVT due to compression of major vessels, which results in reduced blood flow, endothelial perturbation and proliferation, collagen and elastin deposition, and, ultimately, partial or complete vessel occlusion.[56] This can result in extensive and life-threatening thrombosis, which may result in the need for thrombolysis, surgical intervention, or long-term anticoagulation.

May–Thurner Syndrome

May–Thurner syndrome (MTS) is an anatomic variant wherein the left iliac vein is compressed between the overlying right common iliac artery and the lumbar vertebrae. Iliac vein compression causes obstructed venous return and subsequent development of symptomatic DVT. MTS should be considered in adolescents with left-sided iliofemoral thrombosis. The risk of DVT in MTS is relatively low, with an incidence of 2% to 5%, and is often associated with prothrombotic risk factors, such as immobility, hormonal therapy, obesity, recent surgery, inflammatory syndromes, or underlying thrombophilia.[56–58] Diagnosis of DVT is initially made with compression Doppler ultrasound; however, diagnosing MTS requires cross-sectional imaging, such as MR or CT venography, or angiography, to identify the anatomic compression and to visualize the detailed vascular anatomy. There is no established treatment approach to MTS, and treatment is based on the extent of DVT and risk to life/limb. Treatment with anticoagulation, such as LMWH, is used to reduce the risk of progression, embolization, and recurrence. Catheter directed thrombolytic therapy has been utilized in this population without life or limb threatening ischemia and has shown to be effective in the treatment, but not in the prevention of recurrent thrombus.[57] Literature regarding stenting of the vasculature is limited, and complications, such as stent migration secondary to growth, stent narrowing, and thrombosis, should be considered if selecting this option.[57] Children and adolescents should be followed long term for the risk of recurrence and long-term side effects, such as post-thrombotic syndrome.[58]

Thoracic Outlet Syndrome

TOS, also known as Paget-Shroetter syndrome or axillary-subclavian vein effort thrombosis, is a neurovascular bundle disorder resulting from compression by the clavicle, first rib, and scalene muscles. Vascular damage is thought to be a consequence of repetitive venous injury related to arm use, hyperextension of the neck, or hyperabduction of the upper limb, which often occurs in activities that involve repetitive upper extremity movements, such as swimming, weightlifting, and baseball pitching.[59–61] Patients with TOS may present with symptoms of neck discomfort, upper limb weakness, sensory loss, or vascular symptoms, such as swelling, pain, distended superficial veins, heaviness of the limb, and discoloration of the skin of the affected extremity. A high index of suspicion is required in healthy active children and adolescents who present with these symptoms.[60] Clinical signs include a positive Wright maneuver, elevated arm stress test (EAST),[59] and Adson's test.[62] Doppler ultrasound with compression is the initial diagnostic modality of choice. However, due to technical limitations, contrast-enhanced CT or MR venography with the arm positioned in the resting and overhead position is suggested to provide increased accuracy.[60] Management is controversial, and there is no standard approach for treatment of children with TOS. Re-establishing venous flow and prevention of thrombus propagation is the preliminary aim of treatment. Therapeutic options include anticoagulation, thrombolysis, thrombectomy, and balloon angioplasty.[63] Long-term management options involve surgical decompression of the thoracic inlet, first rib resection, as well as supportive management, such as physiotherapy.[62] Timing of surgery is controversial and complications, such as hemothorax and pneumothorax, can occur.[61,63] Prolonged follow-up is required to assess for thrombus recurrence.

Principles of Therapy

Treatment of DVT in childhood is largely extrapolated from the adult literature and practice. As with other age-groups, therapeutic modalities available to children include supportive care, anticoagulation, thrombolytic agents, and surgical thrombectomy. The British Hemostasis and Thrombosis Task Force, American College of Chest Physicians, and the American Society of Hematology have proposed guidelines for the management of neonatal and pediatric TE.[64] Supportive therapy is recommended for clinically silent thrombi, including catheter-associated events. As soon as practical, clotted catheters should be removed, and all documented thrombi should be followed by serial imaging. If venous access is required, one can either monitor the clot closely or provide anticoagulation therapy.

Vitamin K Antagonist Therapy

Warfarin is an oral anticoagulant used in the pediatric population primarily in the context of congenital heart disease and in older, reliable children who require long-term anticoagulation. It is a vitamin K antagonist that initially requires bridging with UFH or LMWH until therapeutic internationalized normalized ratio targets are achieved (see Chapter 143). Warfarin use is limited in children due to age-related changes in vitamin K dietary intake, lack of a liquid formulation, and differences in the levels of the vitamin K–dependent procoagulant proteins in childhood.

Heparin (Unfractionated Heparin or Low-Molecular-Weight Heparin)

UFH or LMWH is the mainstay of anticoagulant therapy in neonates and pediatrics. The UFH and LMWH dosing regimens are outlined in the box on Treatment of Neonatal and Pediatric Thromboembolism. Neonates require higher doses of heparin compared with adults due to lower AT levels, increased volume of distribution and faster clearance.[3,4,65,66] Anticoagulation is monitored using anti-FXa assays. Therapeutic anti-FXa levels are 0.3 to 0.7 units/mL for UFH and 0.5 to 1 unit/mL for LMWH. There are two types of anti-FXa assays: (1) with exogenous AT added and (2) without exogenous AT.[67] Studies comparing the two types of anti-FXa assays found a lack of correlation. Hence, it is necessary to know the type of anti-FXa assay conducted in a particular laboratory when interpreting results. The aPTT can also be used to monitor UFH; aPTT values that correlate with anti-FXa levels of 0.3 to 0.7 units/mL are considered therapeutic.

TREATMENT OF NEONATAL AND PEDIATRIC THROMBOEMBOLISM

Unfractionated Heparin (UFH)

Bolus: 75 units/kg over 10 min
Maintenance: neonatal: 28 units/kg/h; pediatric: 20 units/kg/h; therapeutic goal, anti-FXa of 0.3–0.7 units/mL
Prophylaxis: 10 units/kg/h
Follow platelet count to detect possible HIT (risk is low)

Enoxaparin

Neonatal: 1.5 mg/kg subcutaneously every 12 h; Pediatric ≥ 2 months: 1 mg/kg subcutaneously every 12 h (with normal renal function; round dose to nearest milligram; consider higher dose [see text][42])
Check anti-FXa level by peripheral venipuncture 4–6 h after second or third dose; therapeutic goal, anti-FXa of 0.5–1 unit/mL (0.4–0.6 unit/mL if concurrent thrombocytopenia or other bleeding risk factor)
Follow platelet count to detect possible HIT (risk is low)
Hold for 24 h before procedures

Prophylaxis With Enoxaparin

Neonatal: 0.75 mg/kg subcutaneously every 12 h; Pediatric ≥ 2 months: 0.5 mg/kg subcutaneously every 12 h
If checked, anti-FXa level 4–6 h after second or third dose should be less than 0.4 units/mL
Hold for 12 h before procedures

Purpura Fulminans

Concurrent heparin: UFH dose of 28 units/kg/h with target anti-FXa of 0.3–0.7 units/mL; LMWH dose of 1.0–1.5 mg/kg every 12 ho with therapeutic target anti-FXa range of 0.5–1 units/mL and replacement with FFP or protein C concentrate
FFP: 10–20 mL/kg every 6–12 h for purpura fulminans
Protein C concentrate for severe protein C deficiency: load with 100–120 units/kg, then 60–80 units/kg every 6 h × three doses (goal protein C activity 100%). Once therapeutic anticoagulation is achieved, maintenance therapy with 4–60 units/kg every 6–12 h (goal protein C activity >25%).

Warfarin

Loading dose day 1: 0.2 mg/kg (maximum 10 mg)
  Loading dose day 2–4 based on INR:
  1.1–1.3: repeat initial loading dose
  1.4–1.9: 50% of loading dose
  2.0–3.0: 50% of loading dose
  3.1–3.5: 25% of loading dose
  >3.5: hold dose until INR <3.5, then re-start at 50% of the previous dose
Target INR range is based on the warfarin indication

Antithrombin Repletion

AT (functional) should be maintained at >50% of normal levels for effective heparin-based anticoagulation
Dose in international units = (desired − current AT[a]) × weight (kg)

[a] Expressed as % normal level based on functional AT level.

AT, Antithrombin; *FFP*, fresh frozen plasma; *HIT*, heparin-induced thrombocytopenia; *LMWH*, low-molecular-weight heparin; *TE*, thromboembolism; *UFH*, unfractionated heparin.

Prophylactic UFH is recommended to maintain patency of umbilical arterial lines (0.25 to 1 unit/mL, 25 to 200 units/kg/day, the lowest dose possible) and for cardiac catheterization (bolus 100 to 150 units/kg with catheter insertion, repeat for prolonged procedures). In most other cases, LMWH has emerged as the anticoagulant of choice both for prophylaxis and treatment. The advantages of LMWH include better bioavailability, longer half-life allowing twice daily administration, dose-dependent clearance, predictable anticoagulant response, and a lower risk of heparin-induced thrombocytopenia (HIT) and osteoporosis compared with UFH (see Chapter 143). While the current American College for Chest Physicians guidelines recommend a dose of 1.5 mg/kg of LMWH for treatment of neonatal TE,[10] there is growing evidence to suggest that neonates may, in fact, require higher doses up to 1.7 and 2.0 mg/kg for term and preterm neonates, respectively, to obtain a therapeutic anti-FXa level.[68] Dosing for children greater than 1 year of age is similar to adult dosing of 1 mg/kg of LMWH.

HIT antibodies are found in up to 1.5% of neonates, particularly in those who have undergone cardiac surgery. A systematic review, conducted by Avila et al., reported an estimated incidence of 0.33% in older children, primarily associated with cardiopulmonary bypass surgery. Overt HIT with TE, however, is rare, but it can occur. Diagnostic criteria for HIT are described in detail in Chapter 131. Treatment includes cessation of heparin and anticoagulation with argatroban, danaparoid, or lepirudin.[69]

Direct Oral Anticoagulants

DOACs targeting thrombin or FXa show potential as an alternative to LMWH or warfarin for treatment of TE. Several pediatric clinical trials with the DOACs have been completed. Dabigatran, a direct oral thrombin inhibitor, showed non-inferiority with similar safety and efficacy compared with the standard of care in the DIVERSITY trial that enrolled children less than 18 years of age. Complete and partial thrombus resolution was demonstrated in 46% and 32%, respectively, of children treated.[32] Compared with the standard of care, rivaroxaban, a direct oral FXa inhibitor, shows promise showed safety and efficacy in neonates and children without a significant difference in the rate of recurrent VTE in the EINSTEIN-Jr trial.[70] Notably, both trials evaluated DOAC use after at least 5 days of parenteral anticoagulation.[32,70]

Thrombolytic Therapy

Guidelines for thrombolytic management of neonatal and pediatric TE are provided by the British Hemostasis and Thrombosis Task Force,[64] Scientific Subcommittee on Perinatal and Pediatric Thrombosis of the International Society of Thrombosis and Hemostasis,[71] and the American College of Chest Physicians.[10] All groups agree that thrombolysis should be considered for extensive TE associated with organ dysfunction or limb-threatening ischemia (e.g., PE with hypotension or shock, superior vena cava syndrome, large mobile right atrial thrombus, and congenital heart disease with shunt thrombosis). The choice of using systemic or catheter-directed thrombolysis depends on the bleeding risk, availability of correct catheter size, and expertise of the interventional radiologist, thrombosis team, and intensive care unit.

Low-dose thrombolysis is recommended to open occluded catheters. tPA is the drug that has been most widely studied in pediatric patients. Transfusion support for hypofibrinogenemia and thrombocytopenia should be provided to minimize the bleeding risk. Contraindications for thrombolytic therapy include active bleeding and major surgery or bleeding within the past 10 days. If UFH or LMWH is given concomitantly with tPA, it should be administered at prophylactic doses (0.75 mg/kg every 12 hours for LMWH or 10 units/kg/h for UFH; see the box on tPA Thrombolysis for Neonatal and Pediatric TE). Surgical thrombectomy is reserved for organ-, limb-, or life-threatening thrombosis when tPA administration is impractical or predicted to be ineffective.

TISSUE PLASMINOGEN ACTIVATOR THROMBOLYSIS FOR NEONATAL THROMBOEMBOLISM

Concurrent Heparin (UFH or Enoxaparin) Should Be Considered at Prophylactic Dosing; UFH Preferred

Low dose: 0.01–0.06 mg/kg/h (max 2 mg/h)
High dose: 0.1–0.5 mg/kg/h
Life- or limb-threatening thrombi: starting dose of 0.1–0.5 mg/kg/h for up to 6 h
If no response, consider increase by 0.1 mg/kg/h increments to maximum 0.5 mg/kg/h
Consider using FFP 10 mL/kg before thrombolytic therapy in neonates
Maintain fibrinogen greater than 100 mg/dL
Maintain platelet count above 100,000
Reversal of severe bleeding with aminocaproic acid at 100 mg/kg intravenously every 6 h

FFP, Fresh frozen plasma; *TE*, thromboembolism; *tPA*, tissue plasminogen activator; *UFH*, unfractionated heparin

Post-Thrombotic Syndrome

Post-thrombotic syndrome (PTS) is a common, long-term complication of pediatric patients with extremity DVT with a frequency of approximately 26% but ranging from 10% to 70%.[72] The diagnosis is made at least 12 months after acute DVT diagnosis, with a median time ranging between 2 and 10.5 years. PTS is a result of luminal narrowing from residual thrombosis and damage to the venous valves through inflammation and during vascular recanalization, ultimately leading to venous outflow obstruction and vascular hypertension.[73] Clinical symptoms of swelling, pain, heaviness, cramping, dilation of superficial veins, ulceration, and skin changes of the affected limb are secondary to capillary leakage of plasma proteins and inflammatory cells.[72] Symptoms may be intermittent or persistent and are frequently worsened by physical activity. PTS associated risk factors include extent of DVT, lack of resolution, the number of vessels involved, and CVL-associated thrombus.[73] Avila et al. also documented an association between sex and line-related thrombosis in the lower extremity. They found that males with line-related thrombosis had a higher risk of PTS compared with females. Additionally, females with non-line-related DVT were at higher risk for PTS than females with line-related thrombosis. The Manco-Johnson Instrument (MIJI), modified Villalta Scale (MVS), and CAPTSure score are PTS tools used in the pediatric population which have good reliability.[73] Management of PTS is predominantly supportive with the use of compression stockings to manage symptoms.[73]

COVID-19 and Thrombosis in Children

Severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) caused a worldwide pandemic in 2020 and 2021 (and is ongoing), impacting global morbidity and mortality. Children with Coronavirus Disease of 2019 (COVID-19) account for a small percentage of cases (2.1% to 7.8%) and generally present with milder clinical symptoms.[74] The cumulative incidence of COVID-19 associated hospitalizations in children and adolescents was 49.7/100,000 in the USA from March 1, 2020, to August 14, 2021.[75] Additionally, a discrete entity, COVID multisystem inflammatory syndrome in children (MIS-C), manifested in children. This condition is now well described in the literature and generally arises weeks after SARS-CoV-2 infection. Patients with MIS-C can present with mild to life-threatening symptoms and often have clinical Kawasaki-like symptoms.[74,76]

Although the pathophysiology of COVID-19 is still under investigation, its association with the development of thrombosis has been established predominantly in adults. The hypercytokinemia and immune dysregulation in COVID-19 is thought to contribute to the thromboembolic risk in patients. This is possibly instigated by binding of SARS-CoV-2 to the angiotensin-converting enzyme 2 (ACE-2), which is expressed on vascular endothelium, causing local injury.[77–79] Autopsies have reported that thromboembolic disease in patients with COVID have manifested in both macro- and microvasculature.[80]

In children, COVID-induced hemostatic imbalance and thrombosis is described in the literature. Abnormalities in coagulation parameters, such as prolongation of PT and aPTT, elevated D-dimer and fibrinogen, mild thrombocytopenia, or thrombocytosis, can be present during COVID-associated illnesses.[81] The thrombotic risk in pediatrics is still being established and current thromboprophylaxis guidelines are extrapolated from adult experience and expert opinion.[82] A multi-institutional retrospective cohort study conducted in the USA documented an incidence of VTE in hospitalized patients with COVID-19 and MIS-C of 2.1% and 6.5%, respectively.[82] Children with asymptomatic SARS-CoV-2 infection had an incidence of 0.7%. Thrombotic complications included DVT, PE, intracardiac thrombosis, CSVT, and AIS.[76,82] Prothrombotic risk factors included age ≥12, underlying cancer diagnosis, MIS-C, and elevated D-dimer.[82]

There are various approaches to thromboprophylaxis in COVID-related illness. Thromboprophylaxis guidelines suggested by the pediatric/neonatal hemostasis and thrombosis subcommittee leadership of the ISTH Scientific and Standardization Committee recommend prophylactic anticoagulation in children with additional clinical risk factors in the setting of COVID-associated illness or markedly elevated d-dimer levels, in the dearth of contraindication.[83] Choice of anticoagulant is either low-dose LMWH or UFH, with consideration of post-discharge anticoagulation in patients with persistent risk factors, including elevated d-dimer. Aspirin, an antithrombotic therapy, commonly used in Kawasaki disease, is suggested by the American College of Rheumatology in all patients with MIS-C until the platelet count normalizes, and echocardiography shows normal coronary arteries at least 4 weeks from diagnosis.[84] Despite utilizing thromboprophylaxis, current literature reports that approximately one-half to two-thirds of patients with COVID-related illness develop thrombosis, which establishes the need for further investigation.[81,82] At present, the safety and efficacy of low- versus high-dose anticoagulation has not been established in this population and is currently under investigation with the COVAC-TP clinical trial (NCT04354155). One can adopt what is currently accepted for thromboprophylaxis in adults with COVID-19 when the children are older than 16.

PART XII CONSULTATIVE HEMATOLOGY

CHAPTER 149

HEMATOLOGIC CHANGES IN PREGNANCY

Arielle L. Langer, Michael Paidas, and Caroline Cromwell

Hematologic conditions are often seen during pregnancy as part of normal physiology and complications of varying severity. The primary physiologic, hematologic changes during pregnancy relate to the expansion of plasma volume and the prothrombotic state that develops as the pregnancy advances. They are thought to prepare the mother and fetus for eventual placental separation. Understanding the complex physiology of pregnancy and the interplay with hematology facilitates proper planning, anticipation, and discussion with the treating physicians and the patient. Preexisting hematologic conditions may affect pregnancy, and conversely, the effect of pregnancy on proceeding conditions should be considered. The evolving clinical picture as the pregnancy progresses must also be considered. Multidisciplinary planning and communication are essential, especially between obstetrics and hematology.

Common new onset hematologic conditions, such as anemia and thrombocytopenia, are seen for a variety of reasons during pregnancy and addressed in this chapter. The management of congenital and acquired cytopenias will also be covered. Management of hematologic malignancies presents a particular challenge. Inherited and acquired bleeding disorders affect pregnant women, and coagulation parameters must be monitored during pregnancy and delivery, including attention to the use of spinal anesthesia. Venous thromboembolism (VTE) during pregnancy remains a high-morbidity high-risk situation that can be challenging. These hematologic problems in management are discussed in this chapter.

ANEMIA IN PREGNANCY

Anemia in pregnancy affects approximately half of all pregnancies worldwide. It is more prevalent in low-income nations. Anemia in pregnancy is usually defined as a hemoglobin level below 11 g/dL. Common maternal signs of anemia include pallor, tachypnea, fatigue, and headache. Hemoglobin levels less than 6 g/dL in pregnant women can be associated with significant maternal and fetal complications, including high-output heart failure in the mother. Maternal anemia is associated with increased rates of both preterm (less than 37 weeks of gestation) and low-birthweight deliveries.[1,2] The etiology of anemia in pregnancy varies, and potential causes are discussed below.

Physiologic Anemia of Pregnancy

Physiologic anemia of pregnancy, also termed dilutional anemia of pregnancy, occurs because the plasma volume increases to a greater proportion than the red blood cell (RBC) mass, resulting in dilution. Generally, hemoglobin levels decrease throughout pregnancy and may increase modestly during the last month of pregnancy. Total circulatory volume increases by approximately 50% during pregnancy. Erythropoietin levels increase throughout pregnancy in response, but increased erythropoiesis does not fully compensate for the expanded plasma volume. Hemoglobin as low as 10 g/dL can be credibly attributed to physiologic anemia of pregnancy. However, this is a diagnosis of exclusion, and other causes should be considered before this attribution is made. Plasma volume and RBC mass return to baseline within approximately 6 weeks postpartum.

Iron Deficiency Anemia

Iron deficiency anemia, which is the most common cause of anemia in pregnancy, is a risk factor for preterm delivery and low birthweight. Iron requirements increase during pregnancy because of maternal and fetal erythropoiesis. Anemia and low ferritin levels are considered diagnostic of iron deficiency (see Chapter 37). However, ferritin levels may increase in the last several weeks of pregnancy because ferritin is an acute-phase reactant. Consequently, concurrent determination of the transferrin saturation is important in women with an ambiguous picture. The clinical symptoms of iron deficiency are the same as in other contexts, including fatigue, pallor, pica, tachycardia, and poor exercise tolerance. The diagnosis and treatment of iron deficiency anemia is generally like those in nonpregnant patients, except for a greater emphasis on the use of intravenous iron given time constraints.

Iron supplementation is routinely provided during pregnancy because the typical diet in the United States provides only 50% of daily iron requirements for pregnant women and is due to the relatively high prevalence of iron deficiency in women of childbearing age. Typically, supplementation with 15 to 30 mg/day of elemental iron is administered to prevent adverse outcomes from iron deficiency anemia. Supplementation should begin at the start of gestation and continue until several months postpartum. The side effects associated with iron therapy include constipation, diarrhea, and nausea. Such side effects may be particularly troublesome because constipation and nausea are common symptoms of pregnancy.

Multiple studies have shown that routine iron supplementation in pregnancy decreases the incidence of iron deficiency anemia. In a randomized double-blind study in which 275 iron-replete pregnant women at no more than 20 weeks' gestation received either a daily iron supplement or placebo from the time of enrollment to 28 weeks' gestation, the incidence of both low-birthweight and preterm low-birthweight infants was lower among women who received daily iron. [3] Research indicating that low fetal and infant iron stores predict worse cognitive function[4,5] provides further support for normalizing maternal iron stores and optimizing transfer of iron to the fetus. In addition to justifying routine iron supplementation in prenatal vitamins, this is the primary motivation for increased use of intravenous iron.

There are limits to the effectiveness of routine iron supplementation. Patients may develop iron deficiency despite supplementation or be intolerant of oral supplementation. As mentioned, the side effect of constipation can be particularly troublesome with oral iron because constipation and hemorrhoids are common complaints during pregnancy. Active inquiry about these side effects may uncover nonadherence to oral iron when iron deficiency anemia persists.

Intravenous iron is appropriate in certain circumstances: intolerance of oral iron therapy has not improved iron stores and anemia, perhaps even severe iron deficiency anemia, persists. Due to lack of safety data, intravenous iron is generally avoided in the first trimester of pregnancy. All intravenous formulations of iron deficiency are effective and safe in pregnancy. For convenience and expediency, especially given the time constraint of pregnancy, formulations that can be administered in one or two visits are preferred.

Indications for intravenous iron in pregnancy
- Intolerance of oral iron
- Failure to improve with oral iron
- Severe anemia

Folate and Vitamin B_{12} Deficiencies

Folate and vitamin B_{12} (cobalamin) deficiency also occur more commonly during pregnancy (see Chapter 40). Vitamin B_{12} and folate are critical for fetal growth because they are used to produce tetrahydrofolate, which is essential for DNA synthesis.

Folate deficiency accounted for most cases of megaloblastic anemias in pregnancy prior to routine supplementation. The folic acid requirement for nonpregnant women is 50 to 100 μg/day, but this increases to 150 μg in pregnancy because of the increase in maternal RBC mass and fetal demands for folate because of rapid cell proliferation. With fortification of the food supply with folate and the routine use of folate-containing supplements during pregnancy, folate deficiency is an uncommon cause of anemia in pregnancy but should be considered, particularly in women not adherent to folate supplements.

The diagnosis of folate deficiency is best based on RBC folate levels, although many laboratories only offer serum folate assays. An elevated homocysteine level also helps confirm the diagnosis. Pregnant women should receive a minimum of 400 μg of folic acid per day. There are harms associated with excess supplementation because folate, which is a water-soluble vitamin, is readily excreted in the urine if ingestion exceeds requirements.

Vitamin B_{12} deficiency can also occur during pregnancy. Serum vitamin B_{12} levels may be less reliable during pregnancy due to altered protein binding. Diagnosis of vitamin B_{12} deficiency can be confirmed by elevated levels of homocysteine and methylmalonic acid. If a woman is found to be deficient in vitamin B_{12} during pregnancy, vitamin B_{12} injections are usually preferred over oral supplementation for initial therapy. A vitamin B_{12} dose of 1000 mcg intramuscularly is given weekly for 4 weeks and then monthly thereafter. Alternatively, after initial repletion with parenteral vitamins or if anemia and deficiency are mild, supplementation can be administered with vitamin B_{12} 1000 mcg by mouth daily. For ongoing therapy, oral dosing has been shown to be equivalent to parenteral administration, even in individuals with malabsorption of vitamin B_{12}.

HEMOGLOBINOPATHIES AND PREGNANCY

Sickle Cell Disease

Every year, more than 300,000 children are born with either sickle cell disease or thalassemia (see Chapters 41 and 42). Prenatal counseling is now routine in many countries. In the United States, all newborns are screened for sickle cell disease (see Chapters 42 and 43). Management of pregnant patients with sickle cell disease requires coordination of care between the hematologist and obstetrician. Many women with sickle cell disease experience more frequent vaso-occlusive crises and other sickle cell–related complications during pregnancy. The increased frequency of vaso-occlusive crises, particularly during the latter half of pregnancy, results from heightened metabolic requirements in pregnancy, increased venous stasis, and the physiologic prothrombotic and inflammatory states associated with pregnancy. In addition, pathophysiologic changes in the renal and immune function of patients with sickle cell disease increase their susceptibility to urinary tract infections and pyelonephritis. By causing tissue hypoxia, sickling of RBCs within the placental vasculature may have deleterious effects on the fetus.

Additional complications in pregnant women with sickle cell disease and thalassemia include an increased risk of preeclampsia, thromboembolic events, placental abruption, intrauterine growth retardation, low birthweight, and postpartum infections. Studies have shown that women with sickle cell disease experience a higher incidence of stillbirths and perinatal mortality,[6] as well as an increased risk of preterm labor and premature rupture of membranes. [7] Consequently, women with sickle cell disease require close medical attention throughout the prenatal period, including counseling about intrauterine diagnosis of sickle cell disease, when appropriate. Pregnant women can undergo chorionic villi sampling as early as the 9th week of gestation or amniocentesis in the 15th to 16th weeks if fetal evaluation is desired (see Chapter 43). The reticulocyte count should be monitored to assess for bone marrow suppression or the development of nutritional deficiency. Urinalysis with urine culture is performed at least every trimester to monitor for asymptomatic bacteriuria, as this is more common in women with sickle cell disease than in those without and is treated, unlike in nonpregnant patients, because of its association with preterm birth and low birthweight infants. Finally, beginning at between 24 and 28 weeks' gestation, patients should have weekly clinic visits and begin serial ultrasonography to monitor fetal growth.

Pregnant women with sickle cell disease should receive 5 mg/day of supplemental folic acid to address the extra demands of chronic hemolysis and pregnancy. Hydroxyurea can be continued in women with sickle cell disease who wish to become pregnant provided that they track their menstrual cycles and stop taking the drug as soon as a pregnancy test is positive. Hydroxyurea should be withheld during pregnancy but may be restarted in the late second or third trimester in women with serious symptoms. Use of hydroxyurea in pregnancy may be associated with low birthweight and prematurity, but it is difficult to ascertain if it is causal because women with severe sickle cell disease are already at risk of these complications. Ultimately, the risks associated with hydroxyurea must be weighed against the negative effect of poorly controlled sickle cell disease.

Studies examining the benefit of prophylactic blood transfusions have yielded mixed results; the only randomized trial revealed a reduction in vasoocclusive crises with transfusion but no improvements in fetal or other maternal outcomes.[8] Given the risk of alloimmunization and iron overload, prophylactic simple or exchange transfusion is not appropriate for all pregnant women with sickle cell disease. However, individualized care is needed, and prophylactic transfusion may be appropriate for women with severe disease phenotypes.

Transfusion should be considered if the hemoglobin level falls below 6 g/dL if there are progressive complications related to sickle cell disease, or in the face of obstetrical complications. With these criteria, many women require transfusion during pregnancy, although at a lower volume than that needed for prophylactic transfusion. Women with a sickle cell crisis during pregnancy should receive analgesics, hydration, and oxygen while undergoing evaluation for infection or other precipitating causes.

At delivery, pregnant women with sickle cell disease are at risk of high-output heart failure. Supplemental oxygen and cautious hydration should be given to prevent sickling of RBCs and the associated complications. During the postpartum period, hemoglobin levels must be monitored, and VTE prophylaxis should be given unless there are contraindications to anticoagulation. VTE prophylaxis should be continued for 5 to 7 days after vaginal delivery and 2 to 6 weeks after a cesarean section (see Chapters 140 and 141).

Thalassemia

Pregnant women with thalassemia typically have β-thalassemia minor or α-thalassemia minor—conditions with relatively benign clinical phenotypes rather than β-thalassemia major, β-thalassemia intermedia, α-thalassemia major (also called hemoglobin Barts), or hemoglobin H disease (see Chapter 41). Pregnancy is a common setting for the diagnosis of thalassemia minor in previously asymptomatic women who are found to have anemia on routine laboratory evaluation. Dilutional anemia of pregnancy may be exacerbated in women with thalassemia minor, although this effect is variable and more common with β-thalassemia minor than α-thalassemia minor. Thalassemia minor does not adversely affect fetal development, fetal morbidity and mortality, or maternal morbidity and mortality.

Due to delayed pubertal growth or hypogonadism with associated anovulation, women with α- and β-thalassemia major have diminished fertility. Fertility is more variable with hemoglobin H and β -thalassemia intermedia. In the setting of widespread transfusion and iron chelation therapy, pregnancy has become more frequent in these women, and most have successful pregnancies without complication. [9] However, there is an increased risk of maternal complications, especially heart failure. Women with β-thalassemia major and, to a lesser extent, those with β-thalassemia intermedia are at risk of intrauterine growth restriction (IUGR) and low-birthweight babies. Women with β-thalassemia intermedia and hemoglobin H disease often require transfusion during pregnancy.

Iron chelators carry a risk of teratogenicity and must be stopped at least during the first trimester of pregnancy; use in the third trimester—or, even more rarely, in the second trimester—is reserved for women in whom it is unsafe to withhold therapy throughout pregnancy. Therefore, cardiac status and the presence and extent of iron overload must be assessed when counseling women with thalassemia about the risks of pregnancy. Every effort should be made to optimize control of iron overload prior to conception to minimize the risk of decompensation during pregnancy and facilitate tolerance to discontinuation of iron chelation therapy during pregnancy.

Like those with sickle cell disease, women with thalassemia require vigilant follow-up throughout pregnancy. This includes interval monitoring of maternal vital signs and fetal heart-rate, maternal hemoglobin levels, and fetal growth as assessed by ultrasonography beginning between 24 and 28 weeks' gestation. Prenatal genetic testing can be performed if desired, with results used for counseling and guidance of optimal care of the fetus. Women may choose to undergo testing after conception with the intention of terminating the pregnancy if the test is positive; in such cases, chorionic villus sampling may be indicated. Genetic testing is required for antepartum diagnosis of β-thalassemia because silencing of the beta globin gene until after birth results in a normal hemoglobin electrophoresis during pregnancy. Alpha thalassemia major can be diagnosed early by genetic testing, but it will also manifest as severe fetal anemia during the second trimester. When counseling about α- thalassemia major, it is important to note that intrauterine transfusion has rendered fetuses with this disorder viable, albeit still at high risk. Referral should be made to a maternal fetal medicine specialist trained in intrauterine transfusion if women with α-thalassemia major wish to continue their pregnancies.

Iron overload and pregnancy: Women at risk for iron overload due to chronic transfusion, sickle cell disease or thalassemia should have iron status investigated and optimized prior to pursuing pregnancy to reduce the risk of maternal complication, especially heart failure.

OTHER HEMOLYTIC ANEMIAS

Hereditary Spherocytosis

Hereditary spherocytosis is the most common inherited hemolytic anemia among people of northern European descent (see Chapter 46). Since some patients have low levels of hemolysis under normal conditions, the disease may not become clinically apparent until pregnancy. Pregnant women with hereditary spherocytosis are susceptible to pigment gallstones and folate deficiency related to the increased requirements of pregnancy superimposed on accelerated hemolysis. Pregnancy outcomes for women with hereditary spherocytosis are generally good, with better outcomes in those who have undergone splenectomy.[10] Care is primarily supportive with folate (5 mg/day) and transfusion as needed. Splenectomy should not be undertaken during pregnancy. Accelerated hemolysis during pregnancy abates after delivery, and the need for splenectomy can be determined at that time.

Glucose 6-Phosphate Dehydrogenase Deficiency

Glucose 6-phosphate dehydrogenase (G6PD) deficiency leads to hemolytic anemia in the face of oxidative stress (see Chapter 45). The condition may increase the risk of spontaneous abortion, low-birthweight fetuses, and neonatal jaundice if oxidative stressors are not avoided. Women with G6PD deficiency should be instructed to avoid medications with oxidative potential. Complications after the ingestion of oxidative drugs have been reported in carriers of the G6PD deficiency gene if a male fetus has inherited the disease, particularly with medications that cross the placenta.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare clonal disorder caused by somatic mutation in the membrane-anchoring protein PIGA (see Chapter 32). *PIGA* mutation leads to abnormal function of critical membrane proteins that in wild-type individuals are anchored by the gene product of *PIGA*. Features of the clinical phenotype include hemolysis, thrombosis, and bone marrow failure. Hemolysis results from deficiency in the membrane proteins CD55 and CD59, which renders affected individuals susceptible to complement-mediated intravascular hemolysis.

The clinical manifestations of PNH can have a devastating impact on pregnancy if left untreated. Prior to the availability of complement inhibitors, common complications included severe anemia, thrombocytopenia, thrombotic events, preterm delivery, low-birthweight infants, neonatal death, and maternal death, with a maternal mortality rate as high as 20%.[11] As with treatment of PNH in other contexts, eculizumab, a C5 inhibitor, has significantly improved pregnancy outcomes. Accelerated clearance of eculizumab can occur during pregnancy. As such, patients should be monitored for breakthrough hemolysis and eculizumab dosed more frequently if this is noted. A structurally similar C5 inhibitor with a longer half-life, ravulizumab, is likely also appropriate for treatment during pregnancy, but there is less experience with the use of this agent. Pegcetacoplan is a C3 inhibitor with proven efficacy for PNH, but its use in pregnancy should be avoided because animal studies have shown potential for harm, and human data are not yet available.

For women not already on therapeutic anticoagulation, prophylactic dose anticoagulation with low molecular weight heparin should be initiated and continued for 6 to 12 weeks postpartum because of the high risk of thrombosis. Women on therapeutic anticoagulation should have this continued with therapeutic dosing of low molecular weight heparin (further discussed in the section on VTE).

PNH in pregnancy: In addition to control of hemolysis with a C5 inhibitor, all women should receive at least prophylactic dose anticoagulation during pregnancy and the postpartum period.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia (AIHA; see Chapter 47) can occur de novo during pregnancy or be a flare of preexisting disease. Warm AIHA poses a greater risk than cold agglutinins because the relatively small size of immunoglobulin (Ig) G molecules allows them to cross the placenta and adversely affect the fetus. In contrast, the larger IgM antibodies in cold agglutinin disease do not cross the placenta. Patients with AIHA are treated with glucocorticoids and, less commonly, intravenous immunoglobulin (IVIg), both of which have an excellent safety record in pregnancy. Supportive transfusions can be administered when needed. For more severe cases, rituximab can be given during pregnancy and has not been clearly associated with birth defects. However, rituximab can cross the placenta and induce temporary B-cell lymphopenia in the neonate with a subsequent increased risk of infection. As such, rituximab administration during pregnancy is usually reserved for women with hemolysis that cannot be controlled with corticosteroids alone or who require a high dose of corticosteroids. For other women, rituximab is best deferred to the postpartum period. While rituximab is detectable in breastmilk, concentrations are low enough that this is unlikely to pose a risk of immunosuppression and should not be considered a contraindication while breastfeeding.

In rare instances, pregnancy can precipitate AIHA, likely due to the effect of pregnancy on immune regulation; management is the same as it is for flares of known disease or new onset disease.

THROMBOCYTOPENIA

Thrombocytopenia during pregnancy is common, occurring in 5% to 10% of pregnancies. Although there is not one clear value to define thrombocytopenia in pregnancy, generally, platelet counts less than 100,000/µL are a cause for concern. Gestational thrombocytopenia (GT) is the most common cause of thrombocytopenia in pregnancy followed by pre-eclampsia and immune thrombocytopenia (ITP). Much rarer causes include disseminated intravascular coagulation (DIC), HELLP (hemolysis, elevated liver enzymes, low platelet count) syndrome, thrombotic thrombocytopenic purpura (TTP), complement-mediated hemolytic uremic syndrome (CM-HUS), and medication induced. Although inconsequential for most women, the evaluation of thrombocytopenia is essential to rule out any systemic disorders that may affect pregnancy outcome. In addition to determining the etiology of thrombocytopenia, a key consideration is potential use of epidural anesthesia and spinal block or need for cesarean section. Most obstetrical anesthesiologists require a platelet count of approximately 75,000 for epidural anesthesia and, as with all surgery, a platelet count of at least 50,000 is preferred for cesarean section. Given that the need for cesarean section cannot always be predicted, a minimum platelet count of 50,000 should be the goal prior to delivery.

Gestational Thrombocytopenia

GT is quite common, accounting for most cases of thrombocytopenia in pregnancy. The platelet count nadir is usually greater than 100,000/µL, and a count lower than 60,000/µL effectively rules out this etiology. The nadir occurs in the third trimester and most women with GT have no or minimal thrombocytopenia in the first trimester. Patients are asymptomatic and have no history of thrombocytopenia outside of pregnancy. The platelet count normalizes within 6 to 12 weeks of delivery but usually within 1 week. The etiology of GT remains unclear, but may reflect dilution from increased plasma volume, increased platelet sequestration, including in the placenta, or an autoimmune phenomenon (i.e., mild and self-limited ITP triggered by pregnancy).

Monitoring is all that is required for management of GT. Typically, women with GT can receive epidural anesthesia because the platelet count remains sufficiently high to alleviate concerns about bleeding. If the platelet count falls below 75,000/µL alternative diagnoses should be considered, including ITP.

Immune Thrombocytopenia

ITP is responsible for pregnancy-associated thrombocytopenia in approximately 3% of cases (see Chapter 129). It is the most common cause of significant thrombocytopenia during the first two trimesters of pregnancy, a period when GT is usually mild or not yet present. ITP can recur in women with previously documented disease or can develop de novo during pregnancy.

Most pregnant patients with ITP have a long-standing history of thrombocytopenia. ITP may be difficult to distinguish from GT because patients with these conditions can present with similar clinical and laboratory findings, especially in otherwise well women who may not have prior platelet counts for comparison. It is important to distinguish between ITP and GT because ITP may require intervention during pregnancy and there is a small but significant risk of neonatal thrombocytopenia in the setting of ITP. Approximately one-quarter of neonates born to mothers with ITP have thrombocytopenia, although less than 10% have platelet counts less than 30,000/µL, and only 1% to 2% have bleeding.[12]

For diagnostic evaluation, all patients should be tested for human immunodeficiency virus (HIV), as is the case with any diagnosis of ITP. Depending on the clinical context, it may be appropriate to test for hepatitis B and C and to evaluate for systemic lupus erythematosus (SLE). Platelet antibody testing is not helpful due to poor sensitivity and specificity. The peripheral smear may reveal large platelets but should otherwise be normal, and the absence of giant platelets does not rule out ITP. Bone marrow biopsy and aspirate are not indicated unless there are other hematologic abnormalities present that suggest a different diagnosis.

Treatment options are generally similar to those for nonpregnant patients with ITP (Table 149.1). Glucocorticoids are considered first-line treatment, starting with either dexamethasone 40 mg daily for 4 days or prednisone 1 mg/kg daily followed by gradual tapering. Although dexamethasone is usually preferred over prednisone in nonpregnant patients because of a somewhat better response rate and side-effect profile,[13] the greater fetal exposure may favor prednisone, especially if the patient is not near term or at term. Side effects of corticosteroids should be discussed with the patient and include weight gain, bone loss, hypertension, and gestational diabetes. IVIg can also be used, but given its shorter duration of action, it is usually reserved for women who need a rapidly acting intervention shortly before delivery. Rituximab can be used for patients not responsive to steroids or IVIg, although there is a risk of neonatal B-cell leukopenia, as discussed above (see the section on AIHA). There is limited experience

TABLE 149.1 Safety of Medications for Immune Thrombocytopenia in Pregnant Patients

Treatment	Safety in Pregnancy[a]
Intravenous immunoglobulin (IVIg)	Safe
Dexamethasone	Safe, more fetal exposure than prednisone
Prednisone	Safe, less fetal exposure than dexamethasone
Rituximab	Not associated with fetal anomalies, can result in neonatal lymphopenia and associated immunocompromise
TPO mimetics (romiplostim, eltrombopag)	Limited data available support safety, case of neonatal thrombocytosis reported, use limited to refractory immune thrombocytopenia (ITP)

[a] The usual side effect profile of this medications still apply and should be considered in selecting agents.

with TPO mimetics, such as eltrombopag and romiplostim, and these agents should be reserved for patients refractory to IVIg, corticosteroids, and rituximab or those refractory to IVIG and corticosteroids whose delivery is imminent because the response to rituximab can be delayed for several weeks. In women with refractory ITP in pregnancy, a brief course of a TPO mimetic was not associated with thrombosis or adverse neonatal outcomes, although one neonate did have thrombocytosis.[14] Splenectomy is rarely indicated for refractory thrombocytopenia in pregnancy because other options are available. As with ITP in general, platelet transfusion should be avoided unless there is active bleeding because the response is transient.

As noted above, thresholds for intervention should be approached with nuance in pregnancy. In the absence of bleeding or other invasive interventions, a platelet count as low as 30,000/μL can be tolerated for most of the pregnancy. However, when nearing delivery, it is prudent to intervene to achieve a platelet count great than 50,000/μL for delivery or 75,000/μL if epidural anesthesia is desired by the patient. Most women will be able to achieve these platelet counts with corticosteroid administration in the late third trimester.

As discussed previously, maternal antiplatelet IgG can cross the placenta, and cause thrombocytopenia in fetuses. Percutaneous umbilical blood sampling is the most accurate means to obtain the fetal platelet count, but it is not recommended because the procedure is associated with a high complication rate and 1% fetal mortality. The maternal platelet count and antiplatelet antibody level do not accurately predict the fetal platelet count. The obstetrical and pediatrics team should be aware of the risk of neonatal thrombocytopenia, and cord blood platelet count should be checked. A repeat platelet count between days 2 and 5 of life is also recommended because the nadir platelet count usually occurs during this time.

Pre-eclampsia With Severe Features and HELLP Syndrome

Thrombocytopenia in pregnant women also occurs in association with pre-eclampsia and HELLP syndrome, potentially serious multisystem disorders associated with pregnancy. A platelet count below 100,000/μL is one criterion used to define severe pre-eclampsia and is associated with increased rates of maternal complications, including eclampsia, renal injury, pulmonary edema, myocardial infarction, placental abruption, and mortality. Preeclampsia with severe features also carries an increased risk of poor fetal outcomes including IUGR and stillbirth. Preeclampsia with severe features, regardless of whether the criterion for severe features is thrombocytopenia, may progress to HELLP syndrome, although HELLP syndrome may occur without preceding pre-eclampsia. Risk factors for preeclampsia include but are not limited to pre-eclampsia in a previous pregnancy, a family history of preeclampsia, chronic hypertension, obesity, multiple gestation, and autoimmune disease.

HELLP syndrome represents a severe variant of preeclampsia. Complement activation is present in some cases but its role in the pathogenesis of the disorder remains unclear. As with preeclampsia, most women present in the third trimester, but it can occur in the second trimester or within 48 hours of delivery. Diagnosis is made on the basis of laboratory studies and a blood smear because symptoms such as abdominal pain, nausea, and fatigue are non-specific, especially in pregnancy. Patients can develop severe right upper quadrant pain if intraparenchymal or subcapsular hepatic hemorrhage occurs, but this is a late finding in the evolution of HELLP syndrome.

As the acronym implies, laboratory studies will show thrombocytopenia, hemolytic anemia, and transaminitis (Table 149.2).[15] The blood smear usually reveals a schistocyte (3 or more per high power field) confirming that hemolysis is due to a microangiopathic process. If initial testing is ambiguous, particularly with respect to microangiopathic hemolytic anemia, tests should be repeated to avoid missing this serious diagnosis. If HELLP syndrome is suspected or identified, comprehensive evaluation for other impacts of severe pre-eclampsia should be made, including renal dysfunction and proteinuria, visual disturbances, weight gain or edema, and headache.

TABLE 149.2 **Diagnostic Criteria for HELLP Syndrome**

Hemolysis (at least 2 of 4)	• Schistocytes on peripheral blood smear • Serum bilirubin ≥1.2 mg/dL • Haptoglobin ≤25 mg/dL OR lactate dehydrogenase (LDH) ≥2× upper limit of normal • Anemia not due to bleeding
Transaminitis (required)	• Aspartate aminotransferase (AST) or alanine aminotransferase (ALT) ≥2× upper limit of normal
Thrombocytopenia (required)	• Platelets <100,000/μL

HELLP, Hemolysis, elevated liver enzymes, low platelet.

Pre-eclampsia has complex pathophysiology with both fetal and maternal contributions. Abnormal angiogenesis and remodeling of maternal spiral arteries, endothelial dysfunction, placental hypoperfusion and ischemia, and defective trophoblast differentiation are all thought to play a role. Endothelial dysfunction is the central mechanism that links pre-eclampsia with HELLP syndrome. Injury to the vascular endothelium results in fibrin deposition, platelet activation, and the release of vasoactive agents such as serotonin and thromboxane A_2. The thrombocytopenia in pre-eclampsia likely reflects this cascade of changes. Fibrin deposition in the hepatic sinusoids may be responsible for hepatocellular injury. There often is evidence of abnormal complement activation, but it is unclear whether this is a consequence or driver of endothelial damage. Coagulopathy may develop as a consequence of HELLP syndrome and liver injury, further complicating the risks of delivery. As such, laboratory evaluation should also include determination of the partial thromboplastin time, prothrombin time, and fibrinogen level.

HELLP syndrome may be further complicated by acute renal failure, pulmonary edema, shock, stroke, eclampsia, retinal detachment, diabetes insipidus, placental abruption, and death. With greater recognition of this condition, maternal mortality is rare, estimated at 1.1% in a large review.[16] Unfortunately, fetal demise and neonatal mortality remain as high as 20%.[17] IUGR and neonatal cytopenias can also occur.

HELLP syndrome may be difficult to distinguish from acute fatty liver of pregnancy (AFLP), which usually occurs in the third trimester. Although the origin of AFLP is not clear, microvesicular fatty infiltration of the central zone of the liver is observed. In some cases, fatty infiltration can be detected by ultrasonography or computed tomography (CT). Patients present with a variety of symptoms, including malaise, fatigue, right upper quadrant pain, dyspnea, and mental status changes. Laboratory findings include abnormal liver function tests consistent with cholestatic disease, elevated ammonia levels, low levels of fibrinogen and antithrombin, and a prolonged prothrombin time. These abnormalities may be the result of compromised liver synthetic function alone or hepatic injury leading to DIC (see Chapter 137). Patients with AFLP usually have little or no evidence of a microangiopathic, hemolytic anemia but have more severe liver injury and synthetic dysfunction than those with HELLP syndrome. Women may have overlapping features of AFLP and HELLP syndrome, and both conditions occur more commonly in women with preceding pre-eclampsia. AFLP and HELLP syndrome are both managed with delivery and supportive care. Therefore, distinguishing between them is not essential.

Balancing maternal and fetal risks remains the most difficult consideration in the management of HELLP syndrome, particularly in women who present early in pregnancy. The only well-established treatment is prompt delivery, which carries the attendant risks of prematurity. However, HELLP syndrome itself is associated with poor fetal and neonatal outcomes from complications such as placental abruption. Women with HELLP syndrome should be admitted to the hospital for maternal and fetal monitoring and assessed for stability. Collaboration between hematology and obstetrics is essential. If clinical features are not severe, delivery can be delayed for 48 hours and corticosteroids administered to promote fetal lung maturation. As with other preeclampsia syndromes, magnesium sulfate is administered for seizure prevention, and blood pressure must be controlled. Women at 34 to 35 weeks' gestation or more should be delivered without delay. Vaginal delivery can be attempted if the patient is stable, but monitoring of the platelet count and coagulation status is important. Epidural anesthesia can be considered if the platelet count is high enough. Volume expansion, vasodilators, and eculizumab can be used to attempt to delay delivery when HELLP syndrome is diagnosed early in pregnancy, but the efficacy and safety of these agents is uncertain.[18,19]

Women with HELLP syndrome and hypertensive syndromes of pregnancy should be counseled about the risks with future pregnancies. The risk of recurrence with future pregnancies is about 7% with HELLP syndrome and up to 36% with some hypertensive syndromes of pregnancy.[20] There is increasing evidence that aspirin (81 mg/day) may prevent preeclampsia. As such, all women with a history of HELLP syndrome or preeclampsia associated with thrombocytopenia should receive aspirin prophylaxis in future pregnancies.

Thrombotic Thrombocytopenic Purpura and Complement-Mediated Hemolytic Uremic Syndrome

TTP and CM-HUS (also called atypical HUS) are important considerations when evaluating pregnant women with thrombocytopenia (see Chapter 132). Although rare, the incidence of both disorders is increased in pregnancy. Like HELLP syndrome, TTP and CM-HUS are thrombotic microangiopathies that are associated with significant morbidity and mortality if appropriate therapy is not provided. Microvascular injury and platelet agglutination with resulting thrombocytopenia and microangiopathic hemolytic anemia are hallmarks of TTP and CM-HUS (Fig. 149.1). For TTP, pregnancy remains one of the most common triggers for flares with both congenital deficiency and autoimmune etiologies of ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) deficiency. As discussed elsewhere (see Chapter 132), lack of ADAMTS13, which is a protease that cleaves von Willebrand factor (vWF), leads to an excess of ultra large vWF multimers that cause inappropriate platelet activation and aggregation leading to microthrombus formation. In contrast, the levels of ADAMTS13 are normal in CM-HUS. Instead, abnormal complement activation is the driver of CM-HUS. Many patients with CM-HUS triggered by pregnancy or infection have an underlying mutation in a complement protein, but identification of a mutation is not required for the diagnosis. The potential contribution of complement activation to the pathogenesis of HELLP syndrome may explain why some women with this syndrome fail to improve postpartum, and develop a laboratory picture more consistent with CM-HUS. In such cases, endothelial damage and complement activation due to HELLP syndrome may be the trigger for CM-HUS. Alternatively, there may be an overlap in etiology from the start.

Both timing and laboratory parameters can be useful in distinguishing between TTP, CM-HUS, and HELLP syndrome. Renal injury in TTP is less severe than that in CM-HUS, and profound thrombocytopenia and neurologic symptoms are less common with CM-HUS than TTP. In contrast to HELLP syndrome, serious liver injury is unusual with CM-HUS or TTP. Although TTP can occur at any point in pregnancy, it is most common in the second and third trimesters. Complement levels increase gradually after 20 weeks' gestation. Therefore, CM-HUS most commonly occurs near term or after delivery, and it rarely occurs before the latter part of the second trimester. HELLP syndrome is most common in the third trimester and typically resolves with delivery. Persistence of HELLP syndrome beyond 48 hours after delivery should prompt consideration of CM-HUS.

TTP is treated with plasmapheresis and corticosteroids. Rituximab is generally recommended for autoimmune TTP but can be deferred to the postpartum period if remission is achieved with plasmapheresis and corticosteroids. Women with congenital deficiency of ADAMTS13 as the driver of TTP can be treated with plasma infusion alone.

While plasmapheresis has been used for CM-HUS, eculizumab is now well established as a superior treatment for CM-HUS and there is experience with its use in pregnancy (see the section on PNH). Ravulizumab, a C5 inhibitor with a longer half life, is likely to be at least as effective as eculizumab, but there is less information about its safety in pregnancy.

Delivery is not indicated for the management of maternal complications of TTP or CM-HUS, and treatment usually enables safe continuation of pregnancy. If there is fetal distress, however, delivery may be needed while maternal treatment is ongoing.

The risk of recurrent TTP or CM-HUS in future pregnancies is variable. For acquired TTP, hemolysis parameters, blood counts, and ADAMTS13 levels should be monitored during pregnancy. For congenital TTP, flares during pregnancy are so common that prophylactic plasma infusion (10 to 15 mL/kg every 2 weeks or more frequently if needed) is advisable. For CM-HUS, recurrence is unlikely during the first half of gestation because of the timing of pregnancy-related complement level changes. As such, monitoring of hemolysis parameters and blood counts can be deferred until after 20 weeks' gestation. Treatment for recurrent CM-HUS and acquired TTP can be safely withheld with close monitoring and patient participation in symptom monitoring.

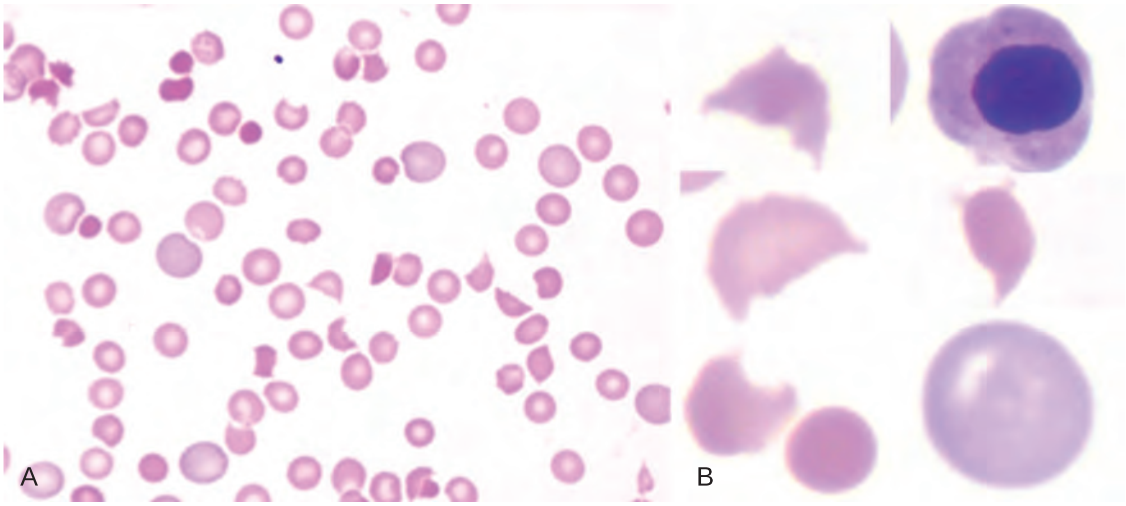

Figure 149.1 MICROANGIOPATHIC HEMOLYTIC ANEMIA . Microangiopathic hemolytic anemia in pregnancy, peripheral blood smear (A and B). Evidence of microangiopathy with the formation of schistocytes, fragmented forms and spherocytes, associated with polychromasia and nucleated red blood cells (A, B, detail).

The prominence of liver injury can be helpful in distinguishing HELLP syndrome from other thrombotic microangiopathies that can flare in pregnancy such as TTP or CM-HUS.

LEUKEMIA AND LYMPHOMA

The diagnosis of hematologic malignancy during pregnancy can be traumatic for the patient and her family and is a treatment challenge. Although significant advances in treatment have been made, there is limited information about treatment in pregnancy where the risk to the fetus must be considered. The risks of chemotherapy for the fetus depend on gestational age.

Diagnosis of hematologic malignancies in pregnancy can be difficult because many of the nonspecific symptoms and signs that accompany these disorders, such as fatigue, loss of appetite, weight loss, and anemia, are not uncommon in pregnancy. Diagnostic procedures such as bone marrow aspiration or lymph node biopsy can usually be performed safely during pregnancy. Because of the risk of radiation exposure to the fetus, ultrasonography and magnetic resonance imaging (MRI) are often the mainstay for imaging, even though CT scanning is associated with limited radiation exposure.

The risk of teratogenicity from chemotherapy is highest if treatment is administered during fetal organogenesis, which mainly occurs during weeks 5 to 10 of gestation. If given before 5 weeks of gestation, chemotherapy is unlikely to affect organogenesis but may be associated with spontaneous abortion. Chemotherapy administration in the second or third trimester has been associated with IUGR, low birthweight, prematurity, and stillbirth. Observational studies have not shown long-term effects of such treatment on cognitive function except for those attributable to prematurity or an increased rate of malignancy.[21,22] Chemotherapy at or near term is linked to neonatal cytopenias from myelosuppression. Chemotherapy dosing is usually based on prepregnancy weight. Radiation may be feasible for fields remote from the uterus such as the thorax or extremities.

Hodgkin Lymphoma

The relatively high incidence of hematologic malignancies during pregnancy compared with other cancers reflects the fact that Hodgkin lymphoma is common in women of childbearing age. The diagnosis of Hodgkin lymphoma in pregnancy rarely impacts pregnancy outcome. Rates of remission and 20-year overall survival in women diagnosed with Hodgkin disease during pregnancy are similar to those in nonpregnant women. If there is no urgent need for intervention, treatment can be deferred until after delivery. If urgent treatment is needed, ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is often used because this regimen does not appear to be associated with teratogenicity when given in the second or third trimester. Safety data with newer agents such as brentuximab vedotin are lacking.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) rarely occurs during pregnancy. There are case reports and case series of pregnant women with NHL who have been treated successfully with chemotherapy during the second and third trimesters of pregnancy. Treatment can be deferred until after delivery in women with indolent NHL. For women with aggressive NHL, treatment considerations depend on the risks of cytotoxic chemotherapy to the fetus.

Acute Leukemias

Treatment of acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) can rarely be delayed. Thrombocytopenia and the potential for DIC, especially with acute promyelocytic leukemia (APL), need to be considered. Women at or near term should undergo delivery prior to initiation of therapy, but treatment should be started promptly thereafter. Women in the first trimester should be counseled about the high risk of a poor outcome, and discussion about therapeutic abortion is warranted. For pregnancies in the second trimester or early in the third trimester, standard induction therapy should be given without delay.

For treatment of AML in pregnancy, daunorubicin is preferred over idarubicin, which has increased placental transfer. Amphotericin B is considered the antifungal of choice in pregnancy because it is not associated with teratogenicity. In general, pregnant women with AML have outcomes similar to those of nonpregnant women.

For treatment of APL in pregnancy, all-trans retinoic acid (ATRA) is not recommended in the first trimester, and arsenic trioxide is not recommended at any stage of pregnancy. The impact on outcome of withholding these agents should be disclosed when women and their families are considering termination of pregnancy.

There is limited safety information on the use of newer treatments for AML in pregnancy. Likewise, given the rarity of AML in pregnancy, the safety of agents such as peg-asparaginase in women of childbearing age is uncertain.

Chronic Myeloid Leukemia

The use of tyrosine kinase inhibitors (TKIs) in the first trimester of pregnancy is associated with a risk of spontaneous abortion and fetal malformations. Outcomes with the use of TKIs during the second and third trimester are less clear but appear to be more favorable. Nonetheless, it is advisable to discontinue TKIs prior to attempting conception.

Two approaches can be considered for women with CML planning for pregnancy. First, temporary or long-term cessation of TKIs should be considered if TKI therapy has been used for at least 3 years and resulted in a deep molecular response for at least 2 years. TKI treatment should be stopped prior to attempting to become pregnant, and women should be monitored for relapse. Second, women who do not qualify for discontinuation of TKI or who have relapsed with discontinuation should be counseled about the risks of withholding TKIs throughout pregnancy. If they wish to proceed, interferon alfa can be used to control blood counts during pregnancy. Interferon alfa is also the preferred agent for treatment of CML in pregnancy; patients can be switched to a TKI in the second or third trimester if an experienced hematologist considers this necessary. Observation alone may be sufficient for pregnant women with minimal blood count abnormalities or if CML is diagnosed late in pregnancy. Aspirin thromboprophylaxis can be considered for women with significantly elevated platelet counts.

TKIs pass into breast milk and are associated with growth retardation. Therefore, if TKIs are given after delivery, breastfeeding is discouraged.

Myeloproliferative Neoplasms: Essential Thrombocythemia, Polycythemia Vera, and Primary Myelofibrosis

Although myeloproliferative neoplasms (MPNs) are associated with spontaneous abortion, placental abruption, IUGR, low birthweight, and preeclampsia, the risk of these complications is low, as is the risk to the mother.

Essential thrombocythemia (ET) has a bimodal peak of distribution and is the most common MPN in women of childbearing age (see Chapter 71). Most women of childbearing age with ET do not require treatment apart from aspirin, which can be safely continued in pregnancy. Although aspirin may be considered optional in low-risk patients with ET, the predisposition to pre-eclampsia and increased risk of pregnancy loss and thrombosis render aspirin advisable in pregnancy. There is no role for prophylactic anticoagulation, but women should be informed about the symptoms and signs of VTE, and seek medical attention if these develop.[23]

The platelet count often decreases during pregnancy, even in women with ET. Women who require anticoagulation therapy during pregnancy should be managed with heparin and those who develop thrombosis during pregnancy may benefit from cytoreductive therapy with interferon alfa. Interferon improves maternal and fetal outcomes. [23] If interferon fails to lower the platelet count, hydroxyurea can be considered for women in the second or third trimester of pregnancy. When administered in the second or third trimester to women with sickle cell disease, hydroxyurea is associated with little risk, although it may predispose to lower birthweight and prematurity. There is limited experience with anagrelide in pregnancy, so it should be avoided.

Women who develop acquired von Willebrand syndrome (AVWS) in pregnancy secondary to ET should be considered for cytoreductive therapy to reduce the risk of postpartum hemorrhage (PPH). Unless there is bleeding, cytoreductive therapy can usually be deferred until the third trimester. However, treatment must be started early enough in the third trimester to reduce the risk of bleeding during labor. The platelet count target is less stringent with AVWS than it is with high-risk ET alone.

Primary myelofibrosis (PMF) is uncommon in women of childbearing age and most women with advanced disease have reduced fertility. If PMF is diagnosed during pregnancy, transfusion support is the primary treatment. Aspirin prophylaxis should be considered if the platelet count is above 50,000/μL. Medications such as ruxolitinib should be avoided because they may be teratogenic.

Of the MPNs, polycythemia vera requires the most active management. Aspirin should be continued in pregnancy. Phlebotomy may be needed to maintain the hematocrit below 45%, although it may be reasonable to aim for a lower target of 40% to 42%. Phlebotomy requirements may decrease during pregnancy due to dilutional anemia of pregnancy. If phlebotomy alone is insufficient for hematocrit control or women are at high risk because of a prior history of thrombosis, interferon alfa can be used. Interferon has a positive impact on maternal outcomes and reduces the risk of pregnancy complications associated with MPNs.[23] Women with a history of thrombosis should be managed with heparins, but prophylactic anticoagulation is rarely warranted. Some experts recommend anticoagulation therapy for 6 weeks postpartum, but data supporting this recommendation are lacking and postpartum hematocrit control is likely to be excellent because of peripartum blood loss.

CLINICAL VIGNETTE: ESSENTIAL THROMBOCYTHEMIA IN PREGNANCY

A 35-year-old G2P1 is noted to have a platelet count of 720,000/ μ L at her first prenatal visit and is referred to hematology. Iron studies are normal and there is no evidence of an inflammatory condition. Retrospective review of complete blood counts indicates that her platelet count was mildly elevated over the last several years with a highest count of 590,000/ μL 1 year ago. Although her platelet count ranged from 450,000/μL to 500,000/μL early in her pregnancy 2 years ago, her count was in the upper range of normal range in the third trimester. The pregnancy was uncomplicated, and she underwent spontaneous vaginal delivery at 39 weeks' gestation. She has no chronic medical conditions or prior thrombotic events. Her only medications are prenatal vitamins.

Gene sequencing reveals a calreticulin mutation and confirms the diagnosis of ET. She is at 13 weeks' gestation at the time of her first hematology clinic visit. She denies bleeding or easy bruising. She is started on aspirin (81 mg daily). Her platelet count decreases to 675,000/μL in the third trimester, and she has a normal spontaneous vaginal delivery at 40 weeks' gestation. The risks and benefits of continued aspirin in the context of low risk ET are discussed, and she opts to stop aspirin 6 weeks after delivery.

BLEEDING DISORDERS

All women with acquired or congenital bleeding disorders should be evaluated by a hematologist prior to delivery. Bleeding disorders increase the risk of PPH and are important to consider prior to neuraxial anesthesia or cesarean section. Some bleeding disorders can be associated with a risk of in the fetus or neonate.

Disseminated Intravascular Coagulation

DIC in pregnant women can occur in the settings of HELLP syndrome, placental abruption, amniotic fluid embolism, uterine rupture, intrauterine fetal demise, sepsis, and AFLP. This condition leads to a consumptive coagulopathy characterized by a low platelet count and reduced levels of fibrinogen (see Chapter 137). The platelet count should be maintained above 50,000/μL in women undergoing cesarean section with transfusion. Regardless of mode of delivery, cryoprecipitate should be given to maintain the fibrinogen level above 100 mg/dL or above 150 mg/dL if neuraxial anesthesia is planned. Plasma may also be needed, but it should be reserved for significant coagulation test prolongation.

When evaluating the etiology of DIC, amniotic fluid embolism, although rare, needs to be considered because it is associated with a mortality rate as high as 80%. Up to a fifth of women with an amniotic fluid embolism develop a coagulopathy, so amniotic fluid embolism should be considered in any pregnant or postpartum woman with DIC.

von Willebrand Disease

von Willebrand disease (VWD) is the most common inherited bleeding disorder (see Chapter 133). Management of VWD in pregnancy depends on the type. VWD does not impair fertility or increase the likelihood of miscarriage but is associated with an increased rate of PPH even when well managed.[24] Up to 75% of women with moderate to severe VWD experience significant peripartum bleeding.[25] Rates are lowest for type I VWD as a result of the physiologic increase in VWF and factor VIII levels starting in the second trimester and peaking near term. VWF levels peak around 35 weeks' gestation, whereas factor VIII levels peak early in the third trimester.[26] The level of VWF in the third trimester at 34 to 36 weeks' gestation informs treatment in patients with type I VWD. No treatment is needed for VWF levels over 80 IU/dL or perhaps even over 50 IU/dL. In patients with type 2 VWD, activity levels (VWF:GPIbM or VWF:RCo) less than 80 IU/dL should prompt intervention for delivery. With type 3 VWD, hemostatic levels are unlikely to be achieved and plans for delivery should not await third trimester values.

Desmopressin can be associated with blood pressure spikes, hyponatremia, thrombosis, and an oxytocin-like effect that may stimulate uterine contraction. Because desmopressin challenge is not recommended during pregnancy, responsiveness to desmopressin should be assessed prior to conception in women with type 1 or type 2 VWD. Desmopressin has been used safely to manage minor procedures during pregnancy in women with known responsiveness. To minimize risks, exposure should be limited.

If not administered earlier to facilitate epidural anesthesia, desmopressin should be given just after umbilical cord clamping to limit fetal exposure. When given, fluid administration should be used with caution because of the risk of hyponatremia. A second dose of desmopressin can be considered 8 to 24 hours later to coincide with removal of the epidural catheter. Women given desmopressin alone remain at risk for delayed PPH; to reduce this risk, concomitant tranexamic acid (1 g every 6 hours for up to 7 days) is often given.

Patients with type 3 VWD and those with type 1 or 2 VWD who have unknown responsiveness to desmopressin or are unresponsive to desmopressin require factor replacement. The goal of factor replacement is to achieve VWF levels of at least 100 IU/dL and ideally over 150 IU/dL. Factor replacement for moderate to severe VWD should continue for 5 to 7 days postpartum to minimize the risk of delayed PPH. Tranexamic acid should be used as an adjunct in women with ongoing heavy bleeding.

Patients without a documented bleeding disorder who have bleeding complications during pregnancy should be assessed for VWD. This assessment begins with a thorough bleeding history with particular attention to menses, and proceeds to VWD testing. If tests are normal, they should be repeated 12 weeks or more postpartum to exclude the influence of pregnancy on factor levels (see Chapter 133).

HEMOPHILIA A AND B

Hemophilia A and B are X-linked recessive diseases causing factor VIII and factor IX deficiency, respectively (see Chapter 134). As such, women are primarily carriers but can be rarely affected with a mild phenotype from asymmetric X-chromosome inactivation (lyonization) or compound heterozygosity as an offspring of an affected father and carrier mother. Female children of affected fathers are obligate carriers.

Women who are carriers should have factor levels measured and receive factor infusion peripartum if levels are below 50%. Like VWD, even when factor levels normalize during pregnancy, there still is a risk of PPH. Normalization of factor levels is more common in hemophilia A than hemophilia B carriers because of the substantial increase in FVIII during pregnancy; changes in FIX levels during pregnancy are more modest. If factor infusion is needed, a level of 100 to 150 IU/dL should be targeted and replacement continued for at least 3 days after vaginal delivery and for 5 to 7 days after cesarean delivery. Concomitant tranexamic acid may be of benefit and can be given for up to a week after delivery. However, tranexamic acid alone is insufficient treatment for women with reduced factor levels.

For women carrying a male fetus, there is a 50% chance of the offspring being affected. Women who would consider termination of an affected fetus may wish to pursue chorionic villus sampling. Due to the risk of hemorrhage, vaginal delivery may be pursued, but vacuum- and forceps-assisted delivery should be avoided, as should scalp electrodes, fetal blood sampling and intramuscular injections. Umbilical cord blood sampling may be used to determine if the child is affected. Up to 10% of affected neonates have bleeding complications in the perinatal period, including intracranial hemorrhage. Ideally, a pediatric hematologist with experience treating hemophilia should be involved in the management prior to delivery and postpartum.

Acquired Hemophilia A

Acquired hemophilia A is a rare autoimmune disease secondary to antibodies or inhibitors directed against FVIII (see Chapter 134). Achievement of hemostasis can be problematic in patients with this condition and eradication of the inhibitor prior to delivery, or more ideally conception, is recommended. Corticosteroids and rituximab are the treatments of choice during pregnancy. If there is serious bleeding, recombinant FVIIa (rFVIIa) or activated prothrombin complex concentrate (aPCC) may be required. Although emicizumab is highly effective in nonpregnant patients,[27] it should probably be avoided in pregnancy until more data are available because it crosses the placenta and has a long half-life (see Chapter 136).

Most inhibitors in hemophilia A are IgG antibodies. Therefore, the r antibodies can cross the placenta, and cause bleeding in the fetus or neonate. As with neonates at risk of congenital hemophilia, instrumentation during delivery should be avoided, umbilical cord blood evaluated, and a pediatric hematologist involved in the care of the neonate.

Factor XI Deficiency

FXI deficiency is heterogeneous in its inheritance and phenotype (see Chapter 135). Inheritance may be autosomal dominant or recessive and is more common in individuals of Ashkenazi Jewish heritage. This condition is increasingly included in genetic screening offered to women during preconception counseling or early in pregnancy. Women with FXI deficiency may or may not have a prior history of bleeding.

The FXI level should be quantified at 32 to 34 weeks' gestation to facilitate planning. Levels measured in the first or second trimester may be less useful because some studies suggest that levels decrease later in pregnancy.[28,29]

TABLE 149.3 Management of Factor XI Deficiency

Factor XI Level	>40%	20%–40%	<20%
Management	No intervention Consider TXA if significant bleeding history	Neuraxial anesthesia: FXI replacement No neuraxial anesthesia: TXA alone	Bleeding history present or neuraxial anesthesia: FXI replacement No bleeding history and no neuraxial anesthesia: TXA alone

FXI, Factor XI, *TXA*, tranexamic acid 1 g intravenously every 6 hours for 24 to 48 hours.
Lee CA, Chi C, Pavord SR, et al. The obstetric and gynaecological management of women with inherited bleeding disorders—review with guidelines produced by a taskforce of UK Haemophilia Centre Doctors' Organization. *Haemoph Off J World Fed Hemoph*. 2006;12(4):301–336.

The FXI level, the presence or absence of a history of bleeding and the intended mode of anesthesia determine the need for intervention. The bleeding history is central because there is poor correlation between FXI levels and the propensity for bleeding. No treatment is needed for women with a normal activated partial thromboplastin time (aPTT), an FXI level above 40%, and no bleeding history, even if neuraxial anesthesia is planned. An approach for women with lower FXI levels or a bleeding history is presented in Table 149.3.[30] Tranexamic acid is useful for patients not requiring FXI replacement; it is administered intravenously at a dose of 1 g every 6 hours for 24 to 48 hours. Women who require FXI replacement should be given plasma (15 to 20 mL/kg) prior to neuraxial anesthesia or active labor, and more should be given 24 hours later if labor is ongoing, or an epidural catheter remains in place (see Chapter 135).

Because of the mild bleeding diathesis associated with FXI deficiency, antepartum diagnosis of affected fetuses and elective termination are rare considerations. Umbilical cord blood sampling is usually limited to neonates of mothers with more severe deficiency (e.g., FXI levels below 20%, although there is no absolute cutoff) and may be a consideration prior to circumcision or other procedures. There is no need to avoid intramuscular injections (e.g., hepatitis B vaccination), even if the mother has a history of bleeding.

CLINICAL VIGNETTE: ASYMPTOMATIC FACTOR XI DEFICIENCY

A 28-year-old woman with no significant past medical history is referred to hematology because Factor XI deficiency was detected on genetic carrier screening. Her partner is not a carrier. She has no history of bleeding, including no heavy menstrual bleeding or excessive bleeding after wisdom tooth extraction or anterior cruciate ligament repair. Her factor XI level is 22%. Her aPTT is at the upper limit of normal. She would like epidural anesthesia during delivery. She is managed with a 48-h course of tranexamic acid with the first dose administered when she is in active labor. She delivers a healthy infant and does not have excessive bleeding.

Other Platelet Function Disorders

Disorders of platelet function other than VWD are rare and heterogenous (see Chapter 128). Disorders may be severe, such as Glanzmann thrombasthenia, or mild, such as granule deficiencies. The rise in VWF during pregnancy may partially compensate for milder platelet defects. Management for delivery should be in accordance with the standard practice for the specific platelet disorder in the setting of bleeding. The risks of neuraxial anesthesia are higher and necessitate more aggressive management. Unassisted delivery is preferred if vaginal delivery is pursued in disorders where there is a risk of an affected fetus.

VENOUS THROMBOEMBOLISM

VTE is a leading cause of maternal morbidity and mortality (see Chapter 141). The risk of VTE, which includes deep vein thrombosis (DVT) and pulmonary embolism (PE), increases two- to fourfold during pregnancy and the early postpartum period. In women with a previous VTE, pregnancy increases the risk of a recurrent event. Factors accounting for the prothrombotic state associated with pregnancy include altered levels of procoagulants and anticoagulants; increased estrogen levels, which lead to venous distention and subsequent venous stasis; increased plasma volume; and compression of the left iliac vein by the gravid uterus, which leads to decreased lower extremity blood flow velocity, particularly in the left leg (Table 149.4).[28,29] Along with these increases in procoagulant proteins, protein S, one of the most important anticoagulant proteins, decreases. Finally, fibrinolytic activity decreases during pregnancy as the levels of plasminogen activator inhibitors 1 and 2 (PAI-1 and PAI-2) increase.

D-dimer testing has no role for risk stratification in pregnant women because no patient with symptoms of VTE should be considered at low risk during pregnancy, and the test has poor performance characteristics in this setting with estimated sensitivity and specificity of 73% and 15%, respectively.[31] Lower extremity compression ultrasound can be conducted in the normal manner in pregnant women. Lower extremity edema may decrease the sensitivity of lower extremity ultrasound for the diagnosis of distal DVT. In cases where the pretest probability is high, and the ultrasound is of poor quality, repeat assessment may be needed. A limitation of ultrasound is the inability to visualize the iliac veins. In such cases, MRI, particularly with direct thrombus imaging, may be useful. If DVT is diagnosed, evaluation for PE is often unnecessary because the treatment is the same.

In pregnant women with symptoms suggestive of PE, such as shortness of breath or pleuritic chest pain, imaging is needed. Options include ventilation/perfusion (V/Q) lung scan and CT pulmonary angiography (CTPA). The calculated radiation risks to the fetus with a V/Q scan and CTPA are 0.5 and 0.1 mGy, respectively, values well below the 50 mGy threshold associated with an increased risk of fetal health problems. However, the calculated minimum radiation dose to each breast for an average 60 kg woman is significantly higher with CTPA than with V/Q scanning, although the dose with CTPA can be reduced by approximately 20% with the use of bismuth breast shields. Therefore, V/Q scanning is often preferred over CTPA in some centers provided the chest X-ray is normal. In pregnant women with documented PE, the severity can be assessed by measuring biomarkers such as troponin and brain natriuretic peptide (BNP) levels. If these are elevated, a transthoracic echocardiogram is indicated for evaluation of right heart strain and admission to a hospital is warranted.

VTE in pregnancy is treated with low-molecular-weight heparin (LMWH) at standard therapeutic doses (e.g., enoxaparin 1 mg/kg twice daily, dalteparin 100 U/kg twice daily, or 200 U/kg once daily). LMWH does not cross the placenta for hemodynamically unstable patients or those with an imminent procedure (e.g., possible cesarean section), unfractionated heparin (UFH) is preferable. The greater difficulty of administration, the requirement for IV access, and the higher rate of heparin-induced thrombocytopenia (HIT) motivate the preference for LMWH.[32] Care must be taken to adjust heparin dosing during pregnancy with accompanying expected weight gain, as well as reducing dosing postpartum, as appropriate. Patients with borderline renal function, extremes of body weight, or evidence of breakthrough thrombosis should have anti-Xa level measurements to ensure appropriate dosing.

VTE in pregnancy should be treated for at least 3 months or at least 6 weeks postpartum, whichever is longer. A course of 6 months of anticoagulation may be considered for women with more extensive or hemodynamically significant VTE. Breastfeeding is safe with LMWH.

Warfarin is contraindicated in pregnancy because it crosses the placenta and is a known teratogen. Women considering pregnancy who are on warfarin should transition to LMWH prior to conception because of this risk. While the risk of teratogenicity rapidly diminishes as organogenesis is complete, warfarin also poses a risk of fetal hemorrhage because it can inhibit fetal vitamin K-dependent clotting factor synthesis. As such, even though teratogenicity is no longer the primary consideration, warfarin should be avoided whenever possible in the second and third trimesters. Rare clinical scenarios, such as women with mechanical heart valves (discussed further in a subsequent section) or impaired renal function, are the primary setting in which warfarin during late pregnancy might be considered. For severe renal insufficiency, subcutaneous UFH can be used at a dose of 250 U/kg every 12 hours. Patients can be transitioned to warfarin in the postpartum period, which is safe while breastfeeding. Women whose course of anticoagulation therapy will stop 6 weeks after delivery may prefer to remain on heparin to avoid the monitoring and dose adjustments required with warfarin.

Although small amounts of fondaparinux may cross the placenta, it has not been associated with teratogenicity or fetal hemorrhage.[33] Fondaparinux is the preferred agent for use in pregnant women with a history of HIT or heparin allergy. Oral direct anticoagulants (dabigatran, apixaban, rivaroxaban, and edoxaban) are not recommended in pregnancy or during breast feeding because they cross the placenta and pass into the breast milk.

Anticoagulation should be discontinued at the time of parturition whenever possible. UFH and LMWH should, in most circumstances, be stopped 12 to 24 hours before delivery. If the risk of recurrent VTE is particularly high or a PE is quite recent, women receiving LMWH can be converted to intravenous UFH, which can be stopped 4 to 6 hours before delivery, thereby minimizing the time of anticoagulation. Neuraxial anesthesia can be safely administered when the aPTT is normal. If spontaneous labor occurs, neuraxial anesthesia should be delayed until 24 hours after the last dose of LMWH and 12 hours after the last dose of subcutaneous UFH. UFH or LMWH may be reinitiated 6 to 12 hours after delivery or removal of the epidural catheter.

For patients with impaired renal function precluding the use of low-molecular-weight heparins during pregnancy, higher doses of unfractionated heparin can be administered subcutaneously.

PROPHYLACTIC ANTICOAGULATION DURING PREGNANCY

Given the prothrombotic state associated with pregnancy, prophylactic anticoagulation should be considered in pregnant women with a history of VTE. Recurrence rates for VTE during pregnancy may be as high as 12% based on the results of retrospective studies, but more recent prospective studies have shown antepartum VTE recurrence rates as low as 2.4%.[34] This exceeds the rate of complications of prophylactic dose anticoagulant and argues in favor of antepartum prophylaxis. Women with prior pregnancy- or estrogen-associated VTE, as well as those with prior unprovoked VTE, are at highest risk of recurrence and should routinely receive prophylactic dose LMWH heparin during pregnancy with a transition to UFH at 36 to 37 weeks' gestation to facilitate delivery. Women with a single prior provoked VTE that was not in the context of pregnancy or exogenous estrogen use can forgo antepartum prophylactic anticoagulation, but postpartum prophylaxis for 6 weeks is recommended, as this is the highest risk period for VTE, particularly PE.

THROMBOPHILIAS AND PREGNANCY

Inherited thrombophilias often prompt a consideration for VTE thromboprophylaxis during pregnancy. Inherited thrombophilias include factor V Leiden, prothrombin gene mutation (G20210A), antithrombin deficiency, protein S deficiency, and protein C deficiency (see Chapter 138). Multiple studies have shown that these disorders have no influence on the risk of recurrent VTE. Therefore, their presence does not impact on the decision about antepartum thromboprophylaxis.

Women may be diagnosed with an inherited thrombophilia through family history or commercial genetic testing. In the absence of a personal history of VTE, the type of thrombophilia and the family history may help guide the need for prophylactic anticoagulation. Guidelines from the American Society of Hematology use a threshold risk of VTE of at least 2% antepartum and 1% postpartum to recommend prophylactic anticoagulation.[35] These cutoffs were determined by weighing the benefits of anticoagulation against the risk of bleeding. Following this guidance, most women with inherited thrombophilias do not require anticoagulation prophylaxis because the risks outweigh the benefit (Table 149.5).

Methylenetetrahydrofolate reductase (MTHFR) polymorphisms are not a risk factor for VTE. Women with MTHFR polymorphisms should be counseled about the need for folate supplementation, but do not require an increased dose.

Screening for inherited thrombophilia solely on the basis of recurrent pregnancy loss is controversial. Negative testing does not exclude the possibility that the patient has an inherited or acquired hypercoagulable state causing pregnancy loss; positive testing does not establish causality. The only tests that confer a clear management approach are antiphospholipid antibodies. Therefore, it may be more fruitful to discuss the risks and benefits of empirical treatment with prophylactic dose LMWH rather than pursue laboratory testing apart from antiphospholipid antibodies. A metanalysis of studies evaluating the use of aspirin and heparin in women with recurrent pregnancy loss failed to demonstrate an increase in live birthrate attributable to these medications.[36] This analysis included women with inherited thrombophilias and women who had tested negative. As such, there is no clear evidence for anticoagulation to support pregnancy carriage in women who do not have antiphospholipid antibodies. Guidance against testing and prophylactic anticoagulation in this setting is in accordance with American College of Obstetricians and Gynecologists (ACOG) guidelines.[37] These guidelines also recommend against thrombophilia testing and anticoagulation in women with prior placental abruption, preeclampsia, or IUGR.

TABLE 149.5 Prophylactic Anticoagulation for Inherited Thrombophilias

Inherited Thrombophilia	Prophylactic Anticoagulation Recommendation[35]
FVL or PGM heterozygous	No
FVL homozygous or FVL and PGM compound heterozygous	Antepartum and postpartum
PGM homozygous	Only postpartum
Protein S or Protein C deficiency	Only postpartum if positive family history, otherwise no
Antithrombin deficiency	Antepartum and postpartum if positive family history, otherwise no

FVL, Factor V Leiden; *PGM*, prothrombin gene mutation.

In a rare instance that placental infarction is documented, empirical prophylactic anticoagulation may be considered for future pregnancies. It is vital that a pathologist experienced in the examination of placentae makes this determination because some thrombosis is expected with placental separation. An accurate determination that infarction occurred antepartum and not during parturition is central to considering this as pathologic or evidence of a propensity for thrombosis.

Motivation to undertake the anticoagulation is often higher in women undergoing assisted reproduction due to its complexity and the expense involved. If LMWH is considered in this setting because of recurrent pregnancy loss, hematologists should acknowledge the lack of evidence supporting its use so that patients can make an informed decision.

CLINICAL VIGNETTE: FACTOR V LEIDEN DURING PREGNANCY

A 25-year-old woman wishes to become pregnant. Her mother was diagnosed with deep vein thrombosis at the age of 70 years and was found to be heterozygous for the factor V Leiden mutation. The patient has no history of VTE, even while taking an estrogen-containing oral contraceptive for 7 years. She is currently trying to become pregnant and had one spontaneous abortion at approximately 6 weeks' gestation. Her primary care physician tested her for factor V Leiden, and she was found to be heterozygous for the mutation. She is asking if she should be on anticoagulation therapy during her next pregnancy. She sees a hematologist and is counseled against prophylactic anticoagulation. She becomes pregnant again 3 months later and has an uneventful pregnancy with a normal spontaneous vaginal delivery at term.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibody syndrome (APS) is the most common form of acquired thrombophilia and is a well-established cause of thrombosis and pregnancy loss (see Chapter 139). Antiphospholipid antibodies include the lupus anticoagulant and antibodies against cardiolipin and β_2-glycoprotein I. Antibodies can occur as a manifestation of various conditions, such as SLE and other rheumatic diseases, infection, and drug reactions. Since most antiphospholipid antibodies have no clinical impact, a distinction is made between individuals who are solely antibody positive and those who have APS. APS is defined by the combination of laboratory testing and either pregnancy loss or thrombotic events (Table 149.6). When pregnancy loss is the only clinical manifestation, the term obstetrical APS is used.

Antiphospholipid antibodies exert their prothrombotic effects through multiple mechanisms, including interacting with phospholipids on the surface of platelets, increasing platelet adhesiveness and production of von Willebrand multimers. In pregnant patients, antiphospholipid antibodies may cause pregnancy loss by inducing thrombosis in the placenta or interference with placental trophoblast function. This latter mechanism may explain why many women with

TABLE 149.6 Antiphospholipid Syndrome

Vascular Thrombosis
One or more episodes of arterial or venous thrombosis confirmed by imaging
Pregnancy morbidity
Three or more consecutive spontaneous abortions before 10 weeks of gestation
Death of a fetus beyond 10 weeks of gestation with normal fetal morphology
Premature birth before 34 weeks of gestation
Laboratory Criteria (all measured on two or more occasions at least 12 weeks apart)
Lupus anticoagulant
Anticardiolipin antibody IgG or IgM
Anti-B_2 glycoprotein IgG or IgM

obstetrical APS do not develop thrombotic manifestations despite persistent antibody positivity. It is therefore possible that their autoantibodies inhibit placental trophoblast function but are unable to activate coagulation. Other women have both obstetrical APS and thrombotic complications.

Any individual with a thrombotic event attributed to APS, whether venous or arterial, requires lifelong anticoagulation therapy, including during pregnancy. Patients with prior obstetric APS should be managed with prophylactic dose LMWH and aspirin in pregnancy and for 6 weeks after delivery; aspirin is added for prevention of preeclampsia. Many hematologists and obstetricians omit LMWH if the clinical criterion for APS is delivery before 34 weeks' gestation because the primary pathology can then be attributed to the preeclampsia spectrum and may be sufficiently mitigated by aspirin alone. If antibodies are identified without qualifying as APS (e.g., as part of serologic testing during the work-up of SLE), women are managed with aspirin alone due to the increased risk of preeclampsia. Women receiving aspirin alone antepartum are often given a concomitant 6-week course of LMWH prophylaxis after cesarean delivery because of the risk of thrombosis with this procedure.

For women with significant renal insufficiency, which is of relevance in APS because of its association with SLE, UFH can be used in place of LMWH. Direct oral anticoagulants and warfarin should not be used during pregnancy.

Mechanical Heart Valves

Coupled with the prothrombotic physiology of pregnancy, mechanical heart valves increase the risk of thrombosis. While this topic is complex and beyond the scope of this review, and management is usually left to cardiology, there are several points that are important for hematologists. Although warfarin is the standard of care for prevention of valve thrombosis, warfarin is usually contraindicated in pregnancy because it is teratogenic, and it increases the risk of fetal and neonatal bleeding. Options for management are (1) continuing warfarin throughout pregnancy, (2) substituting LMWH for the first trimester of pregnancy (the period of highest risk for teratogenicity) and then resuming warfarin during the second trimester, and (3) LMWH for the entirety of pregnancy and resuming warfarin postpartum. The decision must be individualized, but factors that raise the risk of substitution of LMWH include mechanical valves in the mitral and tricuspid positions, concurrent atrial fibrillation, multiple mechanical valves, and prior thrombosis of the valve. In these circumstances, the risk to maternal health of using LMWH is high enough that the recommendation for most, if not all, women will be to continue warfarin. The dose of warfarin correlates with thrombotic risk, so risks to the fetus are higher for women requiring higher doses to achieve a therapeutic INR. For patients who switch to LMWH during pregnancy, anti-Xa monitoring every 1 to 2 weeks is warranted and the dose of LMWH levels should be adjusted to achieve levels at the upper end of the therapeutic range. The frequency of anti-Xa monitoring is motivated by the dire consequence of valve thrombosis as well as the expected change in GFR during pregnancy. If renal insufficiency precludes the use of LMWH, UFH can be substituted. Collaboration between obstetrics, cardiology, and hematology through pregnancy is vital for these high-risk patients.

FUTURE DIRECTIONS

Management of the hematologic complications of pregnancy continues to be a challenge due to both maternal and fetal factors. Hematologic problems remain among the most common complications of pregnancy, and many chronic blood disorders interact with the physiology of pregnancy. The physicians and patient involved benefit from a multidisciplinary approach with hematology collaborating with obstetrics and obstetrical anesthesiology to deliver optimal care. In certain disorders, the management is clear and will likely remain unchanged in the future. In other disorders, treatment paradigms may shift as new treatments are discovered for nonpregnant patients or the safety of existing therapies are better characterized. In all instances, further well-designed studies will continue to advance evidence-based management of the pregnant patient.

CHAPTER 150

HEMATOLOGIC MANIFESTATIONS OF END-ORGAN FAILURE

Marissa Laureano and Christopher Hillis

The hematologic system is intricately connected to other vital organs. There are multiple pathways that affect the red blood cells (RBCs), white blood cells, platelets, and hemostasis. This chapter will discuss the hematologic abnormalities encountered in liver disease, renal disease, splenic dysfunction, heart failure, respiratory disease, and endocrinopathies. For further details about the individual blood systems affected, the reader should refer to the specific chapters dealing with those components (e.g., anemia, coagulopathies).

HEMATOLOGIC MANIFESTATIONS OF LIVER DISEASE

The liver plays key roles in hematopoiesis and hemostasis. It produces the hematopoietic growth factors thrombopoietin and erythropoietin (10% of total production),[1] contributes to heme biosynthesis, and is a site of extramedullary hematopoiesis. It contributes to hemostasis through synthesis of coagulation factors, coagulation inhibitors, and fibrinolytic proteins.[1] It is also involved in the clearance of plasma proteins, including activated coagulation factors, proteolytic enzyme—inhibitor complexes, fibrin, and fibrinogen degradation products.[2]

Liver cirrhosis is associated with the development of portal hypertension, which leads to the formation of portal gastropathy and varices, which can result in gastrointestinal (GI) bleeding. Portal hypertension also causes hypersplenism decreasing the fraction of circulating platelets, leukocytes, and erythrocytes through splenic sequestration.[3]

RED BLOOD CELL ABNORMALITIES

Morphologic Abnormalities

In liver disease, the size and shape of the RBC membrane is affected by abnormal lipid metabolism. Excess cholesterol in the outer RBC membrane bilayer causes macrocytosis and target cells (Fig. 150.1).[4] These morphologic changes usually do not lead to significant anemia by themselves, but they are sometimes encountered in the setting of anemia due to other impairments of red cell homeostasis in liver disease (e.g., hypersplenism, GI bleeding). Excess membrane cholesterol also decreases RBC membrane fluidity due to impaired migration of integral membrane proteins and inability to repair peroxidized membrane lipids.[1] When these less deformable RBCs traverse the splenic microcirculation, cytoskeletal damage and permanent deformation can occur, resulting in the formation of acanthocytes (spur cells) and increased clearance in the reticuloendothelial system.[5]

Spur cell anemia is a hemolytic anemia associated with severe cirrhosis.[6] It is rare and associated with a poor prognosis. Treatments for spur cell anemia associated with liver disease are limited. The most effective therapy is liver transplantation. Clinical improvement using flunarizine, pentoxifylline, and cholestyramine has been reported.[7]

Anemia

Anemia in patients with liver disease occurs through hemodilution, sequestration, reduced production, and blood loss. The anemia may be related to the liver disease or the underlying cause of the liver disease itself. Fluid retention increases whole blood volume in patients with cirrhosis which can result in normal red cell mass but a subnormal hematocrit from hemodilution. Portal hypertension related to liver disease can result in hypersplenism with subsequent sequestration of erythrocytes.[8] Erythropoiesis is reduced by nutritional deficiencies in folate or vitamin B_{12} resulting from poor intake or malabsorption. Bone marrow suppression can occur from alcohol consumption, viral hepatitis, hepatitis-associated aplastic anemia, and anemia of chronic disease.[9] Patients with chronic liver disease or cirrhosis can also experience nonimmune hemolysis because of acquired alterations in the RBC membrane (e.g., spur cell anemia), Zieve syndrome (hemolytic anemia, hypertriglyceridemia, and jaundice), or treatment-related marrow suppression (e.g., ribavirin).[9]

The therapeutic approach to anemia in liver disease includes transfusion support for symptomatic disease, identification and treatment of GI bleeding, nutrient supplementation for deficiencies, discontinuation of bone marrow suppressive medications, alcohol cessation, and treatment for the primary cause of liver disease.

WHITE BLOOD CELL ABNORMALITIES

Leukopenia

Leukopenia, particularly neutropenia, has also been noted in patients with cirrhosis. Causes of leukopenia include splenic sequestration, medications, or bone marrow suppression mediated by primary infections or toxins (e.g., hepatitis B or C, alcohol).[3] Patients with cirrhosis may also be at higher risk for severe infections due to impairment in neutrophil recruitment and phagocytic function.[10] Granulocyte colony-stimulating factor (G-CSF) is thought to improve neutrophil transendothelial migration in patients with cirrhosis.[11] The use of G-CSF in patients with decompensated cirrhosis was shown to improve survival in a randomized trial[12]; however, the role of G-CSF in the treatment of patients with cirrhosis and the exact mechanisms through which it may ameliorate liver disease are still uncertain and warrant further research.

PLATELET ABNORMALITIES

Thrombocytopenia

Thrombocytopenia is the most common cytopenia associated with liver disease, occurring in up to 77% of patients with cirrhosis.[13] Severe thrombocytopenia ($<30 \times 10^9$/L) and spontaneous bleeding are uncommon.

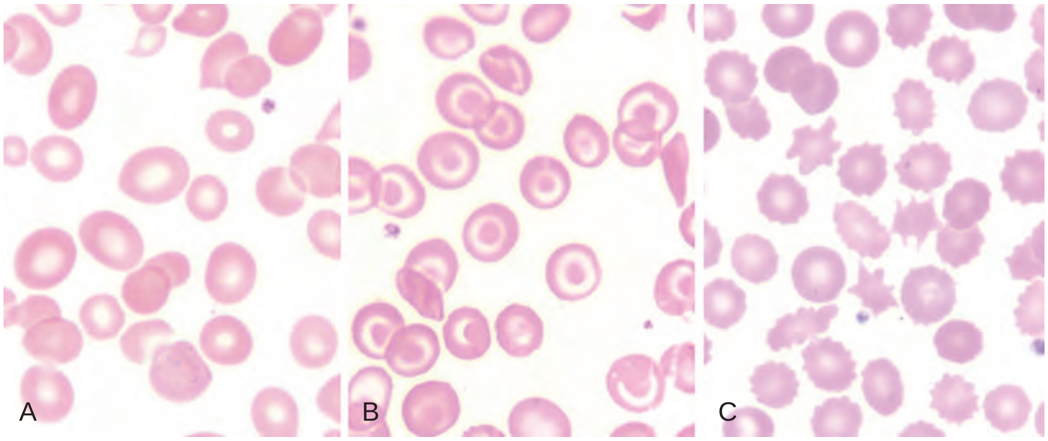

Figure 150.1 RED BLOOD CELL MORPHOLOGY IN LIVER DISEASE. (A) Macrocytes have a mean corpuscular volume greater than 100 fL and can be oval shaped. Commonly associated disorders include liver disease and vitamin B_{12} and folate deficiency. (B) Target cells are characterized by the bull's-eye appearance of the red blood cell (RBC). They are a result of an increased surface-to-volume ratio related to excess RBC membrane (e.g., liver disease) or disproportionate reduction of cytoplasmic content (e.g., hemoglobinopathies, iron deficiency). (C) Acanthocytes, or spur cells, typically appear as contracted RBCs lacking central pallor with multiple irregular membrane projections. The morphologic appearance reflects the irreversible cytoskeletal damage that has occurred because of passage of nondeformable RBCs through the reticuloendothelial system. They are most commonly seen in severe liver disease but can also be features of rare neuroacanthocytosis syndromes or lipoprotein disorders.

Many factors contribute to thrombocytopenia in liver disease. Decreased platelet counts may result from hypersplenism, impaired thrombopoiesis related to nutritional deficiencies (folate or vitamin B_{12}), direct toxicity of alcohol, viral hepatitis, or reduced hepatic synthesis of thrombopoietin.[14] Autoantibodies to platelet antigens have been demonstrated in patients with cirrhosis, suggesting that accelerated destruction of platelets may occur via immune-mediated mechanisms.[15] Hepatitis C is a secondary cause of immune thrombocytopenia. Thrombocytopenia in patients with cirrhosis, especially in combination with leukopenia, is associated with increased morbidity and mortality.[3]

Platelet Dysfunction

Intrinsic platelet defects leading to abnormal platelet aggregation or adhesion include impaired transmembrane signaling and thromboxane A2 synthesis, storage pool deficiency, or defects in platelet glycoprotein Ib or $\alpha_{IIb}\beta_3$ receptors.[16] Extrinsic defects resulting in platelet dysfunction include circulating fibrinogen degradation products, bile salts, abnormal high-density lipoproteins, and excess production of nitric oxide.[16]

The clinical significance of platelet dysfunction demonstrated in vitro is unclear. This discordance between laboratory findings and clinical bleeding may be explained by two observations. First, platelets studied under physiologic flow conditions show normal adhesion to fibrinogen and collagen even in cirrhosis.[17] Second, elevated levels of von Willebrand factor (vWF) are commonly found in patients with cirrhosis and may compensate for thrombocytopenia or platelet dysfunction.[18]

Platelet transfusions can be considered in thrombocytopenia associated with liver disease; however, they are generally not indicated unless the patient has severe thrombocytopenia ($<10 \times 10^9$/L) or platelets less than 50×10^9/L with bleeding. Platelet counts greater than 50×10^9/L are usually considered adequate for invasive procedures. Thrombopoietin (TPO) mimetic agents (e.g., eltrombopag, romiplostim) may offer potential treatment for these patients. Avatrombopag, a second generation TPO agonist, has been examined in patients with chronic liver disease in a pre-procedural setting. Compared to placebo, avatrombopag reduced the frequency of platelet transfusion or rescue therapy.[18] The 2020 American College of Gastroenterology guidelines suggest that TPO agonists can be considered for patients with cirrhosis and a platelet count $< 50 \times 10^9$/L in anticipation of an elective procedure (conditional recommendation, very low level of evidence).[19]

COAGULATION AND LIVER DISEASE

The manifestations of aberrant coagulation in liver disease reflect an interplay between procoagulant and anticoagulant mechanisms. Patients with cirrhosis are at an increased risk of both bleeding and thrombosis.

Coagulation factor and vitamin K deficiency, dysfibrinogenemia, and systemic fibrinolysis contribute to impaired hemostasis. Clinical manifestations range from asymptomatic laboratory abnormalities to life-threatening hemorrhage. However, most cases of spontaneous bleeding in chronic liver disease are due to variceal bleeding rather than abnormalities in coagulation.

Hepatic dysfunction leads to reduced synthesis of most coagulation factors. The number and degree of clotting factor deficiencies reflect the severity of liver damage. Factor VII, having the shortest half-life (6 hours) of the coagulation factors, often declines early and is reflected by prolongation of the prothrombin time (PT)/international normalized ratio (INR). Conversely, factor VIII and vWF levels may be normal or elevated in liver disease because of upregulated compensatory extrahepatic synthesis or impaired hepatic clearance.[2]

Reductions in factors II, VII, IX, and X in patients with liver disease may also result from vitamin K deficiency caused by malnutrition, malabsorption, use of antibiotics, or biliary tract obstruction. For these coagulation factors, vitamin K is required as a cofactor in γ-carboxylation, a process that converts inactive precursors to biologically active factors.

Defects and deficiencies in coagulation factors are suggested by prolonged PT/INR and partial thromboplastin time (PTT) measurements and confirmed by individual factor levels. The INR is incorporated in the Child-Pugh and Model of End-stage Liver Disease scores as a marker of synthetic dysfunction to estimate the severity of liver disease and stratify patients for transplant, respectively. Despite routine use in clinical practice, there are limitations to the PT/INR or PTT in the context of liver disease. First, the INR is not validated for patients with cirrhosis. Second, there is a paucity of evidence that correcting these abnormal values by treatment with plasma or procoagulant agents prevents bleeding.[20]

Several reasons account for the lack of correlation between PT/INR or PTT with bleeding. Liver disease results in deficiencies of procoagulant proteins, but also deficiencies in anticoagulant proteins (antithrombin, proteins C, and protein S). PT/INR and PTT assays only reflect procoagulant protein levels and do not reflect alterations in anticoagulant proteins, the endothelium, or platelet number and function. Tests of thrombin generation such as thromboelastography (TEG) have been studied in randomized control trials (RCTs) to guide transfusions in variceal[21] and nonvariceal bleeding[22] in patients with liver disease. Use of TEG was associated with a lower use of blood products without compromising hemostasis.

Fibrinogen synthesis is generally preserved unless liver disease is severe.[1] Acquired dysfibrinogenemia has been described in approximately 75% of patients with acute and chronic liver disease.[23] Aberrant polymerization of fibrin monomers may be related to excess sialic acid residues on fibrinogen, interfering with the activity of thrombin.[24] Laboratory findings of dysfibrinogenemia include elevated PT, PTT, or thrombin time, low or normal fibrinogen by immunologic assay, and reduced fibrinogen by functional assay (see box on Hemostatic Indices in Liver Disease).

The presence of hyperfibrinolysis in liver disease and its contribution to bleeding risk is controversial. Aside from tissue plasminogen activator (t-PA) and plasminogen activator inhibitor-1 (PAI-1), all fibrinolytic and antifibrinolytic proteins are synthesized by the liver. Increased fibrinolysis may involve release of t-PA in the setting of infection, surgery, ascitic fluid, and altered synthetic functions of the liver.[25] Laboratory tests can indicate increased fibrinolysis (see box on Hemostatic Indices in Liver Disease), but they cannot adequately assess the overall activity of profibrinolytic and antifibrinolytic components. Hyperfibrinolysis may theoretically aggravate bleeding through consumption of coagulation factors, inhibition of fibrin polymerization, and reduced platelet aggregation via degradation of vWF and glycoprotein Ib and $\alpha_{IIb}\beta_3$.[26]

HEMOSTATIC BALANCE IN LIVER DISEASE

	Promotes Thrombosis	Promotes Bleeding
Primary hemostasis	• Increased vWF • Decreased ADAMTS13	• Thrombocytopenia • Platelet dysfunction
Secondary hemostasis	• Increased factor VIII • Decreased protein C, protein S, antithrombin	• Factor deficiencies: II, V, VII, IX, XI • Vitamin K deficiency • Hypofibrinogenemia • Dysfibrinogenemia
Fibrinolysis	• Reduced plasminogen • Increased PAI-1	• Reduced α2-antiplasmin, TAFI, factor XIII • Increased t-PA

ADAMST13, A disintegrin and metalloproteinase with thrombospondin; PAI-1, plasminogen activator inhibitor-1; TAFI, thrombin activatable fibrinolysis inhibitor; t-PA, tissue plasminogen activator; vWF, von Willebrand factor.

TREATMENT OF LIVER DISEASE–RELATED BLEEDING

Correction of asymptomatic hemostatic abnormalities in patients with liver disease is not indicated and potentially harmful.

In bleeding patients, multiple blood products can be considered. Platelet transfusions can be considered to maintain a count greater than 50×10^9/L. RBC transfusions should maintain adequate hemoglobin or hematocrit levels and address symptomatic anemia. An RCT demonstrated that a restrictive RBC transfusion threshold (<7 g/dL) in patients with an acute upper GI bleed reduced rebleeding and increased survival.[27] Prothrombin complex concentrates (PCCs) have been shown to improve coagulation tests, but further studies are required to assess the effect on clinical outcomes.[28] Diverse effects of PCCs include thrombotic complications and allergic reactions. Frozen plasma (FP) can also be considered, but there is a high risk of volume overload with the amount of product required to improve coagulation parameters. For this reason, guidelines suggest that FP should not be used.[19]

A trial of oral vitamin K can be considered in patients with possible vitamin K deficiency. Vitamin K can be given intravenously for earlier onset of action but carries a small risk of anaphylaxis. Subcutaneous and intramuscular administrations should be avoided due to inconsistent absorption and risk of hematoma formation, respectively.

Recombinant factor VIIa (rFVIIa) has been shown to transiently normalize the PT,[29] yet correlation with improved clinical outcomes has been inconsistent. Randomized trials examining rFVIIa in active GI and variceal bleeding did not show any benefit over placebo.[30] rFVIIa appears to reduce blood loss and blood product requirements when used prophylactically in some invasive procedures[31,32]; however, the optimal dosing and settings in which to use rVIIa is still unclear. These potential benefits may be offset by an observed increase in arterial thromboembolic events.[33] The 2016 American Association for the Study of Liver Diseases (AASLD) guidance does not recommend FP or rFVIIa to normalize the INR in cirrhotic patients with portal hypertensive bleeding.[34]

HEMOSTATIC INDICES IN LIVER DISEASE

Laboratory Changes	PT	PTT	TCT	Fib	Clauss	Plt	Platelet Aggregation	FVII	DD	ELT
Thrombocytopenia	N	N	N	N	N	↓	N	N	N	N
Platelet dysfunction	N	N	N	N	N	N	Abnormal	N	N	N
Vitamin K deficiency[a]	↑	↑	N	N	N	N	N	↓	N	N
Factor deficiency	↑	↑	N	N	N	N	N	↓	N	N
Hypofibrinogenemia	N/↑	N/↑	↑	↓	↓	N	N	N	N	N
Dysfibrinogenemia	N/↑	N/↑	↑	N	↓	N	N	N	N	N
Hyperfibrinolysis	N/↑	N/↑	N/↑	N/↓	N/↓	N	N	↓	↑	↓
DIC	N/↑	N/↑	N/↑	↓	↓	↓	N	N/↓	↑	↓

[a] Differentiating between vitamin K deficiency and liver disease can be challenging with conventional laboratory tests. If available, performing a factor II assay with and without Echis venom (factor II biologic and factor II Echis) may be useful. Ecarin is derived from *Echis carinatus* snake venom and can activate prothrombin irrespective of γ-carboxylation. Factor II activity (biologic) is reduced in both vitamin K deficiency and liver disease. In contrast, the factor II Echis is reduced in liver disease but is normal in vitamin K deficiency.

Clauss, Clauss fibrinogen; *DD*, D-dimer; *DIC*, disseminated intravascular coagulation; *ELT*, euglobulin lysis time (measure of fibrinolysis); *Fib*, fibrinogen; *FVII*, factor VII functional assay; *N*, normal; *Plt*, platelet; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *TCT*, thrombin clotting time.

Hyperfibrinolysis and dysfibrinogenemia may exacerbate bleeding. Administration of fibrinogen concentrate or cryoprecipitate may help control bleeding in those with low fibrinogen. Hyperfibrinolysis has been associated with conditions such as trauma and postpartum hemorrhage (PPH). Cochrane Systematic Reviews revealed that tranexamic acid, an antifibrinolytic agent, reduces postpartum blood loss[35] and decreases mortality in trauma patients.[36] Tranexamic acid has also been shown to reduce blood loss and the need for transfusion in liver transplantation.[37] Thrombotic risks must be considered before use (see box on Managing Bleeding due to Coagulopathy of Liver Disease).

HYPERCOAGULABILITY AND THROMBOSIS IN PATIENTS WITH LIVER DISEASE

Variable rates of venous thromboembolism (VTE) in patients with cirrhosis are reported; however, these patients are still at risk of VTE and are not "autoanticoagulated."[38] Reported incidences of deep venous thrombosis (DVT) or pulmonary embolism (PE) have ranged from 0.5% to 6.3%.[39] Thrombotic complications can involve portal, mesenteric, and hepatic veins. The prevalence of portal vein thrombosis (PVT) is approximately 0.6% to 15.8% of patients with cirrhosis, [40] and is associated with inferior prognosis in liver transplantation.[41]

Despite increased bleeding risks in liver disease, patients still benefit from prophylactic or therapeutic anticoagulation. PVT has been associated with poor prognosis and a higher risk of variceal bleeding.[42] Furthermore, microvascular thrombosis has been proposed to promote hepatic fibrosis and progression of cirrhosis.[43] Clinical decisions are limited by a paucity of studies establishing the optimal dose, duration, monitoring, or choice of anticoagulant and importantly, clear clinical benefit and safety. Use of vitamin K antagonists (VKAs) for anticoagulation in patients with liver disease is complicated by unreliable INR measurements.

There are currently no standard means of identifying patients with liver disease requiring thromboprophylaxis nor means to reconcile the perceived increased risk of bleeding in these patients. The 2020 American College of Gastroenterology (ACG) guidelines recommend pharmacologic VTE prophylaxis for inpatients with cirrhosis in the absence of bleeding or thrombocytopenia (platelets $<50 \times 10^9$/L).[19] Patients who may benefit from perioperative primary prophylaxis are those awaiting liver transplantation, because PVT worsens the long-term posttransplant prognosis.[41]

MANAGING BLEEDING DUE TO COAGULOPATHY OF LIVER DISEASE

- Basic coagulation tests should be ordered; these include CBC, PT (INR), PTT, thrombin clotting time, fibrinogen, D-Dimer, FDP, and mixing studies. The need for more specialized tests (e.g., specific factor levels) will be dictated by the clinical situation.
- It is important to identify any localized source of bleeding (e.g., varices) amenable to procedural intervention.
- A trial of 5–10 mg of vitamin K is reasonable with prolonged PT and PTT but should be used with other therapies.
- In patients with thrombocytopenia platelet transfusions can be used, targeting platelet counts greater than 50×10^9/L.
- In the setting of hypofibrinogenemia, replacement can be attempted with 10–20 units of cryoprecipitate or 4 g of fibrinogen concentrate initially while following laboratory results.
- PCC can be considered to improve coagulation parameters, but it must be used judiciously given the paucity of evidence around clinical outcomes and possible risks associated with its use.
- Factor rVIIa can be considered as a temporizing measure. Its use in liver disease is off label and the thromboembolic risk must be considered.

CBC, Complete blood count; *DIC*, disseminated intravascular coagulation; *FDP*, fibrin degradation product; *FP*, frozen plasma; *INR*, international normalized ratio; *PT*, prothrombin time; *PTT*, partial thromboplastin time; *rFVIIa*, recombinant factor VIIa.

There are several indications for therapeutic anticoagulation in the setting of cirrhosis such as DVT, PE, PVT, and Budd-Chiari syndrome. The comprehensive management of these disorders is beyond the scope of this chapter. The 2020 ACG guidelines suggest anticoagulation for acute main PVT, mesenteric vein thrombosis, or extension of PVT into the mesenteric veins in patients with cirrhosis.[19] However, the risks and benefits of anticoagulation must be carefully considered. The guidelines also advocate for prevention of variceal bleeding with β-blockers (or endoscopic therapy if β-blockers cannot be used safely) in cirrhotic patients requiring anticoagulation for acute or chronic PVT.[19] The value of anticoagulation for chronic PVT is less certain. It can be considered in the presence of a thrombophilia, progression of the thrombus, history of bowel ischemia due to thrombus extension into mesenteric veins, or in anticipation of a liver transplant.[19]

The use of direct oral anticoagulants (DOACs) is increasing, and they are approved in the setting of non-valvular atrial fibrillation, treatment of VTE, VTE prophylaxis after hip or knee replacement, and cancer associated VTE. However, most randomized control trials examining the use of DOACs excluded those with acute liver disease, cirrhosis, or thrombocytopenia. The risks and benefits of anticoagulation should be discussed, and management individualized to each patient's circumstances. The US Food and Drug Administration (FDA) recommends that all DOACs be avoided in patients with Child-Pugh C liver disease. Dabigatran and apixaban can be used cautiously in patients with Child-Pugh B liver disease.[44] All DOACs can likely be used in those with Child-Pugh A liver disease (Table 150.1).[44]

HEMATOLOGIC MANIFESTATIONS OF RENAL DISEASE

Renal disease and its causes are associated with numerous hematologic abnormalities including anemia, platelet dysfunction, and thrombosis. Morphologic abnormalities may include echinocytes, or abnormal RBC membranes (Table 150.2).

ANEMIA

Anemia in chronic kidney disease (CKD) is associated with poor outcomes, including reduced quality of life, increased cardiovascular disease, hospitalizations, cognitive impairment, and mortality. In a study of 5222 patients with CKD (serum creatinine >1.5 mg/dL and >2.0 mg/dL in females and males, respectively) the prevalence

TABLE 150.1 Primary Routes of Clearance of Various Anticoagulants[44]

	Target	Hepatic Clearance	Renal Clearance
Dabigatran	IIa	20%	80%
Apixaban	Xa	75%	25%
Edoxaban	Xa	50%	50%
Rivaroxaban	Xa	65%	35%
Warfarin	IX,X, II	100%	0%
Unfractionated heparin	II, Xa, IX, XIa, and XIIa (mainly II)	Primarily metabolized through the reticuloendothelial system and liver	-
Low molecular weight heparin	IIa and Xa (mainly Xa)	<10%[45]	Predominantly renal clearance

TABLE 150.2 Summary of Hematologic Manifestations of End-Organ Damage

	Red Blood Cells	White Blood Cells	Platelets	Morphology	Thrombosis/Hemorrhagic Risk
Liver disease	Anemia	Leukopenia, specifically neutropenia	Thrombocytopenia Platelet dysfunction	Macrocytosis Target cells	Increased risk of thrombosis and bleeding (alteration in hemostatic balance) Increased risk of varices
Renal failure	Anemia		Platelet dysfunction	Echinocytes (burr cells)	Increased risk of thrombosis in nephrotic syndrome
Anatomic/functional asplenia		Neutrophilia/lymphocytosis Increased risk of infection from encapsulated organisms	Thrombocytosis	Howell-Jolly bodies Target cells	Increased risk of thrombosis
Endocrine disorders	Anemia				
Respiratory disease	Secondary erythrocytosis		Thrombocytopenia		
Heart failure	Anemia				Increased risk of thrombosis

of anemia was 47.7%.[46] Anemia in CKD is usually normocytic and hypoproliferative. The underlying mechanisms of anemia are multifactorial and can be related to relative erythropoietin (EPO) deficiency, iron deficiency, and disordered iron homeostasis.[47,48]

Relative Erythropoietin Deficiency

EPO is a glycoprotein hormone mainly produced in the kidney by interstitial fibroblasts.[49] With normal kidney function, hypoxic conditions in the outer medulla trigger production of EPO, which binds to receptors on erythroid progenitors increasing RBC production.[50] Patients with CKD have insufficient EPO levels because of two proposed mechanisms: decreased production capacity caused by tissue damage as well as an altered hypoxic set point for EPO production.[51] As a result, anemic CKD patients have 10 to 100 times lower EPO levels compared with similarly anemic patients with normal renal function.[48]

Several RCTs have demonstrated clinical benefits with the use of erythropoiesis stimulating agents (ESAs) for patients with CKD and anemia.[52,53] However, targeting near normal hemoglobin (Hb) levels is associated with hospitalizations, graft/fistula thrombosis, stroke, and a trend towards increased mortality.[52] The 2017 Renal Association clinical practice guidelines recommend the use of ESAs to target a hemoglobin between 10 and 12 g/dL in adults.[54] Iron deficiency should also be addressed prior to initiation of ESAs.[54]

True Iron Deficiency

CKD patients, particularly those on hemodialysis, have increased iron losses because of chronic bleeding, phlebotomy, and blood loss in the hemodialysis apparatus.[55] ESAs also cause iron depletion through increased erythropoiesis. Therefore, optimization of iron status is required. The UK National Institute for Health and Care Excellence (NICE) recommends intravenous IV iron therapy for patients with CKD with iron deficiency.[56] Tests that can be used to diagnose iron deficiency include the percentage of hypochromic cells (>6%), reticulocyte hemoglobin content (<29 pg), or a combination of the transferrin saturation (<20%) and ferritin (<100 µg/L).

Disordered Iron Homeostasis

Patients with CKD often have both functional and true iron deficiency. Functional iron deficiency is related to an excess of hepcidin, a key hormone involved in iron homeostasis (see Chapter 36 and Chapter 37). Excess hepcidin in CKD patients is secondary to increased production caused by chronic inflammation as well as decreased renal clearance.

BLEEDING RISK

Patients with CKD have increased bleeding because of frequent use of antithrombotic medications, defects in platelet aggregation, and abnormal platelet-endothelial cell interaction. One of the major factors contributing to platelet dysfunction is a defect in glycoprotein IIb/IIIa.[57] Other factors include ineffective ADP response to stimulated aggregations and increased production of nitric oxide.[58,59] Anemia also contributes to uremic bleeding caused by altered flow of platelets with reduced proximity and interaction with endothelial cells.[60]

CKD is associated with uremic platelet dysfunction, a bleeding diathesis that is thought to be due to several factors such as vWF dysfunction, reduced thromboxane A2 and adenosine diphosphate (ADP), and accumulation of uremic toxins.[61] Treatment for uremic platelet dysfunction is indicated in patients with CKD who are actively bleeding or scheduled to undergo a procedure with a risk of bleeding. Desmopressin (DDAVP) can be considered for uremic bleeding. It acts by stimulating the release of vWF multimers from endothelial cells.[62] Another treatment option is conjugated estrogen, which achieves peak effect over 5 to 7 days.[63] The mode of action is not well understood but is thought to result from a reduction in nitric oxide.[64] Correction of anemia, whether through ESAs or RBC transfusions to a level greater than 10 g/dL, has also been shown to improve bleeding time in CKD patients.[63,65] Renal replacement therapy such as dialysis clears uremic toxins and can ameliorate uremic platelet dysfunction.[61]

THROMBOSIS

CKD is associated with an increased risk of thrombotic complications and conditions such as atrial fibrillation. The increased thrombotic risk with nephrotic syndrome has been well described and is associated with the degree of hypoalbuminemia as well as a type of nephrotic syndrome (membranous nephropathy being the highest risk).[64] Patients with nephrotic syndrome have increased platelet aggregation and adhesion because of elevated levels of vWF and unbound arachidonic acid (which is usually albumin bound).[67,68]

There is also increased activation of the coagulation cascade caused by an imbalance between synthesis and urinary loss of thrombotic and antithrombotic factors. Decreased fibrinolysis also occurs because of reduced plasminogen levels and reduced availability of albumin as a cofactor for plasminogen-fibrin interaction.[69,70]

The management of thromboembolic events (renal vein thrombosis, DVT, PE) associated with nephrotic syndrome is similar to conventional anticoagulation strategies for DVT or PE, with the use of heparin, low-molecular-weight heparin, or warfarin. There have been few published studies examining the use of DOACs in patients with nephrotic syndrome. DOACs have a variable degree of renal clearance, with dabigatran being the most and apixaban being the least renally cleared.[71] Prophylactic anticoagulation in patients who are high risk for VTE (membranous nephropathy, albumin <2 g/dL) with low to intermediate risk of bleeding can be considered.[72]

THROMBOTIC MICROANGIOPATHIES

Hemolytic uremic syndrome (HUS) is defined by concomitant microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute kidney injury.[73] Pathology demonstrates microvascular platelet thrombi, vessel wall thickening, and detachment of endothelial cells from the basement membrane. Damage to microvascular glomerular endothelium is the inciting and sustaining event involved in platelet consumption and MAHA. HUS may occur secondary to Shiga toxin–producing bacteria, *Streptococcus pneumoniae* infection, drugs, or primary complement dysregulation (atypical HUS). In Shiga toxin–associated HUS, the toxin binds to the high affinity Gb3 receptor expressed on glomerular endothelial cells leading to cell damage. In atypical HUS, the fenestrated endothelium of the glomerulus is particularly susceptible to uncontrolled alternative complement pathway activation arising from impaired regulatory proteins or hyperactive components. The kidney plays a central role in all of these processes, as initial damage to glomerular endothelial cells leads to loss of thromboresistance and platelet activation and consumption, causing thrombocytopenia with microangiopathic hemolytic anemia.[74]

In adults with nondiarrheal or idiopathic HUS, initial management is similar to thrombotic thrombocytopenic purpura (TTP) with plasma exchange therapy. If plasma exchange is not immediately available, plasma infusion may be temporarily used. In patients with atypical or complement mediated HUS, eculizumab, a monoclonal antibody against C5, should be considered.[75] In adults with postdiarrheal HUS, supportive therapy is the mainstay of treatment with intravenous fluids, platelet and red blood cell transfusions, and hemodialysis as indicated for acute kidney injury (AKI).

HEMATOLOGIC MANIFESTATIONS OF OTHER END-ORGAN DISEASES

Functional and Anatomic Asplenia

The spleen has multiple functions which include filtration of erythrocytes and platelets, hematopoiesis, sequestration of RBCs and platelets, and infection prevention. The functional or anatomical loss of the spleen can have various hematologic manifestations.

Red Blood Cell Abnormalities

Multiple morphological abnormalities can manifest in the peripheral blood smears of patients with functional or anatomic asplenia. Howell-Jolly bodies, small basophilic inclusions found in RBCs, represent nuclear material that would typically be removed by the spleen (see Fig. 156.6). The spleen also removes deformed erythrocytes; therefore target cells, RBCs with a relative excess of membrane, may also be present.

Immunological Consequences

The spleen plays a key role in immunological function. It houses cells involved in innate and adaptive immunity and has the unique ability to target encapsulated organisms through IgM memory B cells which reside in the marginal zone of the spleen.[76] Asplenia or splenic dysfunction can subsequently lead to increased risk of severe infection, particularly infections with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitidis*.[77] Patient education and vaccinations against encapsulated organisms in patients with asplenia/splenic dysfunction is recommended.[78]

Thrombosis Risk in Patients With Splenic Dysfunction

Splenectomy is associated with an increased risk of thrombosis. A proposed mechanism is excess circulating procoagulant microparticles that are cleared by the spleen.[79] The underlying conditions that predispose patients to autosplenectomy (e.g., sickle cell disease) or require surgical splenectomy (autoimmune hemolytic anemia, other hemoglobinopathies, RBC enzymopathies and membranopathies) are also hypercoagulable states.[79]

PVT is well described as a potential postoperative complication of splenectomy occurring in approximately 3.3% of cases.[80] VTE risk is also high with a retrospective cohort study using USA census data examining 8149 patients that were admitted to Veteran Affairs hospitals who underwent splenectomy. The risk of being hospitalized for VTE was higher in patients who were splenectomized (relative risk of 2.2).[81]

RESPIRATORY DISEASE

Red Blood Cell Abnormalities

In response to hypoxia, renal erythropoietin production is upregulated.[82] Over time, chronic lung disease can result in secondary erythrocytosis.[83] Management of the underlying condition is key to improving secondary erythrocytosis. In contrast to polycythemia vera, the role of phlebotomy is less clear. There is no evidence to support a hematocrit target and phlebotomy is typically reserved for symptomatic individuals only.[84] It is also uncertain whether there is a connection between secondary erythrocytosis and VTE.[85]

HEART FAILURE

Red Blood Cell Abnormalities

The prevalence of anemia in patients with stable heart failure (HF) is approximately 30%[86] and even higher in hospitalized patients with HF. The underlying pathophysiology involves multiple contributing factors such as renal dysfunction, hemodilution, inflammation, and iron deficiency.[86] Anemia is important to address in this population as it is associated with an increased risk of mortality and hospitalization.[87]

The benefit of transfusion support is transient at best and should be avoided in patients with HF who are asymptomatic. The use of ESAs is controversial and the 2017 American College of Cardiology (ACC) guidelines advise that they should not be used due to lack of benefit demonstrated in randomized control trials (Class III, B-R).[88]

Iron deficiency affects up to 50% of patients with heart failure and it is associated with a poorer prognosis.[89] Randomized control trials demonstrate that IV ferric carboxymaltose may improve quality of life and exercise capacity.[90,91] The 2016 European Society of Cardiology guidelines recommend that IV ferric carboxymaltose be considered in patients with heart failure with reduced ejection fraction (HFrEF) and iron deficiency (Class IIa, Level A).[91] Iron deficiency was classified as a serum ferritin less than 100 μg/L or ferritin of 100 to 299 μg/L and transferrin saturation of less than 20%. The 2017 ACC guidelines also recommend that IV iron be considered to improve functional status and quality of life in patients with New York Heart Association (NYHA) Class II and III HF with iron deficiency (Class IIb, Level B-R).[88]

Thrombosis Risk in Patients With Heart Failure

Heart failure has been associated with a higher risk of VTE. A systematic review published in 2016 demonstrated that hospitalized patients with HF had an increased risk of VTE (relative risk of 1.5) that was independent of their reason for hospitalization.[92] Heart failure is thought to be a prothrombotic due to endothelial dysfunction, inflammation, impaired blood flow due to abnormal cardiac contractility, and a relative increase in procoagulant molecules.[91] Fibrinogen, von Willebrand factor, and plasma viscosity are increased in patients with HF. Anticoagulation for concomitant HF and atrial fibrillation is well accepted, but there is a paucity of evidence with regards to thromboprophylaxis in HF alone.

ENDOCRINOPATHIES

Anemia is the main hematologic manifestation of endocrine dysfunction and there are multiple pathways that affect the production of red blood cells.

Thyroid dysfunction such as hypothyroidism may affect erythropoietin production resulting in anemia.[94,95] The anemia is often normocytic, but it can be macrocytic if there are other concomitant autoimmune disorders, specifically pernicious anemia due to malabsorption of vitamin B_{12} or folic acid. Thyroid dysfunction can also lead to menorrhagia causing iron deficiency with microcytic anemia.[96]

Testosterone is hypothesized to affect red cell productions through multiple mechanisms which include colony forming units for erythrocytes (CFU-E), erythropoietin, hepcidin inhibition, and increases in insulin-like growth factor-1 (IGF-1).[97] A double-blinded placebo-controlled trial published in 2017 examined the use of testosterone gel in men over the age of 65 with low testosterone levels. Testosterone treatment increased the percentage of men whose hemoglobin increased by 1 g/dL over 12 months compared to placebo (54% vs. 15%).[98] This effect was consistent in men with unexplained anemia as well as men with a known cause of anemia.[98]

CHAPTER 151

HEMATOLOGIC MANIFESTATIONS OF SOLID TUMORS

Kathryn DeCarli, Peter Barth, Andrew M. Brunner, and Fred J. Schiffman

Hematologic abnormalities are commonly seen among patients with malignancy. These derangements range from the incidental to the life-threatening and may complicate management or prompt the initiation of additional or alternative therapies. Hematologic abnormalities can be seen as the initial manifestation of cancer, providing a crucial diagnostic clue. In addition, the hematologic aspects of cancer, and the therapies that we use to treat these irregularities, can provide insight into the biology of tumorigenesis. This chapter reviews some of the impact that malignancy can have on erythrocytes, leukocytes, platelets, and hemostasis.

ERYTHROCYTES

Anemia

The most common hematologic manifestation of cancer is anemia; anywhere from 30% to 90% of patients with cancer have documented anemia before the initiation of any treatment.[1] Anemia may be the first presentation of malignancy; for instance, anemia is frequently noted in patients with colon cancer and more frequent in advanced stage disease.[2] The pathogenesis of cancer-related anemia is multifactorial, and can arise from direct cancer tissue invasion with resultant blood loss, tumor involvement of the bone marrow, or hemolysis; it can be a direct effect of chemotherapy or radiation therapy, be associated with chronic renal dysfunction secondary to the malignancy or treatment, among other causes. These causes can be generally divided according to the pathogenesis of the anemia: that resulting from direct blood loss, anemia caused by erythrocyte destruction, and anemia caused by a hypoproliferative marrow state.

A number of cancer-specific mechanisms can be responsible for a hypoproliferative state, including nutritional deficiencies, decreased erythropoietin (EPO) production because of acute or chronic kidney injury, and injury to the bone marrow itself. The most common nutritional abnormality in cancer-related anemia is iron deficiency; roughly 40% of cancer patients may have iron-deficiency,[3] which can be secondary to poor oral intake, as well as from blood loss, commonly seen in gastrointestinal and gynecologic malignancies. Compounding any deficiency in total body iron stores are the myelosuppressive effects on erythropoiesis and iron homeostasis that may result from cancer-associated inflammation and cytokine activation.[4] Many cancers are associated with a systemic inflammatory state,[5] manifested by elevated levels of inflammatory cytokines such as IL-2 and IL-6, which can directly inhibit erythropoiesis and also suppress the amount of iron available for erythropoiesis.

Various systemic mediators of anemia are disrupted in malignancy. When serum EPO concentrations are measured among cancer patients, these levels are inappropriately low in comparison to patients without malignancy but who have the same degree of anemia caused by iron deficiency.[6] Cancer patients also often demonstrate increased levels of hepcidin, a protein critical to iron homeostasis, which acts by decreasing the binding to and breaking down of the iron transporter ferroportin.[7] This subsequently results in increased storage of iron in the form of ferritin, and at the same time decreases free iron that would be used in erythropoiesis. In contrast to iron deficiency, vitamin B_{12} deficiency is less frequently observed in patients with anemia and cancer, seen in only 5% to 10% of patients.

Many chemotherapeutic agents have hematologic sequelae; patients undergoing treatment may experience varying degrees of anemia resulting from chemotherapy-induced bone marrow suppression. The European Cancer Anaemia Survey prospectively studied over 15,000 patients with a variety of solid tumors undergoing treatment. Before therapy, 10% of patients had hemoglobin levels below 10 g/dL, and during therapy this increased to almost 40% of patients and was correlated with a worsening performance status.[8] In the same study, radiation therapy alone had less impact on the incidence of anemia, but the combination of chemotherapy and radiation led to a greater degree of anemia than chemotherapy alone. Anemia caused by chemotherapy is related to the cumulative dose, combination of chemotherapeutic agents, and dose schedule. For example, in the treatment of lung cancer with cisplatin and paclitaxel, anemia worsens with an increasing total dose of cisplatin, or if paclitaxel is given over a 24-hour period rather than shorter courses.[9]

Anemia in cancer patients can also occur in the setting of red cell destruction, such as is seen in autoimmune hemolytic anemia, or in the setting of microangiopathic hemolytic anemia (MAHA), which is associated with concurrent thrombocytopenia. Although the true incidence of MAHA among cancer patients is difficult to determine, it is a well-defined entity that has been described in a small (perhaps <10%) subset of cancers, particularly mucin-producing disseminated adenocarcinomas.[10] It is important to distinguish secondary thrombotic microangiopathies (TMAs), which can occur in patients with malignancy, from thrombotic thrombocytopenic purpura (TTP), given the marked differences in underlying pathophysiology. TTP is the result of congenital or acquired absence or inhibition of the von Willebrand cleaving enzyme called "A Disintegrin And Metalloproteinase with Thrombospondin Motifs-13" (ADAMTS13). In contrast, secondary TMAs may have a slight decrease in ADAMTS13 activity, but do not have the severe deficiency of ADAMTS13 activity, typically characterized by a level of less than 10%, that is seen in TTP.[11] Accordingly, patients with secondary TMAs typically have a poor response to therapeutic plasma exchange. Cancer-associated TMAs may arise from direct endothelial damage rather than diminished ADAMTS13 activity. Cancer patients may also develop a MAHA related to the specific medications used during treatment, including cyclosporine, mitomycin, and gemcitabine, and agents inhibiting vascular endothelial growth factor (anti-VEGF) signaling. (See box on Management of Cancer-Related Anemia.)

Erythrocytosis

Outside of patients with myeloproliferative neoplasms, and specifically polycythemia vera, erythrocytosis is an uncommon manifestation of cancer. Polycythemia vera, and other myeloproliferative neoplasms, are typified by acquisition of somatic mutations that upregulate the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling pathway, most commonly via the

JAK2 V617F mutation, and phenotypically present as an expansion of myeloid-origin cells, with an elevated hemoglobin and suppressed EPO levels. In these cancers, erythrocytosis is caused by primary expansion of the malignant clone. For such patients, various therapeutic interventions may be considered, including therapeutic phlebotomy or hydroxyurea (see Chapter 70, The Polycythemias). In solid tumors, erythrocytosis is an uncommon paraneoplastic phenomenon. Paraneoplastic erythropoiesis has been described in several tumors, including renal cell carcinoma.[18] In some instances, there may be association with a common predisposing condition; for instance, patients with von Hippel-Lindau disease are at risk for renal and central nervous system tumors, and the mechanism of erythrocytosis is typically through paraneoplastic EPO expression. Nonetheless, elevated RBC counts are rare in patients with malignancy, particularly those receiving chemotherapy, and usually do not require intervention.

MANAGEMENT OF CANCER-RELATED ANEMIA

Hemoglobin levels typically decrease early in the course of chemotherapy treatment; more than half of patients experience a greater than 1 g/dL drop over the course of the first 9 weeks of therapy.[8] The treatment of anemia related to malignancy depends upon correct identification of the underlying etiology. As noted previously, iron-deficiency anemia is common in patients with malignancy. Among those patients with cancer who have an absolute iron deficiency (transferrin saturation <20%, ferritin <30 ng/mL), there is evidence that they may benefit from a short course of either oral or low-dose intravenous iron. In this setting, the addition of erythropoiesis-stimulating agents (ESAs) is not necessary.

For many patients, transfusion of blood products is an effective therapeutic intervention. Red cell transfusion provides rapid symptomatic relief and is also a source of iron; one unit of packed red blood cells (RBCs) contains roughly 200 mg of iron. Logistic limitations with RBC transfusion, and transfusion-related morbidities, particularly with a high cumulative transfusion burden, have spurred the incorporation of ESAs as alternative or adjunct agents for treating anemia in cancer patients. The use of ESAs during myelosuppressive treatment may increase the hemoglobin level and decrease transfusion requirements by up to 50%. However, ESA use is associated with an increased rate of cardiovascular and thrombotic events. This relationship between ESA use and thrombosis may be related to the target hemoglobin concentration during therapy, since higher hemoglobin targets are associated with increased rates of thrombotic events in cancer patients.

In addition to thrombotic events, ESA use has been associated with poorer overall survival or time to cancer progression in some settings.[12] Data regarding ESAs and progression of disease are conflicting; some studies in patients with breast cancer and patients with head and neck cancer suggested worsening progression-free survival or worsened local control of disease with ESA use.[13] A number of mechanisms have been proposed, including decreased chemosensitivity in the setting of ESA use, or alterations in tumor vascularity and oxygen supply.[14] Aberrant expression of the EPO receptor has been identified on the cell surface of certain tumor cells, while other putative mechanisms include augmentation of red cell mass and effects on tumor oxygenation.[15] Nonetheless, larger studies on the impact of ESA on progression suggest any effect may be small overall.

Related in part to the above concerns, ESA use is generally restricted to specific limited indications in patients with cancer; notably, such practice recommendations are generally limited to solid tumors with chemotherapy-induced anemia.[16] In specific hematologic malignancies, such as myelodysplastic syndromes (MDS), ESA therapies remain a backbone of the treatment of anemia.[17] For the treatment of anemia in patients with solid tumors, transfusion of blood products and, if indicated, iron therapy, remain the standard of care. There are other scenarios where ESAs may be useful, particularly among patients with moderate or severe chronic kidney disease, or in palliative settings, as well as for specific patient scenarios such as the treatment of patients who identify as Jehovah's Witnesses. In such situations, reversible causes of anemia should be ruled out before ESA use, and the minimal amount of ESA be used to avoid RBC transfusion.

PLATELETS

Thrombocytopenia

Chemotherapy and immunosuppressive agents are the most common causes of thrombocytopenia in the cancer patient. For instance, patients receiving cisplatin/gemcitabine for bladder cancer or carboplatin/gemcitabine for lung cancer have rates of clinically significant thrombocytopenia of 30% to 60%.[19] Among patients with hematologic malignancy, thrombocytopenia is even more common, particularly with induction or conditioning chemotherapy regimens. The typical mechanism by which chemotherapy causes thrombocytopenia is through marrow suppression; although, some agents are also associated with immune-mediated thrombocytopenia, and thrombocytopenia may also occur as a sequelae of other processes such as MAHA or TMA (above). Immune thrombocytopenia is typically characterized by a sudden and isolated drop in platelet count shortly after drug administration. Several chemotherapeutics, including gemtuzumab, trastuzumab, and oxaliplatin, have been associated with immune-mediated thrombocytopenia, potentially related to the presence of drug-dependent antibodies.[20]

Thrombocytopenia may also be a result of bone marrow infiltration by tumor cells, thrombotic microangiopathy, consumptive coagulopathy, or as an autoimmune manifestation of the malignancy itself. Bone marrow involvement, often occult, is more common in prostate, lung, and breast cancer; such patients typically have multiple cell lines involved, and may display a leukoerythroblastic appearance on the peripheral smear. Associated laboratory features of disseminated intravascular coagulation (DIC), including an elevated D-dimer and fibrinogen degradation products, can be seen in cancer patients, and are more common with advanced disease. (See box on Management of Cancer-Related Thrombocytopenia.)

Thrombocytosis

While thrombocytopenia may be more clinically apparent because of bleeding or delays in the administration of chemotherapy, the presence of thrombocytosis—typically reactive to the underlying inflammatory state—is more frequently seen in patients with solid tumors. The clinical impact of thrombocytosis is less clear; however, having an elevated platelet count at cancer diagnosis has been associated with a greater risk for venous thromboembolism (VTE).[24] Cancer-related thrombocytosis is thought to be mediated by inflammatory cytokines, and elevated levels of interleukin (IL)-6, IL-11, and TPO have been documented in cancer patients. Rarely, thrombocytosis may be the result of a paraneoplastic phenomenon, which has been described in breast and ovarian malignancies. In many tumor types, including breast, renal cell, gastric, and advanced stage non–small-cell lung cancer, elevated platelet counts seem to be associated with an adverse prognosis. The mechanism for this association is unclear.

Platelet Dysfunction Secondary to Malignancy

In addition to abnormalities in absolute platelet number, cancer patients may have alterations in platelet function, which have been hypothesized to contribute to tumor progression and coagulopathy. Platelets derived from cancer patients are in an activated state, with increased surface P-selectin expression and elevated serum levels of platelet factor IV and β-thromboglobulin.[25] Activated platelets may contribute to the thrombophilic state in cancer patients, and also interact with leukocytes, endothelial cells, and tumor cells, all of which may contribute to the early stages of tumor cell dissemination. Several platelet receptors may be involved in the platelet support of metastasis, including glycoprotein (GP) IIb/IIIa, adenosine diphosphate (ADP) receptors, P-selectin and thrombin receptors, and others, with likely multiple mechanisms underlying the platelet effects on malignancy.[26] Platelets stabilize otherwise short-lived tumor cells in the circulation. Platelet-tumor cell interaction enhances tumor cell adhesion to the vessel wall, and appears to alter vessel wall permeability, and in this way may facilitate tumor cell invasion. Platelets protect tumor cells from immune surveillance and destruction, in part by shielding tumor cells from natural killer cells, although other mechanisms are likely. Platelets may provide nutrient support (growth factors) and release proangiogenic factors. Platelets also contain numerous growth factors, coagulation factors and adhesive molecules, chemokines, and bioactive lipids that may enhance metastatic efficiency. Platelets are similarly enriched in angiogenic growth factors such as basic fibroblast growth factor and VEGF, as well as other mediators, and may play a role in angiogenesis. Selective P-selectin and thrombin receptor activation on platelets may release α-granules enriched in either VEGF or endostatin. Platelet-derived transforming growth factor-β and direct platelet–tumor cell interactions promote epithelial mesenchymal transformation and tumor metastases. Together, these suggest numerous putative roles for platelets in tumorigenesis and evolution itself.

LEUKOCYTES

Neutropenia

Neutropenia is common during treatment with chemotherapy, particularly with antimetabolite use.[27] Other etiologies of neutropenia in cancer patients include infiltration of the bone marrow space and occasionally, radiation therapy, particularly when sites of active hematopoiesis are included in the radiation field, such as with the pelvis or spine. In addition, particularly in the course of treatment, cancer patients may experience viral or antibiotic-associated neutropenia. (See box on Management of Cancer-Related Neutropenia.)

An important consideration during chemotherapy is to recognize that chronic benign neutropenia, as can be seen in those of African and Middle Eastern descent,[37] may be a contributing factor and does not require dose-adjustment of chemotherapy. Rather, such neutropenia may reflect a common single nucleotide polymorphism (SNP) variant in the *ACKR1* gene.[38]

Bone Marrow Metastases

Multiple lineage cytopenias in association with cancer warrants consideration of bone marrow metastasis (Fig. 151.1) or secondary/concurrent hematologic malignancy. Metastatic carcinoma can involve bone marrow and may lead to subsequent marrow fibrosis and failure. Bone marrow metastases are relatively infrequent, with early reports suggesting they are present in fewer than 10% of patients with metastatic disease, most frequently in metastatic sarcoma or melanoma, or prostate, breast, or lung cancer.[39] Patients with solid tumors who have bone marrow involvement are more likely to experience cytopenias from chemotherapy, and typically carry a worse prognosis. It has long been recognized that some patients will have metastatic disease involving the bone marrow that may even precede more overt metastatic burden. Patients with early marrow involvement of non-small-cell lung cancer are more likely to relapse compared to those without marrow involvement[40]; similar findings are reported in patients with breast cancer.[41,42] The precise mechanism for poor outcomes is likely multifactorial, potentially related to greater overall tumor burden, as well as to the specific biologic features that allow the tumor to grow in the bone marrow niche, potentially also rendering it more resistant to chemotherapy.[43] Such tumor cell evasion strategies could include changes in homing, adhesion, immune escape, and angiogenic potential. Indeed, there may be specific molecular signatures within tumor subclones that facilitate metastasis to the bone marrow.[44] The bone marrow niche itself may also play a role in promoting tumor survival and in decreased immune surveillance. One example is the occurrence of bone marrow micrometastases in women

MANAGEMENT OF CANCER-RELATED THROMBOCYTOPENIA

Treatment of thrombocytopenia in cancer patients is generally supportive. For patients with active bleeding, platelet transfusion and correction of other coagulopathies are the mainstays of therapy. The use of agents such as tranexamic acid in these patients may also be considered. In the absence of active bleeding, a threshold of $<10 \times 10^9$/L for prophylactic platelet transfusion is generally recommended. This is based on a study that randomized 600 patients with hematologic malignancies to prophylaxis or no prophylactic transfusions. Both were treated for bleeding events.[21] Rates of World Health Organization grade 2, 3, or 4 bleeding were high in both groups, but higher in the no-prophylaxis group (50%), compared with the prophylaxis group (43%). Prophylactic platelet transfusion has been used in patients with solid tumors, but without as much evidence-based support.

Other therapies, with or without platelet transfusion, may also have a role in chemotherapy-related thrombocytopenia. Thrombopoietin (TPO) receptor agonists are an area of increasing interest in the management of thrombocytopenia during chemotherapy, particularly as a means to maintain treatment schedules, which may be delayed by thrombocytopenia. For instance, a randomized phase II trial compared placebo to eltrombopag in patients receiving gemcitabine-based chemotherapy and found that fewer patients receiving eltrombopag required dose delays and/or reductions in chemotherapy compared with those receiving placebo.[22] Nonetheless, specific interactions with other chemotherapeutic agents will likely be important to understand; for instance, in a trial of patients with MDS randomized to receive azacitidine alone or in combination with eltrombopag, the patients receiving eltrombopag actually had worsened platelet transfusion requirements.[23]

MANAGEMENT OF CANCER-RELATED NEUTROPENIA

Patients who develop neutropenia during chemotherapy are at risk for neutropenic fever. A number of comorbid conditions are predictive of the development of neutropenic fever, including older age, poor performance status, comorbid medical conditions, low baseline white blood cell counts, low body mass index/BSA, advanced disease, and the use of myelosuppressive chemotherapy agents.[28,29] General treatment principles for neutropenic fever include the consideration of prophylactic antibiotics or myeloid growth factor support, such as granulocyte colony-stimulating factor (G-CSF).[30–32] Consideration should be given to the elevated risk of neutropenic fever associated with specific chemotherapeutic agents, as well as the specific malignancy, particularly in situations where dose-dense or intense chemotherapy regimens provide survival benefit. Depending on the regimen and disease, prophylactic G-CSF should be considered to reduce the duration of neutropenia, particularly when there is a greater than 20% overall risk of neutropenic fever. Once a patient develops neutropenic fever, G-CSF is typically reserved for situations where they are not responding to appropriate treatment and develop life-threatening conditions.[33]

The benefit of growth factor support for infection and to maintain treatment timing should be weighed with potential risks from such agents. Several tumors express G-CSF receptors; there is a theoretic concern that exogenous G-CSF may increase proliferation of these tumors. In addition, the use of myeloid growth factors during chemotherapy for solid tumors has been theorized to increase the risk of subsequent myeloid malignancy by acting as a survival signal to hematopoietic progenitor cells damaged by chemotherapy.[34] A meta-analysis of 25 randomized clinical trials found that there was an almost twofold increase in acute myeloid leukemia in those patients assigned to receive chemotherapy with growth factor support, compared with those who did not receive growth factor support, although the absolute rates of secondary leukemia were low in each group.[35,36]

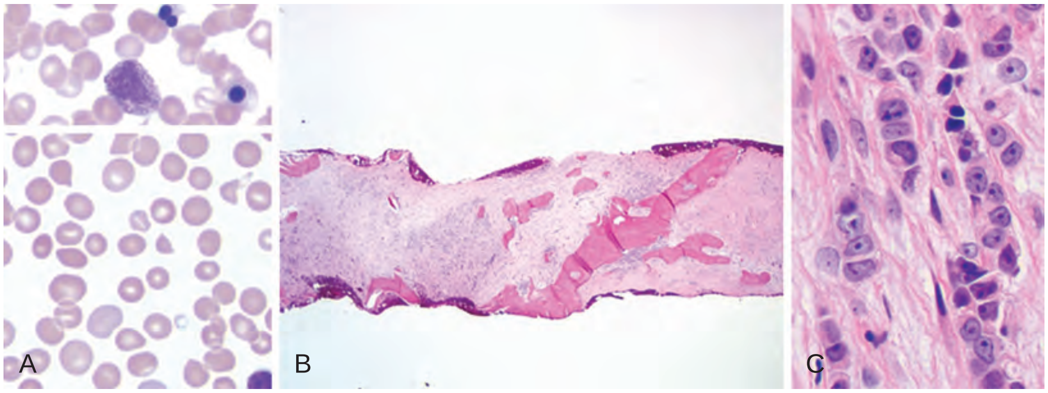

Figure 151.1 PERIPHERAL BLOOD AND BONE MARROW FROM A PATIENT WITH METASTATIC BREAST CANCER . The patient was a 77-year-old woman who presented with anemia and thrombocytopenia. On physical examination, she was found to have a breast mass. (A) The peripheral smear showed a leukoerythroblastosis *(top)* with nucleated red blood cells and immature granulocytic precursors. Platelets were reduced, and red blood cells exhibited anisopoikilocytosis *(bottom)* with occasional teardrop forms and rare schistocytes. (B) The bone marrow biopsy was fibrotic and had thickened bone with new bone formation. (C) The bone marrow cavity was replaced by tumor cells infiltrating through bands of fibrosis.

with early-stage breast cancer; approximately 30% of women with stage I to III breast cancer may have bone marrow micrometastases, which is associated with worse prognosis.[41]

The pathophysiology by which marrow involvement by cancer causes cytopenias is not fully understood. Total marrow replacement by tumor is rare, and only a small percentage of healthy marrow may be needed to support normal peripheral blood counts, as indicated by the observation that normal blood counts are often found in normal older adults with hypocellular marrows. Cancer may disrupt the normal bone marrow interactions required for healthy hematopoiesis, including by directly competing with hematopoietic progenitors in the niche.[45]

THROMBOSIS AND CANCER

The association of thrombosis and cancer is widely recognized, dating to the middle of the 19th century, and can be considered the earliest recognized paraneoplastic syndrome. Armand Trousseau was the first to associate thrombosis and malignancy, the first to suggest screening for malignancy in recurrent or idiopathic thromboembolic disease, the first to suggest that the pathophysiology was not mechanical obstruction, but a change in the character of the coagulation system itself, and the first to suggest that the association may be integral to the cancer growth itself. Particularly poignant was the fact that Trousseau predicted his own occult malignancy when he developed “phlebitis,” dying 6 months later of gastric cancer. More recently, some of the biologic mechanisms underlying the increased risk for thrombosis in patients with cancer have been better delineated.

The incidence of cancer-associated thrombosis has steadily increased in recent years,[46] possibly related to the increasing age of the population, with an associated increase in cancer prevalence, longer survival with active malignancy, and better detection tools. Patients with active malignancy have a higher risk for thrombosis than other medical patients: for instance, surgical oncology patients have a higher thrombosis rate than other surgical patients undergoing major procedures.[47,48] Although reports of thrombosis rates vary, in general approximately 10% to 15% of cancer patients develop VTE at some point during their illness[49]; conversely, approximately 20% of all VTE events occur in cancer patients.[50] Together, a cancer diagnosis may increase the relative risk of venous thrombosis by up to 15-fold.[51] In comparison, heterozygous carriers of the common hereditary thrombophilia, factor V Leiden, increases the risk for venous thrombosis by approximately five-fold.[52] Virtually all solid tumor types, as well as hematologic malignancies, carry this significantly increased risk for thrombosis. Certain tumor types, particularly mucinous adenocarcinomas, appear to have particularly high risk for thrombosis, including lung, gastrointestinal cancers—notably pancreatic adenocarcinoma—as well as primary brain tumors.[53]

Development of thrombosis in the cancer patient generally carries adverse prognostic impact. In patients with advanced solid tumors, those who have venous thromboembolic disease at the time of presentation have a 1-year survival nearing only 10%, compared with 1-year survival of closer to 40% among those without thrombosis at diagnosis.[54] It is less clear whether this thrombotic tendency is simply a marker of aggressive disease or whether the development of thrombosis itself is the cause of the increased mortality. Thrombosis is second only to disease progression as a cause of death among cancer patients, and accounts for nearly 10% of deaths among patients receiving outpatient chemotherapy.[55] This mortality risk appears to be independent of cancer stage at the time of thrombus identification, and therefore may reflect the underlying cancer biology. Mucinous adenocarcinomas, for example, may directly release tissue factor (TF) and circulating mucin molecules that activate the clotting cascade and platelets, thereby promoting thrombosis.

Biologic Mechanisms Underlying Thrombosis in Cancer

The etiology of thrombosis is typically described in the context of the classic Virchow triad: stasis or altered blood flow, injury to the vessel wall, and hypercoagulability intrinsic to the blood and circulating plasma. Cancer can promote thrombosis by all three of these processes. Mechanical compression and/or disruption of blood vessels by a tumor may cause disrupted flow or stasis. Upon interaction with cancer cells, monocytes or macrophages release cytokines, including tumor necrosis factor, IL-1, and IL-6, which create a procoagulant state within the vessel.[56] The damaged vessel surface has reduced expression of naturally occurring anticoagulants, such as thrombomodulin, heparan sulfate, CD39/ecto-ADPase, nitric oxide, and prostacyclin.[57,58] The damaged endothelium also has increased expression of procoagulant proteins, particularly TF; circulating blood is exposed to the procoagulant subendothelial matrix, which contributes to a hypercoagulable state.

Despite the contributions of stasis and vessel changes in cancer-associated thrombosis, the best-documented contributing factor to thrombosis in the cancer patient is elevated procoagulant plasma factors, many of which are generated by the tumor itself. TF plays a critical role in the initiation of the coagulation cascade, particularly via the extrinsic pathway, by binding to and activating factor VII.[59] TF is increased in many malignancies, including pancreatic cancer, breast cancer, and non–small cell lung cancer, compared with the non-transformed epithelium.[60] Low oxygen levels are often found in the tumor microenvironment, which result in the activation and upregulation of proteins encoded by oncogenes, such as *RAS*[61] or *MET*,[62] and inactivation of tumor suppressor genes such as *PTEN*.[63] The downstream effect of this is to directly induce TF expression, as well as other genes involved in hemostasis. Targeting the human *MET* oncogene to mouse liver using a lentiviral vector results in hepatocarcinoma, associated with a coagulopathy similar to that in malignancy, with striking thrombotic events, similar to Trousseau syndrome, the migratory thrombophlebitis associated with malignancy.[64] Elevated TF expression and activation of the coagulation system appear to correlate with both thrombotic tendency and disease progression.

In addition to TF expression in tumors, activated endothelium, and tumor-associated macrophages, TF is also increased in platelets and microparticles from cancer patients compared with healthy controls.[65] The generation of TF-expressing microparticles may be an important mechanism of cancer hypercoagulability. Microparticles are vesicular structures, generally between 100 and 1000 nm in diameter, that are released from cell membranes under a variety of situations, including activation, malignant transformation, stress, or death.[66] They can be detected in plasma in a wide range of disease states, including sepsis and cancer. Microparticles have been reported to arise from platelets, monocytes, endothelial cells, and tumor cells, and carry on their surfaces a range of proteins that are derived from the cell of origin, including TF.[67] Cancer cells, directly and indirectly, lead to the generation and circulation of TF-bearing microparticles, and the levels of circulating TF-bearing microparticles in cancer patients appear to correlate with the subsequent risk for venous thromboembolic disease. In one study, approximately a third of patients with detectable TF-bearing microparticles developed venous thrombosis, compared with no thrombotic events in those without detectable TF-bearing microparticles.[68]

Coagulation and Tumor Progression

The activation of coagulation pathways in cancer may also play a role in tumor progression. For example, TF expression levels often correlate with a more aggressive tumor phenotype, and both clotting-dependent and clotting-independent signaling mechanisms of TF may be important in regulating tumor metastasis.[69,70] TF has been described to induce angiogenesis via upregulation of vascular endothelial growth factor (VEGF).[71]

Thrombin is the key terminal enzyme of the coagulation cascade, resulting in fibrin deposition and platelet activation. It also serves as a growth factor for a number of cell types, including fibroblasts, endothelial cells, smooth muscle cells, and tumor cells. The cellular effects of thrombin are mediated through seven transmembrane-spanning G protein–coupled protease-activated receptors (PARs), principally PAR1.[72] PAR1 is activated by thrombin through cleavage of its N-terminus, which exposes a tethered ligand that then binds to the second transmembrane domain of the receptor. PARs are expressed on platelets and other cells, as well as on tumor cells.[73] Thrombin-activated tumor cells have PAR1-dependent enhanced expression of a number of cell surface integrins.[74] Thrombin may enhance tumor progression via several mechanisms, including enhancing tumor cell proliferation, activating tumor–platelet adhesion, tumor adhesion to the matrix or endothelium, tumor implantation, growth, and metastasis, and tumor angiogenesis.[75] Thrombin alters tumor cell gene expression with upregulation of angiogenesis-related genes such as *VEGF*, matrix metalloproteinase 2 (*MMP-2*),[76] angiopoietin 2 (*ANG2*),[77] and other genes and microribonucleic acids affecting tumor cell proliferation and invasion.

Diagnosis of Coagulopathies in Cancer Patients

Thrombotic events in patients with cancer are diagnosed similarly to those in patients without cancer. However, several subtleties exist. For example, thrombosis may be confused with either intravascular disease progression or other processes such as intravascular fungal infections. In many cases, the diagnosis of thrombosis, or an abnormality in coagulation, may be made in an asymptomatic patient, leading to a more complicated decision regarding the risks and benefits of therapy. The process of fibrin formation and degradation is continuous in the setting of many patients with malignancy, and may relate to elevated thrombin-antithrombin complexes and fibrin degradation products. Thus, cancer is thought by some to be a process of "chronic DIC."[78] The clinical spectrum of coagulopathy in cancer ranges from asymptomatic to life-threatening thrombohemorrhagic disease. Thrombotic manifestations of DIC include arterial and VTE, migratory thrombophlebitis, marantic endocarditis, and microvascular thrombosis with organ failure or skin necrosis. The consumptive phase of DIC may manifest as bleeding, treatment of which is supportive and patient specific. Some may respond favorably to low-dose heparin, and/or plasma therapy, while waiting for treatment of the underlying malignancy. In general, the treatment of cancer-associated DIC is centered on the treatment of the underlying tumor and adjunctive care for any coagulopathic sequelae.

With increased use of high-resolution computed tomographic imaging studies, pulmonary emboli (PEs) are increasingly being identified incidentally, in the absence of clinical suspicion. This has led to the question of how to manage incidentally discovered thrombosis. A retrospective cohort study of the period from 2004 to 2010 compared the rate of recurrent VTE and overall survival between those patients whose PEs were detected incidentally on imaging studies with those whose PEs were suspected by classic clinical criteria; there was no difference in recurrent VTE or overall survival when both groups were anticoagulated.[79] A separate prospective observational study enrolled consecutive cancer patients newly diagnosed with combined deep venous thrombosis and PE from 2006 to 2009; 60% of the incidental thromboses were PEs, whereas only 26% of the symptomatic events were PEs. There was also a lower risk for recurrent thrombosis among those patients with an incidental thrombus compared with those with a symptomatic thrombus, and no differences in major bleeding and overall survival between groups.[80] Taken together, these two studies support the routine anticoagulation treatment of an incidentally found thrombosis, and provide some insight into the risk of recurrent thrombosis according to the mechanism of presentation.

Intravenous Catheter Thrombosis in Malignancy

Many patients with cancer undergo placement of a central venous catheter (CVC), commonly in the form of an implantable "port-a-cath" or "port," for chemotherapy infusion. Presence of an indwelling central line is a risk factor for thrombosis; this is augmented in patients with underlying cancer. Nearly 4% of patients with cancer who undergo port placement may develop a CVC-associated thrombosis, and the risk of thrombosis is increased with age, previous VTE, anemia, or leukocytosis prior to initiation of chemotherapy[81]; risk also varies according to the type of catheter, being higher with a peripherally inserted central catheter compared with an implanted portal catheter. Because of the high risk of bleeding in cancer patients, routine VTE prophylaxis is not recommended among cancer patients with CVCs, in spite of the known thrombotic risk. For those patients who develop CVC-associated thrombosis, general treatment recommendations are for anticoagulation for 3 months. Low-molecular-weight heparin (LMWH), apixaban, edoxaban, or rivaroxaban are preferred over the vitamin K antagonist, warfarin, in this population. Anticoagulation is continued while the line is in place. (See box on Management of Thrombosis in Patients With Cancer.)

TABLE 151.1 Studies of Direct Oral Anticoagulants in Patients With Cancer

Name of RCT (Author, Year of Publication)	DOAC Investigated	Population	VTE Recurrence Rates	Bleeding Rates
Hokusai VTE cancer trial (Raskob, 2018)	Edoxaban	1046 cancer patients with VTE at 114 centers in 13 countries, randomized to receive edoxaban or dalteparin	At 12 months, VTE recurrence was 7.9% in the edoxaban group vs. 11.3% in the dalteparin group (HR 0.71; 95% CI 0.48–1.06)	At 12 months, the rate of major bleeding was 6.9% in the edoxaban group vs. 4.0% in the dalteparin group (HR 1.77; 95% CI 1.03–3.04)
SELECT-D trial (Young, 2018)	Rivaroxaban	406 cancer patients with DVT or PE in the United Kingdom, randomized to receive rivaroxaban or dalteparin	At 6 months, VTE recurrence was 11% in the dalteparin group vs. 4% in the rivaroxaban group (HR 0.43; 95% CI, 0.19–0.99)	At 6 months, the rate of major bleeding was 4% in the dalteparin group vs. 6% in the rivaroxaban group (HR 1.83; 95% CI, 0.68–4.96)
ADAM VTE trial (McBane, 2019)	Apixaban	300 cancer patients with VTE at 28 sites in the United States, randomized to receive apixaban or dalteparin	At 6 months, VTE recurrence was 0.7% in the apixaban group vs. 6.3% in the dalteparin group (HR 0.099, 95% CI, 0.013–0.780)	At 6 months, the rate of major bleeding was 0% in the apixaban group vs. 1.4% in the dalteparin group ($P = .138$; HR and 95% CI not estimable)
Caravaggio (Agnelli, 2020)	Apixaban	1155 cancer patients at 119 centers in 9 European countries, Israel, and USA, randomized to receive apixaban or dalteparin	At 6 months, VTE recurrence was 5.6% in the apixaban group vs. 7.9% in the dalteparin group (HR 0.63; 95% CI, 0.37–1.07)	At 6 months, the rate of major bleeding was 3.8% in the apixaban group vs. 4.0% in the dalteparin group (HR 0.82; 95% CI, 0.4–1.69)

MANAGEMENT OF THROMBOSIS IN PATIENTS WITH CANCER

Cancer patients with a VTE have a high rate of recurrent thrombosis and bleeding after anticoagulation when compared with the general population, and merit a tailored treatment approach. In one study, the 12-month cumulative incidence of recurrent thromboembolism among cancer patients was 20.7% versus 6.8% in patients without cancer, whereas the 12-month cumulative incidence of major bleeding was 12.4% in patients with cancer versus 4.9% in patients without cancer.[82]

A variety of anticoagulants have been studied in the cancer population, including unfractionated heparin, weight-adjusted low molecular weight heparin (LMWH), warfarin, and direct oral anticoagulants (DOACs). Warfarin poses many difficulties for the general population, including numerous and often unpredictable drug interactions and a long half-life. These challenges are amplified in cancer patients for several reasons: variable nutritional intake of vitamin K, an altered bioavailability of dietary vitamin K due to frequent use of antibiotics, and a frequent need to interrupt anticoagulation for procedures and inconsistent degrees of thrombocytopenia.

The long-term use of LMWH in cancer patients has been compared with warfarin. In the CLOT trial, patients with cancer and VTE received dalteparin 200 IU/kg subcutaneously once daily for 5–7 days, and were then randomized to either continued dalteparin 150 IU/kg subcutaneously once daily, or to dose-adjusted warfarin with a target international normalized ratio of 2–3. Patients treated with dalteparin had a lower hazard ratio for recurrent thromboembolism compared with the oral-anticoagulant group (0.48); rates of major (6% vs. 4%) and all bleeding (14% vs. 19%) were similar. In this study, there was no difference in overall survival.[83] A similar study that compared enoxaparin with warfarin for treatment of venous thrombosis in cancer also showed an approximately 50% reduction of combined outcome of major bleeding or recurrent VTE within 3 months with enoxaparin compared with warfarin (10.5% vs. 21.1%).[84] Until recently, LMWH was generally preferred for cancer patients with VTE.

Oral anticoagulation agents that directly inhibit factor Xa or thrombin are increasingly used in the treatment of VTE. Four randomized, controlled trials of the anti-Xa agents rivaroxaban, apixaban, and edoxaban have been performed to date, with major findings summarized in Table 151.1.[85–88] In general, DOACs have been associated with lower rates of VTE recurrence among cancer patients and higher rates of major bleeding and clinically-relevant, non-major bleeding (CRNMB). As of this writing, the ASCO Clinical Practice Guidelines support the use of apixaban, rivaroxaban, or LMWH for thromboprophylaxis in selected high-risk outpatients with cancer. Safety concerns regarding these agents include the possible interactions with chemotherapeutic agents as well as the inability to reverse them quickly in a population that has potential to rapidly develop cytopenias and bleeding.

FUTURE DIRECTIONS

Future studies on hematopoiesis and coagulation in cancer patients have the potential to provide insight into new treatment strategies for the many hematologic manifestations of cancer, as well as the treatment of the underlying malignancy. Historically, management of the hematologic manifestations of malignancy have centered on supportive care; however, hematologic abnormalities themselves may also play a role in tumor survival and growth. A deeper understanding of how growth factors may play a role in tumor growth could identify new therapeutic targets and strategies. Similarly, platelets appear to play increasingly intricate roles in tumor metastasis and survival. Given the prevalence of thrombosis in cancer patients, new anticoagulation strategies will also prove increasingly important in the management of this unique population.

CHAPTER 152

HEMATOLOGIC MANIFESTATIONS OF HIV/AIDS

Maryam Own and James B. Bussel

Human immunodeficiency virus (HIV) infection is associated with a number of hematologic complications throughout the course of the disease. To a certain extent, these complications depend on the stage of the disease and how well controlled HIV infection is but to a certain extent it does not. In untreated infection, the major hematologic complications were cytopenias, either isolated or multiple simultaneously. As combination antiretroviral therapy (ART) became standard of care in developed countries, cytopenias were observed far less frequently, and other complications were seen as a function of a longer life span. In particular, these are lymphomas and venous thromboembolic events; Kaposi sarcoma is not covered in this chapter because it is not a hematologic malignancy. Therefore, this review will focus on lymphoma (both Hodgkin and non-Hodgkin including acquired immunodeficiency syndrome [AIDS]-defining lymphomas) and on thromboembolic events with a section on cytopenias (Table 152.1). The introduction will be a state of the art description of HIV itself and will focus on adults.

INTRODUCTION TO HUMAN IMMUNODEFICIENCY VIRUS

An estimated 38 million people are living with HIV worldwide, of which approximately 25.4 million are on ART. Most cases currently come from sub-Saharan Africa, followed by the Caribbean. In 2019, there were 1.7 million new infections documented and 690,000 AIDS-related deaths recorded, with 23% attributed to men who have sex with men (MSM), 19% to clients of sex workers and their partners, 8% to sex workers themselves, 10% to drug use, 2% to transgender individuals, and the remaining 38% were unknown in the report (other factors include sexual assault of women and vertical transmission). Compared to 2010, 2019 witnessed a 23% reduction in the incidence of HIV and a 39% reduction in AIDS-related mortality. Furthermore, when looking at patients from 2015 to 2019, 59% of patients had an undetectable viral load. Despite substantial global strides in achieving control of HIV, there are fears expressed by the Joint United Nations Programme on HIV/AIDS (UNAIDS) driven by adverse consequences of COVID-19 on HIV, as a result of which 20% of individuals were unable to access therapy for longer than 6 months. As a result, UNAIDS projects an increase of 110,000 AIDS-related deaths in the upcoming 2 years.[1]

In the United States,[2] the incidence of HIV between 2014 and 2018 was 36,400 per year diagnosed with HIV due to any cause. Of the newly diagnosed cases, 66% were attributed to MSM, 24% to heterosexual contact, 7% to drug use, and 4% to a combination of MSM and drug use. When stratified by race/ethnicity, new HIV infections were found in 43% Black/African American, 26% Hispanic/Latino, 26% White, and 6% Other. This highlights a racial/ethnic disparity in healthcare, as Blacks/African Americans account for only 13% of the general population. Furthermore, there were evident disparities in geographical locations within the United States, where 52% of all the cases were in the South, 15% in the Northeast, 13% in the Midwest, and 20% in the West of the United States. The geographical disparity of cases in the US may be related to poverty, lack of access to health care, lack of appropriate sex education, or other (unknown) factors. These are all issues that pertain to the application of management strategies in the future.

AIDS is caused by two lentiviruses, HIV types 1 and 2 (HIV-1 and HIV-2) were first documented in the United States in 1981 when clusters of Kaposi sarcoma and pneumocystis jiroveci pneumonia in homosexual men were identified. HIV-1, a single-stranded RNA retrovirus with multiple names, was identified as the culprit. It is believed to have been zoonotically transmitted to humans from African primates of chimpanzee origin in central Africa, harboring simian immunodeficiency virus (SIV) (40% to 60% DNA homology to HIV-1).[3] Although there are no confirmed direct cases of such transmissions, HIV's cross-over to humans is attributed to the exposure of blood from hunting bushmeat, similar to other zoonoses (i.e., Ebolavirus and SARS-CoV-2). HIV-1 consists of four distinct lineages, termed groups M, N, O, and P, each of which resulted from independent cross-species transmission events. The majority of HIV infections are caused by the M group, which is further subdivided into 11 clades: A to K. Subtype B is the predominant type in the Western world, whereas subtype C is dominant in southern Africa. The lesser-known virus, HIV-2, also from the same family and often not accounted for when speaking about "HIV," is mostly found in West Africa and is theorized to have been zoonotically transmitted from sooty mangabey monkeys.[4] It has six phylogenetic lineages, A to F. HIV-2 is characterized by low virulence, lower viral loads (in the thousands rather than millions), and individuals that remain as "long term non-progressors" to AIDS. When individuals do progress, the process mimics HIV-1 in pathology.[5] One needs to be aware of HIV-2, especially when immunodeficiency is suspected in an individual from West Africa, as the fourth generation immunoassay for HIV detection in the United States only tests for HIV-1; the earlier tests identified both.

As mentioned above, most HIV is transmitted sexually. In the US, it is mostly found in MSM, whereas in sub-Saharan Africa, it is transmitted mostly via heterosexual penile-vaginal sex. Exposure to infected blood via injected drug use is another common way to acquire HIV. In the past, hemophiliacs and thalassemics also acquired HIV through contaminated blood transfusions in the 1970s and 1980s before the virus was identified, and other transfused individuals receiving multiple single donor products also were infected. Currently, screening of donors and viral eradication in plasma products has made this mode of viral acquisition very rare to essentially non-existent. Mothers can also transmit HIV either perinatally (maternal-fetal hemorrhage of blood or swallowed blood during delivery) or to neonates via breastmilk. Individuals are at an increased risk of contracting HIV if the exposure involves a high viral load (in the acute phase of the infection) or having damage to the mucosa thus providing access to the virus; this can be seen in co-infections with other sexually transmitted infections (STIs) or in unprotected receptive anal sex. Factors that are protective against acquiring HIV include the use of protection during intercourse and male circumcision since foreskin harbors a concentration of Langerhans cells and T cells that are HIV targets.[6] Protective factors preventing the host from transmitting HIV include achieving an undetectable viral load by the host through compliance with ART. This includes the use of ART during pregnancy and delivery to prevent vertical transmission to the neonate, reducing risk from 25.5% to 8.3%[7] in the first study, with further reductions seen in subsequent studies. Sexual partners of HIV-positive patients can also reduce their risk by taking pre-exposure prophylaxis (PrEP) consisting of tenofovir disoproxil with emtricitabine or lamivudine. If an individual is exposed to a high-risk sexual encounter or a needle-stick injury,

that is, healthcare workers, then post-exposure prophylaxis (PEP) of 28 days duration with tenofovir + emtricitabine with raltegravir is indicated. The efficacy of PEP has been observed in retrospective studies, where a Cochrane systematic review concluded that HIV-positive individuals were less likely to have been taking PEP (OR 0.19, 95% CI 0.06 to 0.52).[8]

HIV is composed of a viral capsule constructed of glycoproteins gp120 and gp41 that form a lipid bilayer. These glycoproteins facilitate entry into cells by binding to the CD4 receptor and chemokine co-receptors CXCR4 and/or CCR5. Within the viral capsule, there are two positive-sense, single-stranded RNA strands that carry nine genes. Of those, three are integral to viral replication and survival: gag, pol, and env genes transcribe core proteins p24 and p17, reverse transcriptase and integrase, and the glycoproteins respectively. In the cytoplasm, the enzyme reverse transcriptase generates a single strand of DNA from which a double DNA strand (dsDNA) is transcribed. dsDNA enters the nucleus, and viral integrase integrates the viral DNA into the host cell's DNA. From then on, the virus uses the host's machinery to replicate. The viral protease enzyme is vital in the final step of cleaving gag and gag-pol precursor proteins into the functional units known as gp120 and gp41.[9]

HIV not only infects T cells and myeloid cells (monocyte/macrophages) but also glial cells in the central nervous system (CNS). Furthermore, there are resting memory CD4 T cells that contain HIV but do not contribute to viral replication, making up a "latent HIV reservoir" posing important challenges to the eradication of the virus despite the ability to achieve an undetectable viral load with ART.[10] This latter can be very important in that CNS virus and/or HIV in other extra-vascular locations may not be eradicated by highly active antiretroviral therapy (HAART) and contributes to viral resurgence and ongoing inflammation. Targeting viral entry as a therapeutic strategy gained traction when a CCR5-delta 32 mutation, found in populations of European descent, conferred resistance to acquiring HIV infection in homozygotes by inhibiting viral entry.[11] Entry inhibitors have been developed to target the CCR5. Further, this was proven in vivo in the only two cases cured of HIV after receiving hematopoietic stem cell transplantation selected for the CCr5-delta 32 mutation as part of the treatment for acute myeloid leukemia and Hodgkin lymphoma.[12] In 2018, a physicist in China used CRISPR-Cas9 gene-editing technology to genetically engineer twin girls with knockout CCR5 to prevent them from contracting HIV from their father.[13] In addition to the questionable clinical reasoning and the unethical nature of his actions, one could speculate that the twin girls may be at increased risk of autoimmune diseases, as *CCr5-delta 32* mutation has been associated with MS[14] and lupus nephritis.[15] Nonetheless, these cases demonstrate the utility of targeting viral entry as a therapeutic modality although once an infection has occurred, the previously described latent cells may vitiate this strategy.

In the United States, the 4th generation enzyme immunoassay is the standard HIV screening test used to detect HIV in the acute setting, where it is able to detect HIV IgM, IgG antibodies, and p24 antigen 15 to 20 days after exposure in comparison to the first-generation enzyme immunoassay, which only detected IgG after 35 to 45 days.[16] The gold standard confirmatory testing for HIV remains the western blot, which has a window of 45 to 60 days. The presence of neutralizing antibodies has raised the question of a possible vaccine, which to this day remains a very active but puzzlingly unsolved area of research. One of the first vaccines developed in 1998 targeted neutralizing antibodies against gp120. Despite achieving high titers in the serum, the vaccine did not work as the targeted region V3 was shielded within a trimeric structure rendering it inaccessible. Surprisingly, in vivo animal experiments demonstrated that neutralizing gp120 antibodies were able to prevent HIV infection in pig-tailed macaques receiving IgG from HIV-1 infected chimpanzees.[17] Other explanations for the lack of neutralizing antibodies in humans include the mutation rate of the HIV reverse transcriptase, giving HIV the ability to escape the host's immune system. Furthermore, there are many clades and subtypes of the virus, another factor making a universal vaccine even more challenging.[18]

The highest viral load is seen in the acute infection phase, accompanied by a drop in the CD4 count. The viral load starts to decline after approximately 4 weeks because of the cytotoxic T-cell immune response. The CD4 count then starts to increase but does not completely recover to what it was prior to the infection, referred to as an immunological set point. This is followed by the asymptomatic phase, which can last for a decade. Without anti-HIV treatment, the virus continues to replicate, and the CD4 T cell count continues to decline until an AIDS-defining opportunistic infection (OI) or a malignancy causes death. AIDS, by definition, occurs either when the CD4 T cell count is below 200 or by having one of the AIDS-defining illnesses irrespective of the CD4 T cell count. This "natural history" of untreated HIV infection is mitigated by starting antiretroviral therapy, where the CD4 T cell count starts to climb up and the HIV plasma viral load declines, potentially to undetectable levels using commercial assays with sensitivity typically down to 50 HIV viral copies/mL, thus reducing morbidity and mortality drastically (see Fig. 152.2).

Currently, HIV is treated with ART targeting the replication process at various stages from entry to maturity. There are nucleoside/nucleotide reverse transcriptase inhibitors (NRTI), non-nucleoside reverse transcriptase inhibitors (NNRTI), integrase inhibitors (INSTI), and protease inhibitors (PI). Additional ART includes entry inhibitors that prevent the virus from entering the targeted cells. These include enfuvirtide (Fuzeon) and maraviroc (Selzentry). Most HIV-infected persons are on 2 NRTI and 1 INSTI. In the past, a person with HIV took 13 or more pills a day, which in addition to side effects, added challenges to medication compliance. Nowadays, patients with HIV take 1 to 4 pills/day depending on the presence of co-infections with hepatitis B or C and the genotypic profile of HIV. Newer medications also offer an improved side effect profile, particularly for cytopenic effects, and there are single pills formulated to contain all of the antiretroviral therapy (Table 152.2). Very recently, long-acting ART was approved, involving a monthly injection.

Antiretroviral therapy protects against opportunistic infections by restoring the CD4 T cell count and suppressing viral replication. The increase in CD4 T cell counts when starting ART can, in a minority of patients (~20%), sometimes lead to a paradoxical effect known as the immune reconstitution inflammatory syndrome (IRIS), especially if the individual had a low CD4 count or a high viral load. IRIS is a strong immune response characterized by cytokine release leading to an array of clinical syndromes. IRIS can resemble an opportunistic infection when the target is an occult infection that has now become unmasked in the setting of increased immune surveillance, that is, TB leading to constitutional symptoms or untreated hepatitis B leading to liver failure; or an autoimmune phenomenon, where the recovery of the immune system aggravates a pre-existing autoimmune disease, that is, thyroiditis, similar to the use of checkpoint inhibition. Depending on the cause, its management can target treatment of the inciting infection, which sometimes necessitates interrupting ART until treatment is completed if concurrent treatment is not possible. IRIS can resolve on its own if it arose from a previously recently adequately treated opportunistic infection, where the immune system precipitously recognizes remnants of it. To this end, IRIS remains

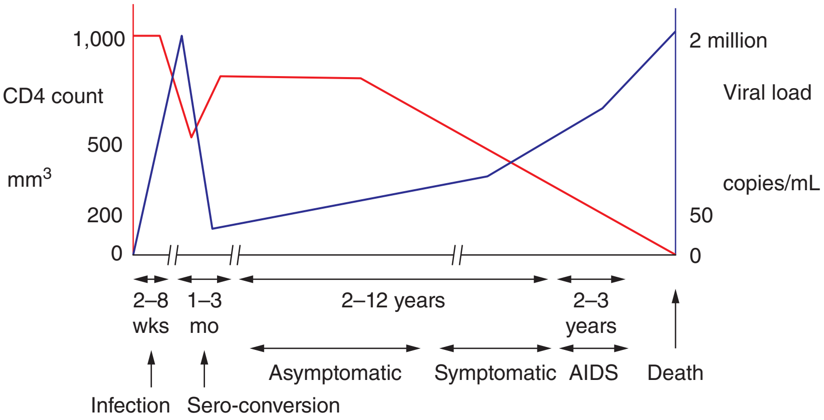

Figure 152.1 CD4 COUNT AND VIRAL LOAD WITHOUT ANTIRETROVIRAL THERAPY (ART). *(From HIV iBase, London, United Kingdom.)*

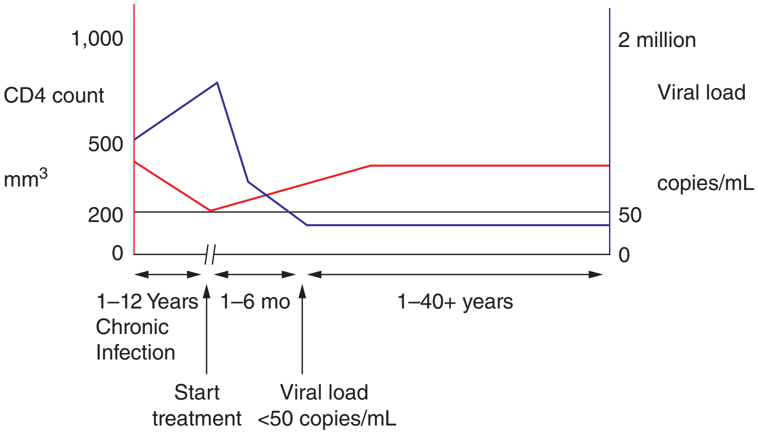

Figure 152.2 EFFECT OF ART ON CD4 COUNT AND VIRAL LOAD. *(From HIV iBase, London, United Kingdom.)*

a diagnosis of exclusion, with the main diagnostic clue being its timing.[19]

In assessing a patient, one should consider the following three factors: the absolute T-cell count (CD4 count), followed by whether they take antiretroviral therapy, and whether the peripheral blood viral load (VL) is undetectable. These three factors determine the risk of imminent mortality (Figs. 152.1 and 152.2). The classic analogy is to think of a train traveling on railroad tracks approaching the edge of a cliff. The speed of the train is the viral load, the distance to the cliff is the absolute T-cell count, and the cliff represents AIDS, where an individual is now at risk of an opportunistic infection or dying from complications of HIV.

Currently, in well-managed care settings, the great majority of HIV-infected patients are taking effective antiretroviral therapy that often involves 1 pill a day covering three agents. Testing for resistance is possible if a compliant patient nonetheless develops a high viral load, and the relatively large number of agents usually makes it possible to identify an effective combination. Isolated cytopenias are infrequent and generally seen in settings without available anti-HIV treatment. As will be discussed, thromboembolic events and malignancies persist, albeit at a lower rate.

HUMAN IMMUNODEFICIENCY VIRUS AND CYTOPENIAS

Cytopenias occur frequently in HIV infection. The effect of HIV on blood counts is pervasive and multifactorial. In the United States when HIV infections became prevalent and recognized (i.e., in the first half of the 1980s), it became clear that leukopenia, especially lymphopenia, anemia, and thrombocytopenia, all occurred but often for different reasons. At one end of the spectrum was uncontrolled HIV infection itself, causing low platelets for multiple reasons. This could be antiplatelet antibodies to amino acids 49 to 66 on glycoprotein IIIa as described in one seminal study by the Karpatkin group at New York University (NYU). Soon thereafter, infection of megakaryocytes by HIV was described as the creation of an inflammatory milieu of the bone marrow, all of which contributed to lower blood counts.

Confirmation of the role of active viral infection in the decrease in the platelet count has come from the use of antiretroviral treatments, which bring up the platelet count when the viral load goes to zero. Early on, there were several examples. First, when the initial randomized azidothymidine (AZT) study was performed, a subsequent letter showed that the patients who entered the study with counts between 100 and 150,000/μL (entry with counts below 100,000/μL was not allowed) showed that platelet counts increased on AZT therapy. This was in marked contrast to the hemoglobin and leukocyte count, both of which decreased in patients on AZT. Another study from Switzerland used a crossover design. Patients were randomized to either receive AZT or placebo, and then after a number of weeks they crossed over to the opposite arm. The results were astonishingly clear that the platelet counts went up dramatically on AZT and did not rise or fall back to baseline on placebo. Finally, Oksenhendler, in a non-randomized study, demonstrated the efficacy of not only AZT but also splenectomy in increasing the count in patients with HIV-related thrombocytopenia. These findings demonstrated that the thrombocytopenia at least resembled immune thrombocytopenia (ITP) in certain ways and furthermore that it was clearly linked to the presence of the virus. The bottom line was that thrombocytopenia was of sufficient importance that Holtzman et al. published a study in 1994 suggesting that at least 40% of patients with HIV

Downl
15, 202

would eventually develop thrombocytopenia and also suggested that worse thrombocytopenia was linked to greater mortality. However, this description is reflective of past history and applies only to a situation in which ART is not readily available.

Currently, thrombocytopenia is very infrequent in patients with HIV who are generally well controlled on ART. Furthermore, the viral load suddenly increasing either from resistance or non-compliance is not typically heralded by thrombocytopenia. In high-income countries, thrombocytopenia is generally not an issue in patients on ART, and neither is platelet dysfunction in general. In lower-income countries, which do not have a wide availability of testing or multiple up-to-date treatments of HIV, there is a substantial incidence of thrombocytopenia in these patients as there was initially in the United States. Thus there are still numerous reports from lower-income countries, for example, Ethiopia, in which thrombocytopenia is relatively frequent. Other causes could be co-infections. The best-described co-infection with HIV has been hepatitis C, in which thrombocytopenia, in particular, occurs relative to liver disease and hypersplenism. Liver disease can be a cause of unexplained thrombocytopenia, as seen in a study of non-HIV-infected ITP patients published by Rajan in 2006. Another co-infection that would cause cytopenias is CMV which is certainly not a rare infection in these or any group of hospital-bound patients.

Leukopenia is the least well-defined cytopenia in HIV-infected patients. Some of it is due to lymphopenia as the virus affects patients with infection, as described in the Introduction. Some of it may be related to other medications, inflammation, and/or infections.

Alternatively, anemia seems to be a result of low-grade inflammation in the marrow. It could also be from poor nutrition, but that is not very common and, if present, is typically very mild. Thrombocytopenia, leukopenia, and anemia, frequently present in the past, were often a result of an overt infection that was rampant and resulted in pancytopenia, which could be substantial and was often a sign of impending mortality. However, this fortunately is quite uncommon in the current climate. Similarly, true autoimmune disease is relatively uncommon in the current climate as well. This means that “ITP” and autoimmune hemolytic anemia are no longer commonly found in HIV-infected patients.

Much of anemia, leukopenia, and thrombocytopenia in the past involved not only viral loads but also the toxicity of medications for HIV such as AZT and medications used as prophylaxis or treatment of associated infections such as Bactrim for *Pneumocystis* pneumonia (PCP) or valganciclovir for cytomegalovirus (CMV). AZT compliance could be measured not so much by identifying a mild degree of anemia but rather by seeing that the mean corpuscular volume (MCV) had substantially increased. However, newer drugs have been designed so that they do not cause cytopenias and therefore these are not much of a problem in the setting of ART. Similarly, the use of Bactrim or trimethoprim sulfa 3 days a week in prophylaxis rarely causes anemia. In the differential diagnosis of anemia, all of the standard causes would need to be considered, for example, GI bleeding, iron deficiency, or B12 deficiency.

Treatments of cytopenias typically depend on the etiology. Management of an underlying disease, including but not limited to HIV itself, is almost always useful. For HIV-related ITP, steroids are generally useful and surprisingly safe if not administered for long periods of time. PCP is certainly a risk during discontinuation and fungal infection, especially candida, is probably the most common if prophylaxis is not given. Two studies from our center demonstrated the utility of a now-infrequently used ITP treatment, IV anti-D (Winrho SD), in the HIV-related ITP. Surprisingly, in this population, a small, randomized crossover study suggested that it was more effective than IVIG. Anemia was not a particular problem in these patients despite the hemolysis from anti-D and the predisposition to anemia. Oksenhendler demonstrated the utility of splenectomy. Other treatments now commonly used for classical ITP, such as rituximab, are either not used (the former) or supported by anecdotal reports (the latter). All of these treatments were developed in the pre-ART era and are now infrequently used.

In summary, in well-treated HIV infection, at the present time, cytopenias are relatively uncommon and have not been a serious problem. In patients that are not well treated either for compliance, resistance, or unavailability of ART medications, cytopenias continue to be seen as they were in the original cohorts in the 1980s before effective, nontoxic, antiretroviral treatments were developed. Again, the better shape a patient is in from the point of view of nutrition, undetectable viral load, inflammation, and not requiring large amounts of concomitant medications, the less likely they are to have cytopenias or other problems.

HUMAN IMMUNODEFICIENCY VIRUS AND LYMPHOMAS

Lymphomas of all types are increased in people living with HIV. This increased occurrence continues even in well-treated patients with low to undetectable viral cultures although the incidence is lower. The explanation for this is complicated and remains not fully worked out. Theories include: (1) failure of adequate immune surveillance resulting in failure to eradicate early lesions, (2) chronic inflammation characterizing HIV may stimulate lymphocytes such that they may then become malignant, and (3) increased co-infections, especially failure to regulate EBV. These explanations tend to be consistent with finding B cell non-Hodgkin lymphoma but do not explain equally well the increased risk of Hodgkin disease.

The link between immunosuppression and cancers has been well established, whether it is related to inherited immune deficiencies, medications (e.g., steroids or chemotherapy), or uncontrolled HIV with decreased immune surveillance. Polymorphic lymphoproliferative disorders are reported in both HIV-positive individuals and solid organ transplant recipients. This overlap is likely related to the state of immunosuppression. Also, in congenital immunodeficiencies, failure of immunoregulation may likely be abnormal and lead to uncontrolled proliferation including the development of lymphoma. Most lymphomas arise from B-lymphocytes; however, HIV does not directly infect B cells, and various theories have been proposed to explain this phenomenon.

The classic theory is that the state of immunosuppression leads to decreased immune surveillance, along with co-infection with oncogenic viruses: herpesviruses, Epstein-Barr virus (EBV), and Kaposi sarcoma-associated herpesvirus (KSHV), leading to a loss of immunoregulatory mechanisms. HIV infection is also often accompanied by a chronic pro-inflammatory state resulting in cytokine overproduction (i.e., IL-6 and IL-10). In turn, this leads to uncontrolled stimulation of B cells. Dysregulated B-cell stimulation aids in the emergence of monoclonal B cells; these can be seen without indicating the presence of malignancy. Certain genetic alterations may then take place, which leads to the emergence of lymphomas. Furthermore, there are unique characteristics of lymphomas that present within the HIV population.[20]

The introduction of HAART, through the suppression of the HIV viral load and normalizing the CD4 count leading to greater immunocompetence, played a significant role in the reduction of cases of NHL in the HIV population. However, non-Hodgkin lymphoma (NHL) still comprises the great majority of lymphoma cases in HIV-positive individuals. There are non-AIDS defining NHL subtypes, i.e., DLBCL and Burkitt lymphoma, that remain higher in prevalence in the HIV-positive population despite viral control with antiretroviral therapy. Some lymphomas, such as Hodgkin lymphoma, tend to present at later stages with extra nodal disease, are more aggressive, and are more likely to have EBV co-infection when compared to those seen in HIV-negative patients described in greater detail below.[21] Prior to HAART, most patients with HIV succumbed to opportunistic infections or one of the aforementioned AIDS-defining malignancies, including Kaposi sarcoma (see Table 152.2). HAART made the prognosis of HIV not dismal and restored the lifespan of patients to more normal. Other malignancies, beyond the AIDS-defining ones, have surfaced and have been likened in prevalence to those who underwent solid organ transplantation and are taking lifelong immunosuppressive therapy, where they were noted to occur at a higher rate when compared to the general population. Of all AIDS-defining cancers, lymphomas make up 50% of cases.

TABLE 152.2 Antiretroviral Therapy

Single Tablet Regimens	Indication	Components	Side Effects/Contraindications	Mechanism of Action for Class/ List of Drugs
Biktarvy	1st line initial therapy for most people (2 NRTIs + INSTI)	Bictegravir Emtricitabine Tenofovir alafenamide	Nausea, headache, and diarrhea. **Cannot be taken with hepatitis B medication**	**INSTI: inhibits HIV integrase from integrating viral genome into the DNA of a host cell** Bictegravir Dolutegravir Elvitegravir **NRTI: competitive inhibition of HIV reverse transcriptase by incorporating into viral DNA and inducing chain termination** Abacavir Bictegravir Emtricitabine Lamivudine Tenofovir alafenamide Tenofovir disoproxil-fumarate **NNRTI: noncompetitive inhibition of HIV reverse transcriptase via binding of the enzyme's active site** Efavirenz Doravirine Rilpivirine **PI: preventing the cleavage of gag and gag-pol precursors by HIV protease, which is required for the formation of the viral capsid** Darunavir **Booster: Inhibits CYP3A, which is responsible for metabolizing darunavir or elvitegravir thus serving as a pharmacoenhancer** Cobicistat
Triumeq		Dolutegravir Abacavir Lamivudine	Insomnia, headache, and fatigue. **Cannot be used in HLA-B*5701 given hypersensitivity to abacavir**	
Dovato		Dolutegravir Lamivudine	Headache, nausea, diarrhea, fatigue. Reversible increase in serum Cr without affecting kidney function. **Cannot be used if VL > 50,000 or HBV co-infection**	
Atripla	1st line for people with certain clinical conditions (2 NRTIs AND NNRTI or INSTI + booster or PI + booster)	Efavirenz Emtricitabine Tenofovir disoproxil-fumarate	Suicidal ideation and QTc prolongation (efavirenz). **Should not be taken with medication treating hepatitis B. Efavirenz should be avoided in pregnancy due to increased risk of neural tube defects**	
Complera		Rilpivirine Emtricitabine Tenofovir disoproxil-fumarate	Insomnia, headache, and depressive disorders	
Delstrigo	1st line for people with certain clinical conditions (2NRTI AND NNRTI or INSTI + booster or PI + booster)	Doravirine Lamivudine Tenofovir disoproxil-fumarate	Dizziness, nausea, abnormal dreams, and headaches, depression, and suicidal ideation.	
Genvoya		Elvitegravir Cobicistat Emtricitabine Tenofovir alafenamide	Weight gain, nausea, and vomiting. Cobicistat can cause a reversible increase in serum creatinine without affecting actual kidney function	
Odefsey		Rilpivirine Emtricitabine Tenofovir alafenamide	Insomnia, headache, depression and suicidal ideation Rash, edema, and urticaria due to rilpivirine. Reversible increase in serum creatinine without affecting actual kidney function	
Stribild		Elvitegravir Cobicistat Emtricitabine Tenofovir disoproxil-fumarate	Nausea, diarrhea, abnormal dreams, weight gain, depression, suicidal ideation	
Symfi		Efavirenz Lamivudine Tenofovir disoproxil-fumarate	Headache, body pain, fever, diarrhea, depression, and rash	
Symtuza		Darunavir Cobicistat Emtricitabine Tenofovir alafenamide	**Contraindicated in patients taking steroids, direct oral anticoagulants, and high dose statin. Relative contraindication to co-administration with Colchicine if renal or hepatic impairment present**	
Triumeq		Dolutegravir Abacavir Lamivudine	Weight gain, suicidal ideation, reversible Cr increase that does not affect kidney function. **Cannot be used in HLA-B*5701 given hypersensitivity to abacavir**	

INSTI, Integrase strand transfer inhibitor; *NRTI*, nucleoside/nucleotide reverse transcriptase inhibitors; *NNRTI*, non-nucleoside reverse transcriptase inhibitor; *PI*, protease inhibitor.[100,101]

A metanalysis by Grulich et al. looked at the incidence of cancers in HIV/AIDS individuals and compared it to immunosuppressed transplant recipients; seven papers were included for the HIV group and six for the transplant group. The incidence of non-Hodgkin lymphoma was 70-fold more in HIV patients when compared to the general population before the introduction of ART. The metanalysis did not consider the CD4 count of the HIV patients and the degree of the immunosuppression in their findings and did not further stratify the results for HIV versus AIDS. Both groups in the metanalysis had an increased incidence of both Hodgkin lymphoma and non-Hodgkin

Downl
15, 202

lymphoma, with a substantially higher meta-analysis standardized incidence ratio (SIR) in the HIV population for both conditions. For Hodgkin lymphoma, the metanalysis SIR for HIV/AIDS was 11.03 (8.43 to 14.4, CI 95%) versus 3.89 (2.42 to 6.26, CI 95%) in transplant recipients. For non-Hodgkin lymphoma in HIV/AIDS, it was 76.67 (39.4 to 149, CI 95%) versus 8.07 (6.40 to 10.2, CI 95%) in transplant recipients.[22] Robbins et al. examined the incidence of cancers in the HIV population over time, obtaining data from US HIV AIDS Cancer Match Study, and included 275,975 HIV-positive patients. They found that the incidence of Hodgkin lymphoma declined by 4%, whereas the incidence of non-Hodgkin lymphoma declined by 15% over the first seven years, followed by a 5.5% decline subsequently.[23] Despite this decline after the introduction of ART, the HIV population still has a higher incidence of both non-Hodgkin lymphoma and Hodgkin lymphoma than the general population (10-fold and 11-fold more respectively).[24]

Non-Hodgkin lymphoma is characterized by multiple subtypes. Many but not all of these are increased in HIV infection, and the subtypes that are increased can be further distinguished between those that are related to the state of the HIV and those that are independent of it.

Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphoma (DLBCL), an aggressive lymphoma, is the most common type of NHL in the HIV population, constituting 50% of lymphomas in HIV. Unlike Hodgkin lymphoma and Burkitt lymphoma, DLBCL is associated with low CD4 T cell counts. Traditionally, DLBCL had been further sub-classified cytologically into centroblasts (multilobulated vesicular nuclei with numerous peripheral nucleoli), immunoblasts (round vesicular nucleus with one central nucleoli), and anaplastic cells (bizarre pleomorphic nucleus). This classification is no longer used when thinking of DLBCL given the lack of both inter-observer and intra-observer reproducibility, advances in molecular genetics that aid in better prognostication of disease, and heterogeneity of DLBCL per se in the general population. However, this classification is not entirely useless in the HIV population, as cytology can still confer information, and the utility of the new World Health Organization (WHO) 2016 classification of DLCBL for HIV remains unclear. DLBCL with centroblastic features is 70% EBV-negative, whereas 80% to 90% of immunoblastic DLBCL are EBV-positive[25] and express latent membrane protein 1 (LMP-1), a viral oncoprotein resembling CD40 that activates nuclear factor kappa B (NF-κB) leading to unregulated B-cell proliferation.[21,26]

In patients with HIV, centroblastic DLBCL occurs in individuals with almost normal CD4 counts, whereas immunoblastic DLBCL occurs late in the course of HIV infection and in those who are immunosuppressed, not surprising given the role of EBV primarily in the latter. Diamond et al. examined data from 1988 to 2000 from the San Diego County AIDS and Cancer registries and found that immunoblastic DLBCL decreased from 26% to 7% in the population of patients with AIDS and cancer after the introduction of ART.[27] Despite increases in both overall CD4 T cell count and survival, centroblastic DLBCL increased from 21% to 44% in the same population.

As of 2016, the WHO classifies DLBCL by cell of origin derived from a micro-array gene expression profile (GEP). There are three categories: germinal center B-cell (GC), activated B-cell (ABC), and unclassified (accounting for 20% of DLBCL).[28] In the general population, this classification predicts response to R-CHOP (rituximab-cyclophosphamide-hydroxydaunorubicin-Oncovin-prednisone) therapy, to which GC has a more favorable 5-year survival response when compared to ABC (60% vs. 35%). The majority of GC are centroblastic, whereas the majority of ABC are immunoblastic.

Unfortunately, GEP is expensive and not readily available. So instead, the Hans algorithm using three immunohistochemical markers, CD10, Bcl-6, and MUM1, is used. With this algorithm, DLBCL is classified as GC if CD10 is positive or if MUM-1 is negative with a positive BCL-6. All other DLBCL cases are classified as non-GC.

HIV-negative individuals with GC DLBCL have a better prognosis when compared to non-GC DLBCL, but this does not apply to HIV-positive patients. A study by Chadburn et al. examined tissue from 81 DLBCL patients with AIDS enrolled in AIDS-malignancy consortium (AMC) trials comparing the effects of R-CHOP versus CHOP (AMC010) and concurrent R+EPOCH versus sequential EPOCH followed by Rituximab. Hans algorithm was used to classify the samples into GC and non-GC. No difference in overall survival between the two groups was observed ($P = 0.859$). The presence of EBV did not correlate with event-free survival. Also, there was no correlation between CD4 counts and the presence of EBV ($P = 0.47$). However, immunohistochemical staining with Ki-67, a marker of cell proliferation, predicted overall survival ($P = 0.05$), with a high proliferation index associated with a better clinical outcome, possibly providing a target for chemotherapeutic agents.[29]

Madan et al. examined differences between HIV-positive and HIV-negative individuals by describing 39 de novo DLBCL in 12 AIDS DLBCL and 27 non-AIDS DLBCL[30] Classically, GC is associated with CD10, BCL-6, Cyclin H, and non-GC with MUM1, BCL-2, CD38, PAL1, and CD44. Each of the immunohistochemical stains was designated a number on the basis of the positivity of the samples. Furthermore, the different markers for GC and non-GC were combined to give a score, which was plotted on a two-dimensional contour plot. For the HIV-negative DLBCL samples, the plot had two separate clusters delineating the two subtypes. When the HIV-positive samples were plotted, the two distinct clusters were not appreciated, instead, an intermediate state of both GC and non-GC was appreciated with overlap with both GC and non-GC from the HIV-negative samples. This alludes to a possibly different underlying mechanism for lymphomagenesis, which may imply a need to consider different targets for therapy.

Another adverse prognostic factor termed the "double-expressor" phenotype exists where MYC and BCL-2 are both overexpressed without genetic re-arrangement. This is distinct from "double-hit" or "triple-hit" lymphomas, a term designated for high-grade B-cell lymphoma (HGBL), which morphologically resemble DLBCL. They are considered a separate entity in the 2016 WHO classification, which denotes that re-arrangements in MYC and BCL2 and/or BCL6 are implicated in a worse prognosis.[28]

The "Double-Expresser" phenotype is also associated with poorer outcomes, where the 5-year overall survival is around 40% with R-CHOP therapy. Dodero et al. compared clinical outcomes in double-expresser DLBCL treated with R-CHOP versus dose-adjusted EPOCH-R (etoposide + prednisone + vincristine + cyclophosphamide + doxorubicin + rituximab). One hundred fourteen patients with the double-expresser DLBCL phenotype were identified in three Italian institutions. Fifty-one patients received dose-adjusted EPOCH-R between 2013 and 2017, and 63 patients received R-CHOP between 2009 and 2017. The two primary outcomes were overall survival (OS) and progress-free survival (PFS). In the dose-adjusted EPOCH-R group, dose-escalation to level 3 was possible in 73% of patients under the age of 65 compared to many fewer patients above 65, where the majority received dose-adjusted EPOCH-R at level 1 because of either comorbidities or therapy-associated toxicities. There were no statistical differences in OS and PFS in patients receiving R-CHOP versus dose-adjusted EPOCH-R; however, when adjusting for age, patients below the age of 65 exhibited favorable clinical outcomes in the dose-adjusted EPOCH-R group when compared to patients receiving R-CHOP, where PFS was 82% versus 43% ($P = 0.02$) and OS 90% vs. 63% ($P = 0.042$). The clinically significant difference after age adjustment likely emerged because younger patients were able to better tolerate higher levels of dose-adjusted EPOCH-R therapy.[31]

Other mutations have been observed in HIV-related DLBCL: over 90% of cases were noted to harbor somatic hypermutations in the immunoglobulin variable genes responsible for extracellular antigen binding. Specifically, there was overexpression of the IGHV4–34 gene in DLBCL, which is normally expressed on the surface of naïve B cells but not expressed by mature activated or memory B cells.[32] This aberrant overexpression in HIV-related DLBCL implies that

Downl
15, 202

there may be an antigen-driven process that indirectly stimulates B cells leading to lymphomagenesis. Similar to HIV-negative lymphomas, other mutations in proto-oncogenes PIM-1 and RhoH/TTF (signal transducers) and PAX-5 and c-MYC (transcription factors) have been observed in HIV-related DLBCL; these are typical features of aggressive lymphomas.[33] Furthermore, over 60% of HIV-related DLBCL harbor mutations in BCL-6,[34] a transcription repressor protein-encoding gene required for germinal center formation, where it normally suppresses p53, a tumor suppressor gene that regulates the cell cycle.[35]

Primary CNS lymphoma (PCNSL) is an AIDS-defining malignancy. It involves the brain, leptomeninges, or spinal cord, is considered a subtype of DLBCL in over 90% of cases and is classified under the immunoblastic variant in which almost all cases are EBV driven and express LMP-1. It is associated with CD4 counts below 50 and thus occurs late rather than early in the course of HIV. Post-transplant patients can also present with PCNSL, comprising around 0.9% of diagnosed lymphomas in these patients. Immunocompetent HIV-negative patients can also get PCNSL; however, it is exceedingly rare with an incidence of 7 per million in the United States, presents in much older individuals (median age of 67 vs. 37 in HIV vs. 52 in transplant patients), and is not EBV driven. In the early 1990s, over 60% of PCNSL cases were found in HIV-positive individuals. In 2007–2011, only 12% of PCNSL cases were attributed to HIV, which correlates with better immunocompetence in ART-treated HIV-positive individuals.[36]

Plasmablastic lymphoma (PBL), a subtype of DLBCL comprising 3% of lymphoma cases in HIV, is also considered an AIDS-defining lymphoma. Half of the cases involve the oral cavity and jaw, with the other half mostly involving the GI tract or any other site, i.e., skin, bones, or sinonasal cavity. This lymphoma is morphologically categorized into a monomorphic and a plasmacytic variant. The former resembles DLBCL, where it appears immunoblastic or centroblastic in morphology (described above), and the latter variant resembles plasma cells. More than half of the cases express EBV with LMP-1, and the remainder expresses HHV8 alone, similar to primary effusion lymphoma (described in greater detail below). The immunohistochemical profile stains $CD38^+$, $CD138^+$, IRF4/MUM1, CD79a, BLIMP-1 and is negative for mature B-cell markers such as CD19, CD20, and Pax 5. Some PBLs are weakly positive for CD45 which confers a positive prognostic factor along with EBV positive cases. It carries an extremely poor prognosis with a median survival between 3 and 5 months.[21,26,37,38,60]

Burkitt Lymphoma

Burkitt lymphoma (BL), also an aggressive NHL, histologically identified by the starry sky appearance is typically seen in children; however, it is the second most common lymphoma subtype in adults with HIV after DLBCL, representing 30% of NHL. BL is classified into three subtypes. Endemic BL typically involves the jaw and is EBV-driven in most cases. Geographically, it is found in tropical Africa and Papua New Guinea, correlating nicely with the incidence of malaria, where the malaria infection is thought to decrease one's resistance to EBV. Sporadic BL is not confined geographically nor has the predilection for EBV (20% of cases) and usually presents in the ileocecal region in the abdomen in children and adolescents in the United States and Western Europe with a predilection for persons of European descent.[39] The third form is immunodeficiency-associated BL, found mainly in HIV patients typically with CD4 counts above 200. It behaves in many ways like the sporadic type, where they both have similarities in staging and organ involvement. Furthermore, this subtype is also observed to a lesser extent in post-transplant patients and also in rare case reports of congenital immunodeficiencies, that is, Common variable immunodeficiency (CVID), Bloom syndrome, and Wiskott-Aldrich syndrome. All three subtypes have translocations leading to constitutive expression of the MYC proto-oncogene on chromosome 8. Eighty percent of BL have a t(8;14), where chromosome 14 encodes the heavy immunoglobulin chain. The remainder of BL translocations involve the immunoglobulin light chain, where 15% are with the kappa chain t(2;8) and lambda chain t(8;22). Immunohistochemically, BL stains for CD20, CD79a, CD10, and BCL-6 and is negative for BCL-2 and TdT.[40] Interestingly, EBV-associated BL does not express LMP-1; instead, it expresses EBNA1, a viral protein responsible for DNA replication in EBV's latent phase, which is thought to contribute to the survival of B cells by protecting them from apoptosis induced by the c-myc gene.[41] For unclear reasons, it was observed that BL increased from 4% to 9% after the introduction of ART in the San Diego County AIDS and Cancer registry from 1988 to 2000.[27]

Primary Effusion Lymphoma

Primary effusion lymphoma (PEL), a B-cell lymphoma, is almost exclusively associated with HHV8, also known as KSHV. Over 90% of cases are also associated with EBV and LMP-1 expression. PEL presents as malignant effusions, most commonly of the pleura. It can also be present in the peritoneum, pericardium, and to a lesser extent, joint spaces. It is associated with severe immunosuppression and represents around 1% to 3% of lymphomas found in HIV, often co-occurring with other HHV8- associated malignancies like Kaposi sarcoma or multi-centric Castleman disease (described below). HHV8 contributes to oncogenesis via at least three viral proteins: (1) Latency-associated nuclear antigen (LANA), which works on multiple pathways that include inhibiting tumor suppressors p53 and Rb, upregulating the WNT/β-catenin pathway by sequestering the negative regulator GSK-3β, thereby promoting oncogenesis; (2) homologue of FLICE inhibitory protein (vFLIP), which activates NFκB; and (3) viral IL-6, which induces VEGF and cell proliferation.[42]

PEL does not have a characteristic cytological appearance as it can look immunoblastic in morphology or even show Reed-Sternberg cells. It expresses CD45, CD30, CD38, CD138, and MUM1 and does not express other B-cell markers such as CD19 and CD20. Furthermore, a solid variant of PEL exists, where it is morphologically similar but lacks effusions and rather affects tissue such as lungs and lymph nodes instead of cavities. It can also differ immunohistochemically in that approximately a quarter of cases do not express CD45 and do express CD20 and CD3.[21]

Hodgkin Lymphoma

Compared to the general population, HIV-positive individuals are at a 5- to 15-fold increased risk of developing Hodgkin lymphoma (HL). Interestingly, unlike some of the subtypes of NHL, HL is not related to the degree of immunosuppression, with the median CD4 count usually ranging between 150 and 260 at the time of diagnosis. The presence of a low CD4 count still confers a poor prognostic factor, as it increases the risk of opportunistic infections during chemotherapy. The incidence of HL after the introduction of ART has not decreased, with multiple retrospective studies demonstrating an increase in the incidence of HL in the United States and some studies demonstrating the incidence is stable and unrelated to the introduction of HART.

Simard et al. examined records from the HIV/AIDS Cancer Match Study, where they looked at data from over 400,000 cases of cancers in patients with HIV or AIDS between 1980 and 2006, which included 15 states. The data were stratified into three periods: 1980–1989, prior to the introduction of antiretroviral therapy; 1990–1995, when monotherapy or dual therapy began; and 1996–2006, when HAART began. The 5-year cumulative incidence was 0.09 (0.07 to 0.11), 0.15% (0.14 to 0.17), and 0.19% (0.17 to 0.21), respectively, with 95% confidence intervals.[43] Similarly, a prospective cohort by Powles et al. followed 11,112 HIV-positive individuals from the Chelsea and Westminster HIV cohort in London and calculated standardized incidence ratios for various cancers before and after the introduction of HAART from 1983 to 2007. The data gathered included immunosuppression, whether AIDS was present, and the type of antiretroviral therapy. The data were grouped into three categories with the

Downl
15, 202

following SIRs for HL with a 95% confidence interval: 1983–1995 pre-HAART era, 4.45 (1.44 to 10.37);1996–2001 dubbed as the early HAART era, 11.06 (4.78 to 21.80); 2002–2007 established HAART era (i.e., widely available) 32.35 (4.78 to 21.80).[44]

Contrarily, a Swiss nested-control study by Clifford et al. failed to demonstrate the increase in HL incidence following the introduction of HAART. The Swiss HIV Cohort study used a total of 14,606 patients with HIV between the years 1984 and 2007 were included. A total of 47 cases of HL were identified in the analysis, and each of the cases were matched to 10 controls with similar age, calendar period, gender, mode of HIV transmission, and treating center. The risk of HL between 2001 and 2007 was similar to 1984 and 1995. The authors attributed the differences present in other studies to the bimodal age distribution of HL and the prolonged survival conferred by HAART, which lead to a falsely increased incidence.[45] Furthermore, a retrospective cohort study by Kowalkowski et al. reported that the incidence of HL decreased from 2.51 per 1000 to 0.06 in 1000 after 10 years of ART.[46] The authors examined 31,576 HIV patients on HAART from the Veterans Affairs HIV clinical Case Registry between 1985 and 2010, of which 211 cases of HL were identified. Data were collected on patients' age (mean age 45) and year of HIV diagnoses (whether it was pre-HAART prior to 1996, early ART 1996–2001, or late HAART 2002–2010; 71% of HIV diagnoses were made in the late HAART era), ethnicity (62% were non-white), and presence of comorbid conditions. Furthermore, CD4 count and HIV viral load were obtained throughout the study as well; 45% of the patients had a CD4 less than 200 prior to antiretroviral therapy. By the end of the study, 55% of patients had a CD4 count greater than 350, and only 25% of patients had a CD4 count less than 200. Half of the cohort had received antiretroviral therapy for at least an average of 5 years. Of note, patients diagnosed with HL were noted to have been on antiretroviral therapy for a shorter duration of time when compared to patients without a diagnosis of HL for both protease-inhibitor-based therapies and NNRTI based therapies ($P < 0.0001$).

HIV-associated HL is EBV-positive in more than 90% of cases when compared to HIV-negative HL, where only a third of cases are positive for EBV.[47] Patients present at later stages, i.e., stage III or IV, and extra-nodal involvement, where the bone marrow is the culprit in 50% of cases, followed by liver and spleen. HL is classified into nodular-sclerosing, mixed cellularity, lymphocyte-rich, and lymphocyte-deplete. The histological classification of HIV-associated HL does not differ from the standard classification. The predominant subtype between the two populations differs in that for HIV patients, the majority are mixed cellularity comprising between 25% and 55%, followed by lymphocyte-deplete, which comprises between 5% and 20% in comparison to immunocompetent HIV-negative individuals in whom nodular-sclerosing is the predominant subtype in the general population. The lymphocyte-depleted subtype is extremely rare in immunocompetent individuals representing around 1% of all HL cases, whereas 15% of cases are LD for those HIV-positive.[34] Furthermore, EBV appears to play a role in the pathogenesis of the LD HIV+, where it is present in 60% to 72% of patients with the expression of LMP-1, which aids in B-cell survival.[48] The immunohistochemical characteristics largely do not differ in HIV-positive individuals when compared to other HL cases with Reed-Sternberg (RS) stain $CD15^{+}$, $CD30^{+}$, faintly $PAX5^{+}$, $CD45^{-}$, and some RS $CD20^{+}$.[34] Interestingly, in HIV-positive cases, there is a reversal of the CD4:CD8 ratio observed with a predominance towards $CD8^{+}$ cells, which is expected given that HIV leads to $CD4^{+}$ depletion.[49]

Before the introduction of HAART, the prognosis of HL lymphoma in individuals with HIV was poor. This was mainly due to the poor tolerability of the chemotherapeutic agents in the setting of low CD4 counts, which made patients susceptible to opportunistic infections and their sequelae. HL in HIV-positive patients has a similar prognosis when compared to HL in the general population, and the treatment approach is similar. The treatment of choice for HL is dependent on staging, whether there is a recurrence of the HL or if it is refractory to the initial therapy, and, like all treatments, is tailored to the patient. Historically, HL was treated with high penetration X-rays and later with nitrogen mustard in 1946. High dose radiation leads to the development of secondary cancers in later years and direct toxic effects on the bone marrow leading to pancytopenias and/or thyroid, lung, and cardiovascular toxicities.[50] Currently, radiation therapy is still used but at much lower doses and in combination with chemotherapeutic agents. ABVD therapy ± radiation therapy is considered first-line given its efficacy and lower side effect profile. Other chemotherapeutic agents such as BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone), Stanford V (vinblastine, doxorubicin, vincristine, bleomycin, mustard, etoposide, and prednisone), and others are also used with varying results, depending on the staging and response of the patient. In HIV-positive patients, HAART is continued with therapy and typically not discontinued.[51]

T-Cell Lymphoma

Lymphomas derived from T lymphocytes are much less common than B-cell lymphomas and account for 7% of diagnosed lymphomas in the United States. Similarly, in HIV-infected patients, the diagnosis of T-cell lymphoma is relatively rare, with most published reports consisting of case reports or small case series.

Biggar et al. examined data from the AIDS and cancer registry between 1978 and 1996 in 11 states in the US. 10,592 patients with NHL and AIDS were identified. Only 96 cases were identified as T-cell lymphomas representing 1.4% of all HIV-related NHL. The authors used histological diagnoses to identify cases but were given incomplete immunohistochemical records in several cases, which might lead to the underrepresentation of T-cell lymphoma. The cases belonged to the following subtypes: 36 peripheral T-cell lymphomas (PTCL), 35 of mycosis fungoides (1 Sézary syndrome), 13 cutaneous lymphomas, 11 adult T-cell leukemia/lymphoma (ATLL), and 1 angiocentric T-cell lymphoma.[52] Similarly, in the general population, T cell lymphoma is most commonly PTCL followed by mycosis fungoides.[53,54]

A retrospective analysis performed by Arzoo et al. examined 429 HIV-positive lymphomas between 1982 and 2001 at Los Angeles County-University of Southern California Medical Center and the University of Southern California/Norris Comprehensive Cancer Center. 11 patients diagnosed with T-cell lymphomas were identified, and their characteristics were compared to HIV-positive patients diagnosed with B-cell lymphoma. The 11 cases of T-cell lymphoma were diverse: 4 had PTCL, 3 anaplastic large cell lymphoma (ALCL), 1 ATLL, 1 angioimmunoblastic, and 1 enteropathy-associated T-cell lymphoma.

There were similarities and differences between the T-cell and B-cell lymphomas. The median CD4 count at the time of diagnosis did not statistically differ between the two groups (101 for T-cell lymphoma vs. 72 for B-cell lymphoma [$P = 0.54$]), but T-cell lymphoma was more likely to have: (1) bone marrow infiltration (45% vs. 15%, $P = 0.019$), and (2) cutaneous involvement (36% vs. 2%, $P < 0.001$). Of those 11 T-cell lymphoma patients, seven died, six within a year, with a median survival of 10.6 months. Remission was only achieved in four patients: three ALCLs were treated with CHOP (one died after achieving CR for 3.6 months) and one patient received COPE; 1 PTCL was treated with radiation. The enteropathy-associated T-cell lymphoma patient relapsed, and his therapy was ongoing at the time of the study.[55] Clinical significance and conclusions from this study should be interpreted with great caution as the sample size was extremely small and not representative of what is known of the demographics for T-cell lymphoma in prior studies with larger sample-sized as demonstrated by Biggar et al.

Case Illustration

A 50-year-old man from West Africa who immigrated to the United States a decade prior with no known medical history presented to the Emergency Department with profound epistaxis mounting to 3

Downl
15, 202

cups of blood over a day. The patient described night sweats, weight loss, and a non-productive cough for the last month that coincided with the appearance of a right groin mass. As far as his social history, he was retired and married with children. He never smoked tobacco nor used any illicit drugs. His physical exam was notable for tachycardia to 106 bpm, hypotension to 90/60 mmHg, palatal petechiae, bilateral posterior and anterior cervical lymphadenopathy that was more appreciated posteriorly, bilateral submental lymphadenopathy, bilateral inguinal lymphadenopathy and a large right inguinal mass measuring 6 × 4 cm. The right groin mass was mobile, non-tender, non-reducible, and non-pulsatile. The nose-bleeding was well controlled with nasal packing. He received 2 L of lactated Ringer solution along with a unit of 1pRBC, to which he responded appropriately.

Initial Labs

His labs on admission were significant for a hemoglobin of 6.4 for which he was transfused. He also had an lactate dehydrogenase (LDH) of 3194 U/L with normal haptoglobin. His reticulocyte index was 0.64, indicative of hypo-proliferative bone marrow. His B12 and folate were within normal limits, his iron was low at 31 μg/dL with an iron saturation of 17.7%, His total iron binding capacity (TIBC) was low at 175, and his ferritin was over 16,500 ng/mL along with other inflammatory markers (erythrocyte sedimentation rate [ESR] 70 mm/h, C-reactive protein [CRP] 20.4 mg/dL) indicating a mixed picture of anemia due to bleeding and anemia of chronic disease.

Other labs were notable for a white blood cell (WBC) 10.2 with a decreased absolute lymphocyte count of 1.00. His globulin gap was elevated at 4.1 (protein of 6.4, albumin of 2.3). His triglycerides were 491 and AST 127. His HIV-1 came back positive with an initial viral load of 617,916 and a CD4 count of 275. He was also tested for HIV-2, which came back negative. He also tested positive for hepatitis B with a viral load of 1219. His Hep B surface and core antibodies were both negative.

The patient's initial presentation and labs were concerned for uncontrolled HIV with a concurrent opportunistic infection, malignancy such as lymphoma, and a systemic inflammatory syndrome-like hemophagocytic lymphohistiocytosis. (He has an H-score of 174, making the probability of a hemophagocytic syndrome around 54% to 70%.)

Further Diagnostic Laboratory Studies

The patient's EBV PCR was positive greater than 400,000, which raised concerns for lymphoma. Serology for toxoplasma was negative; serum cryptococcal antigen was also negative.

As part of an autoimmune workup, an ANA was negative.

Blood cultures on admission had no growth. The fungal cultures were also negative, as was the beta-D-glucan assay. Bronchoalveolar lavage was negative for both *Pneumocystis jiroveci* (PJP) and tuberculosis. His SARS-CoV-2 PCR was negative.

An ultrasound of his right groin was obtained and unexpectedly showed an incidental finding of an enlarged cystic structure measuring 6.1 × 4.4 × 4.8 cm without vascularity representing a seroma. Given extensive evidence of lymphadenopathy on physical examination, a CT chest, abdomen, and pelvis with IV contrast showed mediastinal, bilateral hilar, bilateral axillary lymphadenopathies, bilateral peri-lymphatic nodularity in the lungs, and a 9 mm right lower lobe nodule with multiple retroperitoneal and inguinal lymphadenopathy, and mild splenomegaly. The liver also had two punctate hypodensities in the posterior right hepatic lobe. A brain MR for staging was unremarkable. A positron emission tomography (PET) scan showed diffuse splenic uptake suspicious of lymphomatous involvement. There was also multifocal fluorodeoxyglucose (FDG) avid cervical, abdominopelvic, and extremity lymph nodes consistent with prior findings of lymphadenopathy described above.

The patient underwent an excisional biopsy of the right-inguino-femoral lymph node, which confirmed the diagnosis of diffuse large B-cell lymphoma, not otherwise specified; non-germinal center type, with a "double expressor" phenotype.

The lymph node's architecture was completely effaced and mainly consisted of an infiltrate of medium-large-sized lymphocytes. The lymphocytes stained positive for CD20, PAX5, MUM1 (>90%), BCL-2 (>90%), and c-myc (~60%). The immunohistochemical staining was negative for CD10, BCL-6 (~20%, p53, and Epstein-Barr virus-encoded RNA (EBERs). The sample had an elevated proliferation fraction Ki67 (>90%). Based on the Hans algorithm, which has high concordance with gene-expression profiling, the DLBCL-NOS is classified under the non-germinal center type, traditionally indicative of poor response to R-CHOP. Furthermore, the positive c-Myc and BCL-2 classify the lymphoma under the "double expressor" phenotype, also considered a poor prognostic factor.

The cytogenetic analysis showed t(14;18) with associated IGH-BL2 gene rearrangement, consistent with DLBCL. Furthermore, an unbalanced t(8;17) with loss of 8p and 17p (site of TP53) was also observed, another poor prognostic factor. The patient did not have a BCL6, MYC, or MYC-IGH rearrangement and no PAX5 gene rearrangement either.

Bone marrow biopsy confirmed extra nodal involvement with cellularity greater than 90% (expected cellularity for the patient's age is around 50%) with nodular aggregates of medium to large-sized lymphocytes with irregular nuclei and prominent nucleoli and abundant eosinophilic cytoplasm which were CD20$^+$, Pax5$^+$, CD79a$^+$ but negative for CD34, CD118. LMP1 stain was equivocal (EBV proto-oncogene), LANA (HHV8) negative. The cytogenetics were identical to the ones observed in the lymph node biopsy. The liver biopsy was negative for lymphomatous involvement and unremarkable. Biopsy of the terminal ileum, sigmoid, and rectum showed atypical lymphoid infiltration consistent with B-cell lymphoma at the terminal ileum. Immunostaining was positive for CMV and negative for EBERs.

Management

The patient was initiated on HAART starting with Biktarvy (bictegravir, emtricitabine, and tenofovir alafenamide) with entecavir to treat concomitant hepatitis B. Prior to the initiation of chemotherapy, the patient had a lumbar puncture, where there were no malignant cells in the CSF. He received intrathecal methotrexate prior to the initiation of his chemotherapy for CNS prophylaxis. Over the span of 2 months, his HIV viral load decreased from 617,916 to 344. His hepatitis B viral load became undetectable with treatment, but his CD4 count decreased from 275 to 100.

Given his HIV-1-related immunosuppression and further immunosuppression with lymphoma treatment, the patient was started on Bactrim for PJP prophylaxis, valacyclovir for EB viral prophylaxis, and fluconazole for fungal prophylaxis. The patient developed transaminitis requiring discontinuation of Bactrim and fluconazole and was started on atovaquone instead for PJP prophylaxis. His DLBCL was treated with prednisone which was complicated by CMV viremia to 9036; this was treated with a 3-week-course of ganciclovir. His repeat CMV viral load prior to discharge was 170.

He received two cycles of EPOCH as an inpatient for his DLBCL. This was complicated by neutropenia requiring G-CSF. His EBV viral load was undetectable prior to discharge. The patient was discharged with plans to follow up as an outpatient but unfortunately was lost to follow-up.

Systematic Approach to Lymphadenopathy

Given the example case before, lymphadenopathy is very common in HIV-infected patients and has a broad differential diagnosis in this population. Like TB, lymphomas are typically characterized by lymphadenopathy and constitutional symptoms: weight loss, night sweats, and fevers. Certain lymphomas within the HIV population are almost exclusively present in immunocompromised individuals, such as AIDS-defining primary CNS lymphoma, while other

Downl
15, 202

non-AIDS defining lymphomas such as Burkitt lymphoma are present irrespective of the CD4 count.

Development of lymphadenopathy could be part of HIV, a sign of an opportunistic infection, or even lymphoma. As with CVID patients, lymphadenopathy is relatively common and most likely *not* lymphoma. Even deciding when to biopsy can be very difficult. A more complete set of different etiologies to consider are infectious, including HIV itself, inflammatory (including autoimmune, reaction to drugs), and neoplastic. Lymphadenopathy from drugs can be confounding as drugs that are used in treating opportunistic infections in HIV can cause them. Examples are drugs in the sulfonamides class, such as sulfamethoxazole used in combination with trimethoprim for PJP prophylaxis and pyrimethamine used in the treatment of toxoplasmosis. Even though lymphadenopathy occurs commonly in non-HIV-infected people, there are special circumstances to certain etiologies within the HIV population.

HIV itself can cause lymphadenopathy during the acute viral illness or an exacerbation, and it typically manifests as posterior cervical lymphadenopathy that is symmetrical in nature, often accompanied by diarrhea, myalgias, night sweats, and fevers, all of which are very similar to the presentation of lymphoma. The clinical syndrome can also mimic infectious mononucleosis. Acute HIV is more likely to present with painful mucocutaneous ulcers, whereas infectious mononucleosis presents with exudative tonsillitis covered in a white pseudomembrane, which is usually absent in HIV. Chronic HIV can also cause "persistent generalized lymphadenopathy" in asymptomatic individuals with declining CD4 counts due to viral replication, which can be further classified histologically as either acute/early, intermediate/chronic stage, or advanced/burned out stage. Once the CD4 is less than 200, one can see a worrisome paradoxical regression of the lymphadenopathy.

Declining CD4 counts put individuals at risk of developing OI, malignancy, or lymphoma, and they all typically present with similar constitutional symptoms and further cloud the clinical picture. Prioritizing the differential will depend in part on geography. For example, an HIV-positive patient in the absence of risk factors in the United States is less likely to have *Mycobacterium tuberculosis* infection when compared to a patient in Uganda. A multi-centered retrospective cohort study by Bogoch et al. examined 107 peripheral lymph node biopsies in multiple centers in Boston, where malignancy comprised 42.9%, and tuberculosis (TB) was less than 3% of the cases.[56] Unfortunately, in low-income countries, this can lead to a misdiagnosis of TB and a delayed diagnosis of lymphoma. The delay in diagnosis could be attributed to the lack of resources, equipment, and skills needed for a diagnostic biopsy. Buyego et al. retrospectively reviewed 183 charts of HIV-positive patients diagnosed with lymphoma in the Uganda Cancer Institute, of which a third were initially started on TB treatment for a median of 3.5 months prior to the diagnosis of lymphoma.[57]

The most common opportunistic infection worldwide is scrofula presenting as painless cervical lymphadenopathy caused by TB, which can present with almost normal CD4 counts. HIV infection increases the risk of TB by 20-fold when compared to the general population.[58] This is primarily attributed to the decline in CD4 counts, which normally, upon activation, release cytokines such as interferon-gamma and IL-12 responsible for eliciting the immune response to eradicate intracellular pathogens such as TB.[59] The clinical importance of this response is demonstrated by Mendelian susceptibility to mycobacterial diseases (MSMD), rare immunodeficiency syndrome characterized by deficiencies in IL-12 or Interferon-gamma receptors leading to increased susceptibility to TB, and even mycobacteria of low virulence such as the ones contained in the BCG vaccine.[60] Other infections causing lymphadenopathy include Infectious mononucleosis, disseminated *Mycobacterium avium* complex, cytomegalovirus, secondary syphilis, toxoplasmosis, *Bartonella henslae*, leading to bacillary angiomatosis, and acute EBV. When CD4 counts start dropping below less than 200 one begins to think of *Candida*, *Aspergillus*, and, although rare to present with lymphadenopathy, *Pneumocystis* (PJP w/ PNA) can also have hilar and mediastinal lymphadenopathy. When the CD4 counts drop even lower, the differential broadens further to include *Histoplasma capsulatum* and *Cryptococcus neoformans*.

Rare causes of lymphadenopathy can also be non-infectious and non-neoplastic in etiology. These conditions can affect immunocompetent individuals and include Kimura disease presenting as painless lymphadenopathy in the head and neck with a predilection for Asian males in their late 20 s or early 30 s; Kikuchi necrotizing lymphadenitis, which predominantly affects young women, and Castleman disease, which in the HIV-population, is a lymphoproliferative disorder with two histological categories that encompass the hyaline-vascular type and plasma-cell type. The hyaline-vascular type has a lymphoid subtype variant identified by mantle zone hyperplasia (i.e., lymphocytes surrounding the germinal center), which is potentially mistaken for malignant follicular lymphoma or mantle cell lymphoma. The clinical classification of Castleman can be further subdivided into unicentric and multicentric. Unicentric: involves one lymph node most commonly located in the mediastinum, is less likely to present with constitutional symptoms, and in the majority of cases happens to be classified under hyaline-vascular histological subtype. It is curable with surgical excision. On the other hand, a multicentric form of Castleman disease (systemic subtype) carries a poor prognosis and presents with generalized lymphadenopathy and sometimes splenomegaly along with constitutional symptoms. Histologically, multicentric Castleman disease (MCD) falls under the plasma cell type, and ever so rarely under the hyaline-vascular histological subtype, hence the interchangeability of the terms "multicentric" and "plasma cell type." Unlike the unicentric subtype, it is managed by a combination of immunotherapy, steroids, and sometimes chemotherapy. MCD is further classified as HHV-8–positive and HHV-8–negative. HHV-8+ MCD is found at a higher prevalence in HIV-positive patients when compared to HIV-negative patients. Within the HIV population, MCD tends to almost always associate with HHV-8. Production of IL-6 by the HHV-8 virus is believed to lead to its pathogenesis. Some cases have concurrent Kaposi sarcoma, one of the AIDS-defining cancers where HHV-8 is integral for its oncogenesis.[61,62] These causes of lymphadenopathy remain relatively uncommon within the HIV population; however, they contribute to a comprehensive differential.

Although there are certain characteristics of imaging that may help guide the clinician in discerning the etiology of the lymphadenopathy, it should be taken into the clinical context of the patient, that is, whether well controlled on HAART with very low viral load, and adequate CD4 count. Most cases are often biopsied to reach a diagnosis. There are different imaging modalities one can use: ultrasound (US), magnetic resonance imaging (MRI), computed tomography (CT), and positron emission tomography (PET).

Normally the lymph node consists of an outer layer, the capsule which covers the cortex (B cells and follicular dendritic cells), followed by the paracortex (T-cells rich), then the most inner part, the medulla (lymph sinuses, arteries, and veins), and the hilum from where vessels enter and exit. On imaging, normal lymph nodes are less than 1 cm, homogenous, have well-defined borders, and have a smooth contour. Benign lymph nodes also have a central fatty hilum that can be appreciated on CT and MRI.

When assessing a lymph node, consider location, size (abnormal is typically greater than 1 cm), shape, consistency, adherence, and tenderness to help in the differentiation of benign and malignant. Normally tenderness signifies a rapid increase in size, causing the pain receptors in the capsule to be activated, which usually happens from inflammatory processes. However, tenderness does not exclude malignancy, given tenderness can be from necrosis or hemorrhage into the lymph node. If the lymph node is large and painless, then that raises the index of suspicion.

For lymph nodes that are on the surface, an ultrasound is an inexpensive test that can give information and help in guiding the biopsy. This is most applicable to the commonly present cervical lymphadenopathy. Lymph nodes of the head and neck are normally less than 0.8 cm in size. The outer cortex appears hypoechoic due to the presence of lymphoid follicles, whilst the medulla is hyperechoic. The long-to-short axis ratio of less than two is abnormal, meaning that a normal lymph node will become more round than oval. This happens during malignancy or in TB. An oval lymph node does not exclude malignancy, as early in the course the lymph node still retains

Downl
15, 202

its oval shape. There are also anatomical exceptions to this, as parotid lymph nodes are normally round. The presence of cortical thickening with asymmetry and ill-defined borders is pathological for malignancy. Color flow or power doppler is a mode in the United States that can help in evaluating the vascularity of the lymph node. One would expect the hilar to have flow based on the anatomy. Lack of flow in the hilum is pathologic in addition to the presence of peripheral vascularity, although this can be present in both malignant and inflammatory processes. The lymph node will look more heterogeneous than homogenous.

The lack of certain findings or presence of others is insufficient to distinguish lymphomas from reactive lymph nodes secondary to inflammatory etiologies such as Kikuchi disease, TB, and sarcoidosis from metastatic lymph nodes. Therefore, a biopsy is almost always indicated, and starting with an ultrasound (US)-guided fine-needle aspiration is helpful in excluding metastatic disease (to be discussed in further detail). However, fine needle aspiration is sub-optimal for diagnosing lymphomas, and a larger screwcut or excisional biopsy is needed if an excisional biopsy is not possible or appropriate.

The biggest limitation of US imaging is its inability to access cavitary and retroperitoneal lymph nodes, which are often present in HIV. These lymph nodes are best accessed using cross-sectional imaging modalities discussed below.

Years ago, prior to the introduction of cross-sectional imaging, conventional lymphangiography was used to assess lymph nodes, most commonly in Hodgkin disease. At the foot between the toes, an oil-based contrast is injected. Images are obtained after the procedure to visualize the lymphatic system and lymph nodes; the dye remains in the node for months-years and allows for follow-up imaging after treatment. The major complication is pulmonary oil embolism which can cause symptoms; cardiopulmonary disorders, which are contraindication. Advancements in MR, CT imaging, and positron emission tomography have rendered this obsolete.

The pathological findings of lymph nodes in MR and CT imaging overlap with US findings. The size, shape, borders, and absence or presence of central necrosis and calcification are some of the characteristics used in assessing the suspicious lymph node. Contrast is used with the CT scan to evaluate for enhancement, i.e., infectious lymphadenopathy tends to have peripheral enhancement with perinodal inflammation and central hypoattenuation compared to metastatic disease, which presents with central hypoattenuation alone in comparison.

In MR, the differences in T1 and T2 signaling aid in the characterization of lymph nodes. For example, in Castleman disease, lymph nodes are T1 hypointense compared to muscles and T2 hyperintense with a linear T2 hypo-intensity that correlates with fibrosis. The use of gadolinium-contrast characterizes flow kinetics, blood volume, enhancement kinetics, and microvascular permeability. Diffusion-weighted MRI can also be useful in differentiating between benign and malignant lymph nodes, where the diffusion coefficient is decreased in malignancy.

Ultimately, imaging alone is not enough to make the diagnosis but instead complements the findings of the biopsy. Imaging can help in providing the lymph node needed for the highest yield, usually the largest one. Inguinal and axillary lymph nodes are often not biopsied, as they are more often reactive and will not provide the diagnosis. The gold standard is an excisional biopsy with preserved architecture is preserved and allows for a diagnosis of lymphoma and its classification. Starting with a fine needle aspiration can diagnose metastatic carcinoma if this is suspected.

In half of the cases, a cytologic diagnosis of lymphoma can be made based on morphology alone. A core biopsy helps with architectural evaluation; however, it has "compression artifacts" meaning that cells may appear smaller and nuclei can appear darker when compared to the gold standard. This, along with sending the aspirate for flow cytometry immunophenotyping and immunohistochemical staining of the sample, helps in making the diagnosis. However, this may not be enough in a third of the cases, and an excisional biopsy is required. FNA may later be used for disease surveillance post-treatment.

The pattern of inflammatory etiologies can be divided into follicular/nodular versus interfollicular/paracortical. The former is not neoplastic and is where reactive follicular hyperplasia, Castleman disease, kimura, and rheumatoid lymphadenopathy fall. Interfollicular is further divided into three categories: diffuse, sinus, and mixed. Lymphoma can have an interfollicular or diffuse pattern, and so do viral etiologies like EBV, CMV, and drug sensitivity reactions. Infections that can present in a mixed pattern are toxoplasmosis and cat-scratch disease caused by *Bartonella henselae*. Granulomatous lymphadenitis also appears in a mixed pattern and is subdivided into infectious and non-infectious etiologies. Tuberculosis, tularemia, and later stages of *Bartonella henselae* can present in this manner. Non-infectious would be sarcoidosis or any sarcoid-like etiology, including CVID.

Also, in reactive follicular hyperplasia, the normal anatomy of the lymph node is preserved. The follicles are more prominent in the cortex with a lot of variation in size and shape. There should almost be no inflammatory cells present in the capsule or the fat covering the capsule. One can appreciate follicles with reaction centers. This is not the case in follicular lymphoma, where the normal architecture of the lymph node is effaced, no prominence of the follicles is appreciated, and they are equally distributed between the capsule and medulla without variation in size or shape and appear faded rather than reactive.

Summary

Lymphadenopathy in HIV is common, has a million etiologies, and not rarely can be malignant. Multiple studies (blood tests, imaging, and biopsies) are often needed to resolve the differential diagnosis. Considering the patient context is important to limit the differential at least initially.

HUMAN IMMUNODEFICIENCY VIRUS AND THROMBOSIS

There is an estimated 2- to 10-fold increased risk for venous thrombosis (VT)[63] and 2-fold increased risk for myocardial infarction in the HIV population[64] when compared to the general population. Traditional risk factors for both HIV-infected and uninfected populations are well studied for both types of thromboembolic events (TEE). Arterial thromboses commonly include coronary artery disease (CAD) and cerebrovascular accidents (CVAs), which are often related to hypertension, diabetes, and dyslipidemia. Other less common TEE include acute mesenteric arterial occlusion and embolism to the lower extremities. Venous thrombosis follows the Virchow triad: stasis of blood flow from immobilization due to surgery, hospitalization, or long flights; endothelial damage attributed to oxidative stress either from chronic inflammation or direct trauma such as the case in intravenous drug use or venous catheter placement; and hypercoagulability from inflammation related to active infection or infection, genetic predispositions such as factor V Leiden, or acquired causes in the cases of protein C and/or S deficiency. When it comes to the above-mentioned traditional risk factors, HIV patients are more likely to be hospitalized for either malignancy and/or infection when compared to the general population, given the chronic state of immunosuppression. Other risk factors for VTs in HIV infections stem from the ongoing chronic inflammation leading to endothelial damage from oxidative stress; acquired deficiencies for protein S, antithrombin, and heparin cofactor II; increases in pro-coagulant tissue factor, D-dimer, and von Willebrand factor; and production of antiphospholipid antibodies. As for arterial thrombosis, a combination of dyslipidemia from antiretroviral medication, ongoing inflammation, and endothelial damage increases the risk for cardiovascular disease in this population. This will be discussed in greater detail below.

Markers of inflammation and activation of coagulation are elevated in uncontrolled HIV and, to a lesser extent, even in well-controlled HIV (viral load undetectable) when compared to the

Downl
15, 202

general population. Those markers include interleukin-6 (IL-6), high-sensitivity C-reactive protein (where hsCRP differs from CRP in that it detects values below 0.3 mg/L, whereas CRP only detects up to 3 mg/L), D-dimer, and release of tissue factor from activated monocytes thereby conferring an increased risk of thrombosis. Furthermore, elevated D-dimer levels in particular, have been correlated with all-cause mortality in the HIV population, as described below.

The Strategies for Management of Antiretroviral Therapy (SMART) Study group published a landmark non-blinded randomized trial, $CD4^+$ Count–Guided Interruption of Antiretroviral Treatment, which demonstrated the importance of continuous ART in the management of HIV when compared to intermittent ART use. The rationale behind the study was to determine whether intermittent use increased the quality of life of patients by reducing adverse effects related to medication side effects and to try to decrease the division of multi-drug resistant HIV so that the wild type prevailed. SMART recruited a total of 5472 participants with a CD4 count above 350/mm^3; the study took place between January 2002 and January 2006. The participants were randomly assigned to a drug conservation (DC) group versus viral suppression (VS) group and approximately a quarter of the participants were followed for more than 2 years. In the DC, ART was started once the CD4 count was below 250 or HIV-related infections occurred, or the CD4 comprised less than 15% of the total lymphocyte count. ART was subsequently discontinued once the CD4 count reached 350 and resumed as above. Contrarily, the VS group remained on ART indefinitely. The primary outcome measure was the development of an opportunistic infection or death. Secondary outcomes were the occurrence of a major cardiovascular event and the development of renal or hepatic disease. The study was terminated by an independent data and safety monitoring board, given the lack of benefit in the DC group when compared to the superior outcomes of the VS group, in addition to the increased risk of death (84%, $P < 0.001$). Participants who were in the VS group were less likely to acquire an opportunistic infection and die from other causes, i.e., cancers, cardiovascular disease, and opportunistic infections. Furthermore, the risk of episodes of major events including cardiovascular, renal, and hepatic disease, was higher in the DC group, which is counterintuitive when thinking of the ART side effects profile. This was further demonstrated when accounting for CD4 count in the VS group, where individuals with higher CD4 count were at a lower risk for experiencing major events, thus shedding light on confounding factors such as degree of immunosuppression and ongoing viral replication that may have contributed to major events initially thought to solely be related to medication side effects.[65]

Kuller et al. launched a nested case-control study using stored blood samples from the SMART group study measuring biomarkers of inflammation and thrombosis correlating them to mortality in addition to a study comparing the differences in biomarkers between the DC and VS groups. They hypothesized that viral replication resulted in activation of coagulation and inflammation and that this was associated with an increased risk of all-cause mortality. For the nested case-control study, plasma samples were from 85 deceased participants, who were matched to 170 patients (1:2 matching). Levels of hsCRP, IL-6, and D-dimer at entry were significantly higher amongst the deceased when compared to matched controls. This difference remained statistically significant when looking at the latest obtained plasma levels prior to death as well. The association was strongest for IL-6 and D-dimer for all-cause mortality. For the comparison of inflammatory markers between the DC and VS groups, 499 participants were enrolled, 249 and 250 respectively. Similarly, baseline plasma levels were obtained, followed by levels at 1 month. At baseline, D-dimer was found to be higher in those not taking ART when compared to those with ART with either a viral load below or more than 400 copies/mL. At 1 month, those in the DC group had significantly higher IL-6 and D-dimer levels. Increases in IL-6 and D-dimer were positively correlated to HIV-RNA levels. hsCRP differences between DC and VS groups were not significant. The authors concluded that IL-6 and D-dimer were associated with all-cause mortality and that inflammatory markers were increased in those not taking ART and in participants with high viral replication.[66]

When compared to HIV-negative individuals, increases in inflammatory markers persisted irrespective of the presence of comorbid diseases in HIV-positive individuals. Armah et al. measured IL-6, D-dimer, soluble CD14 (sCD14, marker of monocyte activation) in 1525 HIV-positive and 843 HIV-negative individuals in plasma between 2005 and 2006 obtained from the Veteran Aging Cohort Study, a prospective observational cohort of HIV-positive veterans matched to HIV-negative veterans based age, race, and location. Within the cohort, HIV-positive veterans were more likely to be younger, male, have dyslipidemia, have a hepatitis C co-infection, and smoke. They were less likely to be using a lipid-lowering medication, have cardiovascular disease, renal disease, uncontrolled hypertension, diabetes, obesity, and have a self-reported drinking problem. When adjusting for age and race between the two groups, no significant differences between IL-6, D-dimer, and sCD14 were noted. However, when adjusting for viral copies above 500 copies/mL or CD4 counts below 200, i.e., uncontrolled HIV, IL-6 and D-dimer were significantly higher in the HIV-positive group. Furthermore, when only adjusting for CD4 counts below 200, a significantly higher sCD14 was found, signifying a higher monocyte activation in the immunosuppressed group. This correlation persisted when samples were selected for veterans without comorbid conditions, problematic drinking, or smoking, which emphasizes the role of ART in reducing the viral load and increasing the CD4 counts as a strategy to ameliorate the underlying inflammatory response, thus reducing mortality.[67]

In a randomized comparison, Baker et al. investigated the effects of initiating ART on IL-6, D-dimer, and hsCRP in a subgroup of participants from the SMART study who were either therapy naïve or off ART for 6 months or longer prior to randomization. This included 126 and 128 participants in the DC and VS groups, respectively. The VS group immediately started ART, whereas only 1.6% at 2 months and 10.3% of DC participants were placed on ART. Inflammatory markers were measured at baseline, 2 months, and 6 months. The reduction in D-dimer levels in the VS group compared to the DC were significantly lower, where the VS group had a reduction of 21.7% and 32.2% at 2 and 6 months, respectively. Furthermore, D-dimer levels in the VS group were significantly lower with time (0.40, 0.27, 0.24 µg/mL at 0, 2, and 6 months respectively), with the most substantial reduction observed in those achieving viral levels below 200 copies/mL (i.e., viral suppression). This was not observed with IL-6 and hsCRP, where the two groups were similar, and no statistically significant reductions were observed with the initiation of ART. Not all participants achieved viral suppression at 6 months, and perhaps a longer observation period would be needed to observe a significant change in IL-6 and hsCRP in response to ART.[68]

The chronic inflammation, CD4 depletion, and ongoing viral replication in untreated HIV or ongoing at low levels while on AART all contribute to a net pro-coagulant effect that directly involves the coagulation cascade, the endothelium, and aberrantly activated monocytes that release tissue factors. In addition to monocytes, other sources of tissue factor include endothelial cells, platelets, and microparticles. It is hypothesized that monocytes are activated by lipopolysaccharides (LPS) released by translocated gut bacteria. The activated monocyte then releases TF, which then activates the extrinsic clotting pathway leading to thrombin (and thrombus) formation. The early stage of HIV infection results in CD4 depletion, which occurs markedly in mucosal tissues that include the gastrointestinal tract. The reduction in antimicrobial barriers in mucosa leads to further damage in the GI mucosa, compromising the tight epithelial junctions that prevent the translocation of bacterial products, such as LPS, which is produced by gram-negative bacteria leading to monocyte activation.[69,70] Brenchley et al. published their proof of this through a series of collected data on HIV-infected and non-infected individuals and in vivo experiments on SIV-infected macaques. First, the authors confirmed that chronically HIV-infected individuals had elevated LPS when compared to participants without HIV ($P < 0.0001$) and also noted that newly infected HIV participants did not have this increased LPS—theorized to be from the immune system's ability to neutralize LPS at the initial stages of infection. Second, they demonstrated a similar increase in macaques, where LPS was measured at baseline prior to

Downl
15, 202

being inoculated with simian immunodeficiency virus and measured the levels at day 100 after infection. Third, to prove that the source of LPS was a result of gut translocation, the macaques underwent a 2-week antibiotic course to deplete the gut from bacteria. This was followed by subsequent LPS measurements in the serum along with measurement of bacterial fecal load, which showed a decrease in both parameters. At week 2, the antibiotics were no longer effective in suppressing the gut bacterial load, which was evident by the increase in the bacterial load in fecal samples and the concurrent increase in the measured LPS in the plasma. Next, an in vivo experiment was conducted to prove that LPS activated monocytes. Monocytes are known for secreting sCD14 and IL-1 in response to LPS released by bacteria in infections. Hence, plasma sCD14 levels were measured and correlated significantly with plasma LPS levels ($r = 0.3$, $P = 0.001$). Individuals with acute and chronic HIV, whether well-controlled or with AIDS, had higher levels of sCD14 when compared to HIV-negative individuals ($P < 0.0001$). To prove that this correlation with LPS was not confounding, a second marker LPS-binding protein was measured. LPS stimulates the release of LPS-binding protein from gastrointestinal epithelial cells and is released by gastrointestinal epithelial cells and hepatocytes. Similar to sCD14, LPS-binding protein was increased in those with HIV infections when compared to non-infected individuals ($P = 0.0099$), and similar to LPS, it correlated positively with sCD14 levels ($r = 0.44$, $P < 0.0001$).[70] LPS activation of monocytes leading to tissue factor (TF) production and coagulation activation was demonstrated in humans by Funderburg et al., where mononuclear cells were isolated using flow cytometry from blood collected from 19 non-infected donors (control) and 60 HIV patients[71] and incubated with LPS, flagellin, and IL-6. TF activity was then measured along with levels of D-dimer. Prior to incubation, when compared to non-infected donors, HIV-infected patients stratified by VL load of greater than 400 copies/mL and VL less than 400 had a higher median percentage of monocytes expressing surface TF (11%, 45.4%, 26.8%, respectively; $P < 0.001$). Exposure to bacterial LPS and flagellin showed an increase in surface expression of TF on monocyte, while IL-6 failed to show such an increase. D-dimer plasma levels were higher in HIV patients when compared to controls and correlated positively with monocytes expressing TF ($r = 0.37$, $P = 0.007$). However, correlation does not equal causation, as D-dimer is known to be elevated in pro-inflammatory states, and it is difficult to ascertain the applicability of the above-mentioned data in vivo without eliminating confounders.

Protein S deficiency is the most commonly found coagulation abnormality in individuals with HIV, where 65% of individuals are found to have varying degrees of deficiency. Protein S deficiency can be categorized into different types: Type I, a quantitative deficiency meaning a decrease in the total and free protein S antigen; Type II, a functional deficiency meaning the level of the total and free protein S antigen are normal, but the activity is decreased; and Type III, which is the most commonly encountered in HIV, where the total levels of the protein are normal, but the levels of the free active form are reduced thereby conferring a functional deficiency.[63] The levels also correlate with the CD4 count, where CD4 less than 200 correlates with lower levels of the active form. In healthy individuals, protein S is synthesized in the liver; 40% of it circulates free (not bound to C4b binding protein) in the plasma, whereas the remainder is inactive because it is bound to C4b-binding protein complex—a protein within the classical and lectin complement pathways that inhibits the complement system, and is an acute-phase reactant. Free protein S functions as a co-factor for protein C and forms an activated cell-surface complex that inactivates factors Va and VIIIa, thus limiting coagulation. Many factors could contribute to protein S deficiency. One is decreased synthesis by the liver, but the primary one is HIV infection in response to inflammation with the increased C4bBp reducing the amount of free protein S. There can also be concurrent malnutrition or hepatitis C co-infection, production of anti-protein S autoantibodies, ongoing consumptive coagulopathy in the setting of infection or malignancy, or binding to microparticles that are released during apoptosis of T cells, activation of monocytes, or any cell necrosis.[72,73]

Compared to protein S, the prevalence of protein C deficiency in HIV is not well established in published reports in which it ranges from 0% to 14%. One study found a prevalence of 7% for protein C deficiency compared to 32% for protein S deficiency in HIV-positive individuals with known VTE.[74] Proposed mechanisms are similar in that there is decreased synthesis, presence of inflammation, that is, opportunistic infections, and low-grade consumptive coagulopathy.[75]

Other less elucidated deficiencies that have been observed in HIV patients include antithrombin and heparin cofactor II deficiencies. Acquired antithrombin deficiency is thought to result from decreased synthesis by the liver (from malnutrition, nephrotic syndrome, or protein-losing enteropathy) or consumptive states, that is, DIC; antithrombin in protein C is made in endothelial cells and has a much longer half-life (20 hours) compared to that of protein S (4-hour serine protease inhibitor that irreversibly inactivates thrombin factor IIa), IXa, Xa, XIa, XIIa, and VIIa. Heparin cofactor II is a thrombin inhibitor and is seen primarily in HIV patients with CD4 counts below 200 and is thought to be related to degrees of immunosuppression.[72,73,76] This was measured by Toulon et al., where levels of heparin cofactor activity were measured in 96 HIV-positive patients and compared to 96 age-matched controls. 38.5% of HIV-positive samples were found to be deficient when compared to 2.1% in the age-matched controls.[77] Heparin cofactor II deficiency alone is insufficient for causing thromboembolic events based on case reports in homozygous and heterozygous heparin cofactor deficiencies and can be a normal variant in healthy subjects.[78]

Patients with HIV have been found to have increased levels of von Willebrand factor (vWF), a marker for endothelial damage likely the result of ongoing inflammation, oxidative damage, and increased T cell activation.[79] vWF is a glycoprotein made and released by the endothelium cells and stored in Weibel-Palade bodies and alpha-granules in platelets, where it (1) aids in platelet aggregation and adherence to the endothelium, (2) binds to factor VIII, thereby stabilizing it for clot formation. The highest levels of vWF are seen in HIV patients with lower CD4 counts and/or high viral loads, whereas HAART keeps vWF levels lower, as demonstrated by Aukrust et al., who examined 43 HIV patients in Norway. Plasma levels of vWF were negatively correlated with CD4+ counts ($r = -0.54$, $O < 0.001$) and correlated positively with viral load ($r = 0.52$, $P < 0.01$). Twenty of the 43 patients were followed for a median of 5 years. Of the participants, 50% developed AIDS and were classified as "disease progressors" with CD4 less than 50, and 50% had CD4 counts above 100 and were classified as "slow progressors". At baseline, both groups did not differ in CD4 count at the beginning of the study, nor did they differ in vWF levels; however, "disease progressors" showed a marked increase in vWF during the study period, whereas the "slow progressors" had stable levels of vWF throughout. Furthermore, levels of vWF were examined prior to and after the initiation of HAART in 15 patients at 12 and 26 weeks of therapy, where a significant decrease in plasma vWF in all the patients was observed and also correlated with a maximal decrease in viral load ($r = 0.67$, $P < 0.01$).[80] These findings of higher VWF are all consistent with more active, less well-controlled HIV disease.

Platelets in HIV-positive patients also have a role in the increased risk of thrombosis and plaque formation leading to cardiovascular events as they tend to show greater activation when compared to people without HIV. HIV-1 directly binds to fibronectin found on the surface of platelets via gp120.[81] Activated platelets express P-selectin, an alpha granule glycoprotein, which binds to its corresponding receptor P-selectin glycoprotein ligand-1 (PSGL-1) found on the endothelium and surfaces of leukocytes, thereby facilitating adhesion and migration for clot formation. Mayne et al. isolated platelets from 46 HIV-positive patients and 18 healthy controls and, using flow cytometry, measured the proportion of platelets and microparticles expressing surface P-selectin. Compared to controls, 17.3% of HIV-positive patients were found to express surface P-selectin compared to 1.1% of healthy controls ($P < 0.001$). Furthermore, patients with detectable viremia were more likely to express surface P-selectin compared to those with an undetectable viral load (23.3% vs. 12.5%, $P = 0.022$).[82]

Abacavir, a guanosine-analog NRTI associated with hypersensitivity in individuals with HLA-B*5701, has been also associated with an increased risk for myocardial infarctions for those who were recently exposed to the drug (RR, 1.70 [95% CI, 1.17–2.47]) related

Downl
15, 202

to increased platelet activation.[83] This was demonstrated in vitro by Satchell et al. in a prospective cross-sectional study in Ireland that included 120 patients. Forty of the patients were therapy naïve, forty were on antiretroviral therapy that included abacavir, and forty were on antiretroviral therapy without abacavir. Blood samples were collected and tested for other parameters used in matching that included low-density lipoprotein (LDL), high-density lipoprotein (HDL), total cholesterol, triglycerides, fasting glucose, and creatinine. Platelet reactivity was determined using four different agonists at different concentrations and included: adenosine diphosphate (ADP), collagen, epinephrine, and thrombin receptor-activating peptide (TRAP), where platelet aggregation was determined using light absorbance measured at 3-minute intervals over 21 minutes. Different light absorbances were then translated into percentage aggregation. There was no statistical difference in platelet aggregation appreciated when comparing the ART-naïve group to those who received ART as a whole. Interestingly, the abacavir-ART group had statistically significant greater platelet reactivity when compared to those receiving ART without abacavir (ADP, $P = 0.001$; collagen, $P = 0.008$; epinephrine, $P = 0.002$; and TRAP, $P = 0.078$). The mechanism underlying the observed increased risk of myocardial infarctions is hypothesized to be due to competitive inhibition of soluble guanylate cyclase (sGC)—normally activated by nitric oxide—by the active form of abacavir, carbovir triphosphate; where sGC is needed for the production of cGMP and activation of downstream intracellular protein kinases responsible for vasodilation and inhibition of platelet aggregation.[84]

OI have a weak association with an increased risk of venous thromboembolism (VTE) in patients with HIV when compared to HIV patients without opportunistic infections in a retrospective cross-control study, especially in those with cytomegalovirus (OR 18.89, 95% CI 2.074 to 172.013, $P = 0.003$), both *Mycobacterium tuberculosis* and *Mycobacterium avium-intracellulare* (OR 3.71, 95% CI 1.06 to 12.96, $P = 0.07$), and in those with more than one lifetime opportunistic infection (OR 3.927, 95% CI 1.447 to 10.657, $P = 0.008$).[85] CMV is known to directly infect endothelial cells possibly leading to the activation of the coagulation cascade.[75] Of note, the patients included in the study citing the weak associations above had a statistically significant difference in the Nadir CD4 count (40 in the VTE arm vs. 250 in the control arm, $P = 0.0003$). This raises the question of whether the presence of OIs is a confounding factor, as CD4 count is an established risk factor for the development of VTE and likely accounts for the wide confidence intervals presented by the data above.

Patients with AIDS have antiphospholipid antibodies in the great majority of cases, specifically lupus anticoagulant and anticardiolipin; whether this contributes to an increased risk of VTE and arterial thrombosis remains controversial, as do many studies of anti-phospholipid antibodies. Lupus anticoagulant is associated with thrombosis in systemic lupus erythematosus (SLE); its presence is conferred by a prolonged partial thromboplastin time, which is a result of the antibody targeting the phospholipids present on the clotting assay. Around 1% to 2% of the healthy population is seropositive for lupus anticoagulant.[86] In 1988, Perkocha et al. found that the incidence of lupus anticoagulant was 20% to 73% in asymptomatic AIDS patients with and without the presence of opportunistic infections, with the incidence between 20% to 73%.[87] Similar findings were noted in Chile in 2003 by Palomo et al., where they examined 63 HIV-positive patients for all three antiphospholipid antibodies. In their cohort, 0% of patients were positive for lupus anticoagulant, 12.7% positive for anticardiolipin antibodies, and 6.3% for anti-beta-2 glycoprotein 1 antibodies. The presence of the antiphospholipid antibodies did not correlate with the presence of thrombosis or thrombocytopenia.[88] Furthermore, the presence of antiphospholipid antibodies did not correlate with CD4 count, viral count, or presence of DVT.[73] PJP has also been associated with an increased risk for VTE, where 96% of infected patients have been found to have lupus anticoagulant antibodies.[72] Rarely, anticardiolipin has been reported in association with thrombosis in TIA and skin necrosis in case reports. It is hypothesized that antiphospholipid antibodies may be products of B-cell polyclonal stimulation.[72]

Pregnancy and postpartum are known risk factors for VTE in women, even more so in pregnant women with HIV. In the general population, the relative risk for development of VTE during pregnancy or in the post-partum period is 4.29 (95% CI, 3.49 to 5.33; $P < 0.001$). Moreover, women in the postpartum period had a higher annual incidence of VTE when compared to pregnant women (511.2 vs. 95.8 per 100,000).[89] The increased risk of VTE is attributed to an increased state of hypercoagulability resulting from increased production of factors VII, VIII, IX, X[90] and venous stasis secondary to decreased mobility during pregnancy and direct compression of the uterus on vessels thus decreasing venous capacitance. HIV-positive pregnant women are a 157-fold increase in VTE when compared to HIV-negative pregnant women,[75] and likely the result of additional risk factors relating to inflammation discussed above being present. Warfarin is avoided in the treatment of VTE in pregnancy given its teratogenic profile, and instead, heparin products are used such as low-molecular heparin, enoxaparin, or fondaparinux when heparin-induced thrombocytopenia with thrombosis (HITT) is of concern.

The treatment of venous thromboembolism does not differ in the HIV population; however, special consideration should be given as therapy can interfere with HAART resulting in either subtherapeutic or supratherapeutic anticoagulation. According to the CHEST guideline and Expert Panel Report, patients without cancer diagnosed with their first VTE should be initiated on anticoagulation for a duration of 3 months (Grade 1B). An extended duration (stopped at the clinicians' discretion) can be considered if the VTE is unprovoked and the bleeding risk for the patient is low (Grade 2B). Recurrent VTEs warrant lifetime anticoagulation if bleeding risk is low to moderate (Grade 1B). Novel oral anticoagulants (NOACs) such as apixaban, rivaroxaban, or dabigatran are the preferred agents as they do not require monitoring and have a lower bleeding risk when compared to vitamin K antagonist therapy with warfarin, which requires weekly INR monitoring. NOACs are contraindicated in patients with severe renal impairment. Oral warfarin is preferred over subcutaneously injected low-molecular-weight heparins (LMWH), such as enoxaparin and dalteparin, given the route of administration and price differences. In patients with cancer, extended anticoagulation is recommended over 3 months of therapy (Grade 1B),[91] where LMWH are the preferred agents given superior outcomes in preventing VTE recurrence based on the CLOT trial.[92]

When considering drug-drug interaction with HAART and anticoagulants, it can be helpful to classify drugs into ones that are metabolized by cytochrome P450 isozymes in the liver, where drugs can either lead to enzymatic inhibition or induction versus urine drug secretion mediated by P-glycoprotein protein, a transmembrane efflux pump, that participates in drug elimination in the proximal tubule in the kidney and has another role in drug absorption in epithelial cells in the small intestines.[93] Many drugs are both metabolized by CYP-450 isoenzymes and transported by P-glycoprotein. Inhibitors of CYP3A4 are typically also inhibitors of P-glycoprotein, and such is the case for rivaroxaban and apixaban (NOACs).

This becomes of importance in patients taking PIs as they are a good substrate for P-glycoprotein, inhibit CYP3A4, and are also metabolized by CYP3A4 (except for tipranavir). When PIs are taken with NOACs, the concentration of the PI increases as a result of the CYP3A4 inhibition by the NOAC, which in turn further inhibits the CYP3A4. For example, rivaroxaban is metabolized by CYP-450 (18% by CYP3A4 and 14% by CYP2J2), where further inhibition by PI of the CYP3A4 can lead to increased concentration of the NOAC–around 40% is renally secreted unchanged via P-glycoprotein as well.[94] Contrarily, Dabigatran is a NOAC that is mainly renally secreted via glomerular secretion and not affected by CYP-450 inhibition and is preferred with the use of PI. However, administration of dabigatran must be spaced by 2 hours from taking the PI, as the pro-drug is also a substrate for P-glycoprotein, where concurrent administration with ritonavir (PI) has been shown to increase dabigatran's bioavailability by 200% times[95] as it increases intestinal absorption via P-glycoprotein. Most NNRTIs are inducers of CYP3A4, which as described above affects rivaroxaban and apixaban leading to subtherapeutic anticoagulation.[95] Unlike PIs and NNRTIs, NRTIs do not have any effects on

Downl
15, 202

CYP-450 isozymes and therefore have lower drug-drug interactions with NOACs. Fortunately, NRTIs are considered first-line HAART therapy for HIV (see Table 152.2).

Warfarin metabolism is affected by PIs, NNRTIs, elvitegravir (an integrase inhibitor), and cobicistat (booster used in combination with elvitegravir). Warfarin is a racemic mixture with R and S stereoisomers that are metabolized by different CYP-450 isozymes. The R-warfarin stereoisomer is metabolized by CYP1A2 and CYP3A4, whereas the S-warfarin stereoisomer is metabolized by CYP2C9 and is 3–5 times more potent in inhibiting vitamin K epoxide reductase complex when compared to R-warfarin.[96] Protease inhibitors and NNRTIs exhibit variable effects on warfarin metabolism leading to either increased or decreased anticoagulation.[75] Elvitegravir is a CYP2C9 inducer, and is administered with cobicistat, a strong CYP3A4 inhibitor; as such the effects are difficult to predict as one drug would increase the levels of warfarin while the latter would increase it–literature is sparse, with a case report showing a 42-year-old man requiring a 60% dose increase.[97] In the general population, warfarin requires weekly INR monitoring in all patients and should be monitored more frequently in HIV patients whenever adjustments to their HAART regimen are made.

Finally, LMWH such as enoxaparin can be used with HAART without issues as it is mainly metabolized by the liver via desulfation and/or depolymerization to smaller fragments that are biologically less active.[98] Patients should be monitored for the occurrence of HITT, which typically results in thrombocytopenia 5 to 10 days after starting heparin products. HIV patients are at an increased risk for developing HITT when compared to HIV-negative patients (13% vs. 0.2%), according to a retrospective cohort study by Thomson et al.[99] and is hypothesized to be the result of antibody production from chronic polyclonal stimulation of B cells akin to the production of antiphospholipid antibodies. In cases of HITT, fondaparinux is used and is secreted unchanged in the urine.

SUMMARY

So, where are we with HIV-related hematologic disease at the time of writing this chapter? Many questions are answered, but many remain. ART has changed the face of HIV: HIV infection now does not automatically lead to AIDS, and HIV infection has become a chronic disease with an estimated survival of many years. This, of course, is achieved by dint of taking many medications during this time and monitoring many laboratory parameters. Nonetheless, despite highly active ART, there is an increased incidence of lymphoma (NHL and HL) and thrombosis (TEE) in infected patients who are taking ART, even if the viral load is undetectable. Both NHL and TEE occur more frequently than in non-HIV-infected individuals, although both complications are more common in uncontrolled HIV-infected patients as compared to those on ART.

There are AIDS-defining types of NHL, but these are rare, and most cases of NHL in HIV-infected patients are not AIDS-defining. However, even for the non-AIDS defining lymphomas, the types and the distribution within types (especially for DLBCL) are different than that seen in non-HIV-infected patients. Furthermore, many cases of NHL, but far from all, are EBV driven. While anti-viral treatments continue to evolve, a universal feature is that effective ART is widely available in developed countries.

TEE seems to be related to inflammation and is more commonly venous than arterial. It appears multifactorial, which may mean that a general predisposition to TEE is more likely to be activated if there is a second cause predisposing to TEE, e.g., antiphospholipid antibody and Factor V Leiden. TEE continues to be seen in HIV-infected patients on ART even though, like NHL, the increase compared to non-infected patients is less if the HIV is well-controlled.

Cytopenias were very frequent in the past in developed countries but now occur not at all frequently and only in those not on ART. For example, HIV-TP was seen in essentially half of the HIV-infected patients in the 1980s before the advent of universal ART. Current reports are frequent, but all come from areas in which ART is not in wide use.

Overall in the United States, HIV has become a very chronic disease, and the progress in developing effective but safe ART has been nothing short of remarkable, including finding ways to deliver multiple medications in one capsule a day or now, even one injection a month. The absence of an effective vaccine continues to be palpable, although pre- and post-exposure prophylaxis reduces transmission. Nonetheless, there are more than 30 million cases of HIV worldwide, and all too many of them are untreated, resulting in opportunistic infections as well as hematologic complications.

CHAPTER 153

HEMATOLOGIC FINDINGS AND CONSEQUENCES OF NOVEL CORONAVIRUS (SARS-COV-2) INFECTION

Leonard Naymagon and Douglas Tremblay

At the end of 2019, a novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) lead to a cluster of infections in Wuhan. China. The disease caused by this virus was designated as coronavirus-disease-2019 (COVID-19) by the World Health Organization (WHO). COVID-19 spread globally and went on to infect millions of people on all continents except Antarctica, causing an unprecedented global impact. As of February 2021, over one hundred million COVID-19 cases have been reported globally, with well over two million deaths attributed to the virus. Updated figures can be found on the WHO website: https://www.who.int/emergencies/diseases/novel-coronavirus-2019/situation-reports. The true extent of the pandemic is likely not yet fully appreciated, as only a fraction of cases are evaluated by medical professionals, diagnosed, and reported. Using the prevalence of seropositivity in a population with reported positive cases, it is estimated that the number of infections may be 6 to 24 times higher than reported. The reported death toll is also likely a significant underestimate. A US-based study that assessed excess deaths in 2019–2020 indicated that as many a quarter of all COVID-19 related deaths may not be officially counted.

Clinical manifestations of COVID-19 are primarily respiratory, including dyspnea and hypoxemia, and in many cases can progress to acute respiratory distress syndrome (ARDS). However, manifestations may be varied and multisystemic, and presentations are heterogeneous and range from asymptomatic to fatal (Fig. 153.1). Although healthy patients at any age are susceptible to severe disease, advanced age and comorbidities are clear risk factors for poor outcomes in COVID-19. In a study of 17 million patients in the United Kingdom, the following risk factors were identified to be significantly associated with COVID-19 mortality: age >60; male sex; BMI $>30\,\mathrm{mg/kg}^2$; tobacco use; non-White ethnicity; asthma; diabetes; non-hematological cancer diagnosed within the last 5 years; hematologic cancer; reduced kidney function; liver disease; stroke or dementia; prior organ transplant; rheumatoid arthritis, lupus, or psoriasis; and other immunosuppressed states.[1] Patients with hematologic malignancies, in particular, may have perturbations in myeloid and lymphoid maturation that leave them especially susceptible to the exuberant cytokine storm associated with severe disease. Evidence suggests these patients have very poor outcomes if infected with COVID-19.

Although respiratory failure is likely the primary driver of morbidity and mortality in the majority of COVID-19 cases, mounting experience indicates that severe COVID-19 can be a multisystem syndrome capable of involving multiple organ systems. The hematologic complications of COVID-19 are particularly prominent and have drawn significant interest. Early in the pandemic, clinicians reported thromboembolic complications including pulmonary embolism, deep vein thrombosis, thrombosis of intravascular access catheters, and stroke. In addition, laboratory parameters including some coagulation assays (particularly D-dimer), blood counts (including the lymphocyte count among others), and inflammatory markers (such as ferritin) have been noted to be characteristically altered in COVID-19 (Table 153.1). This chapter reviews the hematologic manifestations of COVID-19 and discusses their significance.

THROMBOSIS IN COVID-19

Evidence for Thromboembolic Disease as a Pathophysiologic Factor in COVID-19

There has been evidence to suggest that, at least among some patients, a pathophysiologic component of severe COVID-19 disease may be related to a provoked thrombophilic state (Table 153.2). Critically ill patients with COVID-19 have demonstrated high rates of overt venous thromboembolism (VTE) in sizable cohorts. In a prospective cohort study of 150 patients with COVID-19 and ARDS, 64 thromboembolic complications were identified, most often pulmonary embolism (PE).[2] Notably, the rate of PE was significantly increased as compared with a propensity-matched non-COVID historical prospective ARDS cohort. A series of 184 consecutive ICU patients with COVID-19 on appropriate thromboprophylaxis yielded a cumulative VTE incidence of 27% (higher than typically seen in comparable non-COVID ICU populations).[3] In a retrospective study of 3334 hospitalized COVID-19 patients, the diagnosis of VTE was associated with an increased risk of mortality (adjusted hazard ratio [HR], 1.37; 95% CI 1.02 to 1.86).[4] Additionally, high rates of central venous catheter clotting have been reported among COVID-19 patients, particularly with regard to hemodialysis access.[2]

Beyond overt venous thromboembolic disease, there has been interest in the role of occult VTE, including microthrombosis, contributing to adverse outcomes. Autopsy studies of COVID-19 patients have revealed extensive micro and macro pulmonary emboli that had been undiagnosed prior to death. For instance, a post-mortem examination of 21 COVID-19 patients yielded 4 instances of overt PE, 5 of diffuse alveolar capillary microthrombosis, and 3 cases demonstrating stigmata of thrombotic microangiopathy in glomerular capillaries.[5] Another small autopsy study reported severe endothelial injury, microangiopathy, and microthrombosis in the lungs of 7 patients who died of COVID-19 (findings that were not present in controls who had died from influenza or other non-COVID causes).[6] Some mechanically ventilated COVID-19 patients have manifested pulmonary physiology more consistent with pulmonary vascular disease rather than pure ARDS, suggesting that a diffuse thrombotic process may contribute to respiratory decompensation among a subset of patients.[7] Interest has also arisen regarding D-dimer levels, which are frequently elevated among COVID-19 patients, and has been associated with poor outcomes and been posited as possible laboratory indicators of thrombotic microangiopathy or other forms of microthrombosis. Observational studies have also noted increased levels of factor VIII and von Willebrand factor among patients with severe COVID-19.

In addition to high rates of VTE, high rates of arterial thrombosis have been reported among COVID-19 cohorts. In a highly publicized single-institution series, 5 cases of acute ischemic stroke were identified among COVID-19 patients within a 2-week period (with all patients younger than 50 years of age, and with generally minimal vascular risk factors).[8] Similarly, 20 COVID-19 patients with acute limb ischemia were reported by a single institution over a

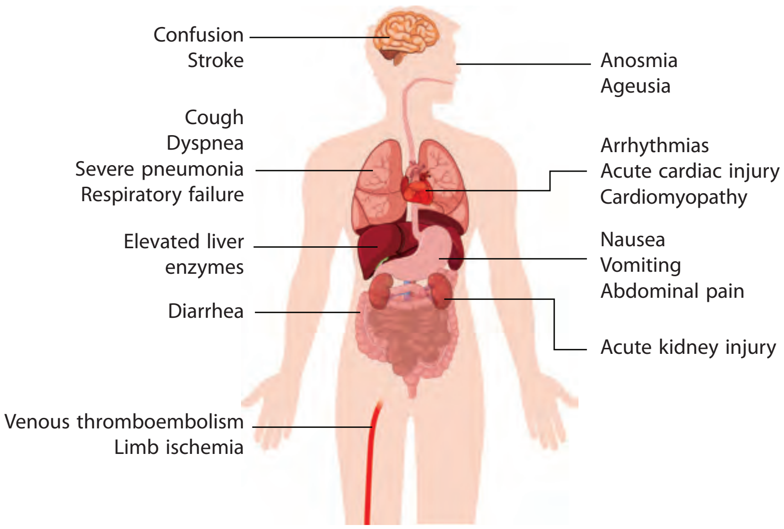

Figure 153.1 THE CLINICAL MANIFESTATIONS OF COVID-19 MAY AFFECT A WIDE RANGE OR ORGAN SYSTEMS.

3-month period.[9] A large retrospective study of over 3000 hospitalized COVID-19 patients reported myocardial infarction among 8.9%.[4]

Limitations to Current Evidence Regarding Thromboembolic Disease in COVID-19

The perception that acquired hypercoagulability and thromboembolic disease (both micro and macro) may play a role in the pathophysiology of COVID-19 has to date been based largely on anecdotal observations that are hampered by numerous limitations (Table 153.3). It is certainly well established that critical illness and prolonged hospitalization are major risk factors for VTE, and in this sense, the finding that VTE is common among severely ill COVID-19 patients is neither novel nor surprising. Although some of the aforementioned studies report VTE rates among critically ill COVID-19 patients that may be higher than historical non-COVID controls, several other COVID-19 studies report more moderate rates that are more in line with historical standards.[4] The high frequency of VTE encountered in some cohort studies may have been overestimated in the setting of inconsistently reported thromboprophylaxis practices and the extensive and nonsystematic use of diagnostic imaging studies. Systematic comparisons of VTE rates among COVID-19 and non-COVID-19 patients are not yet available, and it is presently difficult to assert that COVID-19 is significantly "more thrombophilic" than other comparatively severe respiratory illnesses.

Autopsy studies demonstrating occult pulmonary thromboembolic disease and thrombotic microangiopathy among COVID-19 patients remain few, with the number of confirmed reports paling in comparison to the number of known COVID-19 related fatalities. Further, there may be selection bias in these autopsy reports, with only the most idiosyncratic and otherwise inexplicable deaths preferentially selected for autopsy. Elevated D-dimer, though increasingly interpreted as a measure of occult thrombotic burden in COVID-19 at some centers, is a highly non-specific marker of VTE and may be a manifestation of inflammation rather than thrombosis. In a study of 449 COVID-19 patients, there was no difference in admission D-dimer levels as compared with 104 patients with a non-COVID pneumonia.[10] In a study of 1065 hospitalized COVID-19 patients, although D-dimer levels and trends were associated with poor outcomes, they proved poor predictors both when taken in isolation and when incorporated into multivariable models.[11] Similarly, elevations of factor VIII and von Willebrand factor are likely reflective of the highly proinflammatory nature of COVID-19 and not indicative of any unique prothrombotic process.

Series describing arterial thrombotic complications such as stroke and limb ischemia have been small and few, and it is difficult to form meaningful conclusions from the limited cases available for study. Reported rates of myocardial infarction (MI) have likely included large quantities of cases of type 2 MI (or "demand ischemia"), with cases of true acute thrombotic coronary obstruction likely rare.[4] Like many other purported manifestations of "COVID-19 hypercoagulability," such demand ischemia is a common feature of critical illness across etiologies. Reports of pulmonary physiology reminiscent of venous thromboembolic disease remain purely anecdotal with limited published data to date.

The Role of Anticoagulation in COVID-19

Some limited data suggest that anticoagulation may improve outcomes in COVID-19. In an often-cited study reported early in the course of the pandemic, the use of prophylactic heparin was associated with improvement in mortality in a very specific subgroup (those with a sepsis-induced coagulopathy score ≥4) of 449 patients with severe COVID-19. However, it was unclear why this specific subgroup was chosen, why the rate of prophylactic anticoagulation was so low (only 99 patients received it), and why prophylactic anticoagulation was offered in some cases and not others. In addition, the baseline characteristics of the two groups were not well described and not compared, and the analysis favoring anticoagulation was univariable.[12] In a large single-hospital system retrospective study, therapeutic dose anticoagulation was associated with improved in-hospital survival among intubated patients; however, some potentially significant clinical factors were not controlled for, and the benefit conferred by anticoagulation was not observed in non-intubated patients.[13] A follow-up study from the same group using a largely overlapping retrospective cohort found that prophylactic dose anticoagulation was associated with lower rates of intubation and in-hospital mortality than the group not receiving anticoagulation. However, given that prophylactic anticoagulation is already the established standard of care for the vast majority of hospitalized patients (unless contraindicated), the clinical utility of such a finding is not readily apparent. It should be observed that in such studies that those patients who do not receive prophylactic anticoagulation likely carry contraindications for prophylaxis (such as active bleeding, coagulopathy, or severe thrombocytopenia) which may themselves be associated with poor outcomes. Such deeply ingrained practices may be difficult to account for. Notably, in this study, therapeutic dose anticoagulation did not yield significantly improved outcomes relative to prophylactic anticoagulation.

TABLE 153.1 Common Hematologic Manifestations of COVID-19

	Prevalence (%)	Prognostic implications	Suspected Pathophysiology
Venous thrombosis	5–30 (in severe disease)	May predict mortality	Heightened inflammation, critical illness, prolonged hospitalization
Arterial thrombosis	Likely rare, not well described	May predict mortality	Poorly understood, perhaps vascular inflammation
Elevated D-dimer	50–80 (among hospitalized patients)	May be associated with though not strongly predictive of mortality	Inflammation-driven acute phase reactant Possibly increased fibrinogenesis/fibrinolysis in some instances
Hyperferritinemia	55–80	May predict severe disease	Inflammation-driven acute phase reactant
Lymphopenia	35–85	May predict mortality	Cytokine-driven apoptosis, direct infection of lymphocytes, or destruction of lymphatic organs
Thrombocytopenia	30–40	May predict morality	Infection of megakaryocytes, immune mediate destruction
Anemia	20–35	May predict severe disease and mortality	Decreased production

TABLE 153.2 Frequently Cited Evidence Supporting the Central Role of an Acquired Thrombophilic State in the Pathophysiology of COVID-19

High observed rates of venous thromboembolism (VTE) in many severe coronavirus-disease-2019 (COVID-19) cohorts.
Association between VTE incidence and mortality in some cohorts.
High observed rates of central venous catheter clotting.
Autopsy studies demonstrating evidence of occult pulmonary thrombosis, microthrombosis, and thrombotic angiopathy.
Pulmonary physiology reminiscent of pulmonary vascular disease among some mechanically ventilated patients.
Frequently elevated D-dimers and their association with outcomes.
Reports of otherwise unexplained arterial thrombotic events.

TABLE 153.3 Limitations to Available Evidence Supporting the Notion That an Acquired Thrombophilic State May Play a Major Role in the Pathophysiology of COVID-19

Rates of VTE may be similar to those in comparably severe illnesses of other etiologies.
Lack of systematic comparisons of VTE rates among COVID-19 and non-COVID-19 patients.
Observations of high rates of central venous catheter clotting remain anecdotal and not yet rigorously studied.
Autopsy studies implicating the role of occult thrombotic disease are very few in number and subject to selection bias.
Reports of pulmonary physiology similar to that of pulmonary vascular disease remain few, unsystematic, and speculative.
Elevated D-dimers, though often present, are non-specific and likely represent acute phase response to heightened inflammation.
Arterial thrombotic events have been reported in a small number of series, most ischemic cardiac events represent “demand ischemia.”

There is currently no truly rigorous data that offer convincing evidence that anticoagulation beyond what is typically recommended for generic (non-COVID) hospitalized patients is of benefit in COVID-19. For the time being, it remains unclear whether anticoagulation may truly have a protective effect on COVID-19 infections and if so whether any particular group of COVID-19 patients may benefit most. A propensity-matched analysis of 4343 COVID-19 patients demonstrated no outcome-benefit among those patients who were on anticoagulation for other indications prior to COVID-19 diagnosis.[14] Such finding suggest that if there is benefit to be derived from anticoagulation, it may be more likely later in the disease course and/or among sicker patients (such as those requiring hospitalization). However, some studies investigating intervention with anticoagulation among critically ill COVID-19 patients have demonstrated similarly negative results. For instance, in a multicenter target trial emulation among 2809 critically ill COVID-19 patients, those who received early therapeutic anticoagulation had a similar risk for death as those who did not.[15] A smaller observational study actually demonstrated worse survival outcomes among inpatients empirically treated with therapeutic dose anticoagulation compared to those treated with prophylactic dose anticoagulation.[16] More recently, three large-scale prospective international trials investigating preemptive use of therapeutic heparin among critically ill COVID patients were halted after their data safety monitoring boards determined that such interventions appeared futile and possibly unsafe in interim analyses (although the specific data prompting these decisions are not available at the time of this writing, concerns regarding safety were presumably based on excess bleeding risk detected in the treatment groups).

In spite of the lack of convincing evidence, many clinicians and centers have pursued and advocated for therapeutic (or sometimes intermediate dose) anticoagulation for critically ill patients with COVID-19 in the absence of documented thromboembolism. While it is certainly true that some critically ill patients with high clinical suspicion for VTE may be too unstable or otherwise unable to undergo confirmatory testing, and empiric therapeutic anticoagulation may be reasonable among such patients, routine use of therapeutic anticoagulation among COVID-19 patients with clearly negative VTE testing is not presently evidence based and should be pursued with caution outside the context of a clinical trial. It should also be noted that decision tools employed by some centers to identify those COVID-19 patients who may benefit from therapeutic anticoagulation frequently employ unfounded and seemingly arbitrary criteria such as specific D-dimer cutoffs or thresholds of respiratory support requirement, which have not been validated. Current guidelines for anticoagulation among COVID-19 patients from the International Society of Thrombosis and Hemostasis (ISTH) as well as the American Society of Hematology (ASH) are very similar to the established standards used among all hospitalized patients (Table 153.4). Specifically, they state that hospitalized COVID-19 patients should generally receive prophylactic dose anticoagulation unless contraindicated and that therapeutic dose anticoagulation

TABLE 153.4 Clinical Guidance on the Diagnosis, Prevention,and Treatment of Venous Thromboembolism in Hospitalized Patients With COVID-19 From the International Society of Thrombosis and Hemostasis

Diagnosis of VTE in hospitalized COVID-19 patients	Practitioners should use standard-of-care objective testing (i.e., computed tomography pulmonary angiogram [CTPA], ventilation/perfusion [V/Q] scan, magnetic resonance imaging [MRI] venography, Doppler ultrasonography) to diagnose venous thromboembolism (VTE) based on clinical index of suspicion. A pragmatic approach (i.e., point-of-care bedside ultrasonography or echocardiography) can also be combined with standard-of-care objective testing (50% of respondents).
	Routine screening for VTE using bedside Doppler ultrasonography of the lower extremities or based on elevated D-dimer levels is not recommended.
VTE prophylaxis in non-ICU hospitalized COVID-19 patients	A universal strategy of routine thromboprophylaxis with standard-dose UFH or LMWH should be used after careful assessment of bleed risk, with LMWH as the preferred agent. Intermediate-dose LMWH may also be considered (30% of respondents).
	VTE prophylaxis recommendations should be modified based on extremes of body weight, severe thrombocytopenia or deteriorating renal function.
VTE prophylaxis in sick ICU hospitalized COVID-19 patients	Routine thromboprophylaxis with prophylactic-dose UFH (unfractionated heparin) or LMWH (low molecular weight heparin) should be used after careful assessment of bleed risk. Intermediate-dose LMWH (50% of respondents) can also be considered in high risk patients. Patients with obesity as defined by actual body weight or BMI should be considered for a 50% increase in the dose of thromboprophylaxis. Treatment-dose heparin should not be considered for primary prevention until the results of randomized controlled trials are available.
	Multi-modal thromboprophylaxis with mechanical methods (i.e., intermittent pneumonic compression devices) should be considered (60% of respondents).
Duration of VTE prophylaxis for hospitalized COVID-19 patients	Either LMWH (30%) or a DOAC (direct oral anticoagulant) (i.e., rivaroxaban or betrixaban; 30% of respondents) can be used for extended-duration thromboprophylaxis.
	Extended post-discharge thromboprophylaxis should be considered for all hospitalized patients with COVID-19 that meet high VTE risk criteria. The duration of post-discharge thromboprophylaxis can be approximately 14 days at least (50% of respondents), and up to 30 days (20% of respondents).
VTE treatment in hospitalized COVID-19 patients	Established guidelines should be used to treat patients with confirmed VTE, with advantages of LMWH in the inpatient setting and DOACs in the post-hospital discharge setting. A change from treatment-dose DOAC or vitamin K antagonists (VKA) to in-hospital LMWH should be considered especially for patients in critical care settings or with relevant concomitant medications, and dependent on renal function and platelet counts. Anticoagulant regimens should not change based solely on D-dimer levels.
	A change of anticoagulant regimen (i.e., from prophylactic or intermediate-dose to treatment- dose regimen) can be considered in patients without established VTE but deteriorating pulmonary status or ARDS (50% of respondents).
	The duration of treatment should be at least 3 months (50% of respondents).

Adapted from Spyropoulos AC, Levy JH, Ageno W, et al. Scientific and standardization committee communication: clinical guidance on the diagnosis, prevention, and treatment of venous thromboembolism in hospitalized patients with COVID-19. *J Thromb Haemost*. 2020;18(8):1859–1865.

should be used among those with demonstrated thromboembolism unless contraindicated.[17] Notable differences from standard anticoagulation protocols acknowledged as reasonable in the ISTH guidelines include consideration of intermediate-dose low-molecular-weight (LMW) heparin prophylaxis among some "high-risk" hospitalized patients and consideration of extended VTE prophylaxis following hospital discharge (this likely based on reports of post-discharge VTE among some COVID-19 patients) (see Table 153.4). It should be noted however that these specialized prophylaxis considerations are not based on strong evidence and highlight current uncertainty in clinical practice.

COVID-19 ASSOCIATED COAGULOPATHY

The frequent observation of elevated D-dimer levels among COVID-19 patients early in the course of the pandemic raised concern that disseminated intravascular coagulation (DIC) may be a recurrent feature of the syndrome. However, this is not supported by other laboratory parameters common among COVID-19 patients. Indeed, COVID-19 patients often manifest elevated fibrinogen levels and rarely demonstrate significant prolongation of aPPT and/or prothrombin time (PT) and infrequently have severe thrombocytopenia (though relatively mild thrombocytopenia may be common) (Table 153.5). Further, the observation that D-dimer levels tend to correlate with inflammatory markers such as erythrocyte sedimentation rate (ESR) or ferritin suggests that they are likely more a manifestation of an inflammatory response rather than an indicator of coagulopathy among COVID-19 patients. Indeed, few COVID-19 patients (and likely only the most ill among them) are likely to meet ISTH criteria for DIC. The utility of trending laboratory markers such as D-dimer among COVID-19 patients is of uncertain benefit. Uptrending or downtrending D-dimers may be indicators

TABLE 153.5 Comparison of Coagulation Parameters and Markers of Fibrinolysis in Disseminated Intravascular Coagulation and COVID-19

	DIC	COVID-19
D-dimer	Increased	Increased
Fibrinogen	Decreased	Increased
Platelets	Decreased	Normal or slightly decreased
PT	Prolonged	Normal
PTT	Prolonged	Normal

DIC, Disseminated intravascular coagulation; *PT*, prothrombin time; *PTT*, partial thromboplastin time.

of worsening or improving clinical status, respectively (most likely because they are prone to track with inflammation); however, it is not clear that these trends provide any more information than what might be inferred based on clinical observation, or more limited laboratory monitoring.[11] Based on currently available evidence, monitoring of such parameters among COVID-19 patients need not necessarily exceed typical laboratory assessments among comparably ill patients due to other etiologies.

INFLAMMATORY MARKERS AND CYTOKINE STORM

A key pathophysiologic mediator of severe COVID-19 disease is an acute inflammatory syndrome. This clinical impression was widespread early in the pandemic by marked elevations in C-reactive protein (CRP), erythrocyte sedimentation rate, interleukin (IL)-6, and ferritin in severe COVID-19 cases. Elevations in these inflammatory markers were noted to be prognostically important based on several retrospective cohort studies. In particular, ferritin has been noted to be severely elevated in patients with COVID-19. Although ferritin is a known acute phase reactant elevated in many inflammatory conditions including infections, extreme elevations are also a clinical hallmark of hyperferritinemic syndromes such as macrophage activation syndrome (MAS), adult-onset Still's disease, and catastrophic antiphospholipid syndrome. In addition, extremely high ferritin is also reminiscent of secondary hemophagocytic lymphohistiocytosis (sHLH). However, patients with COVID-19 rarely develop organomegaly and other diagnostic evaluations including natural killer (NK) cell activity, soluble IL-2 receptor, and a bone marrow, liver, spleen, or lymph node biopsy are rarely obtained. In one small single-center study, only three patients out of 40 (7.5%) likely had sHLH based on a predictive scoring model (Hscore).

The prognostic value of ferritin levels in COVID-19 remains uncertain. In an early study from Wuhan, China, ferritin elevation was able to discern between mild and critical COVID-19, although the definitions of severity were poorly defined. In a large New York City based study, patients who died had a significantly higher ferritin level than those who did not. However, mortality was poorly predicted by both admission and maximum ferritin levels, with an area under the curve (AUC) for a receiver operator characteristic (ROC) curve of 0.677 and 0.638 respectively.[18] Interestingly, the AUC increased among younger age brackets. Further data are needed to clarify the prognostic role of ferritin and its integration into risk models to inform the use of COVID-19 therapies.

Parallels can also be drawn between severe COVID-19 infections and cytokine release syndrome (CRS) associated with chimeric antigen receptor (CAR) T-cell therapy. As a result, tocilizumab has been successfully employed for severe COVID-19 and continues to be evaluated. In addition, the JAK-STAT pathway has been identified as a potential target as many inflammatory cytokines are mediated by this intracellular signaling pathway. Dexamethasone has been among the first therapies to demonstrate a survival improvement in COVID-19, a benefit postulated to be due to mitigation of the inflammatory response.[19] Multiple therapeutic trials are evaluating agents that modulate the immune response to SARS-CoV-2 as a means to improve outcomes in COVID-19.

COVID-19 in children is generally mild; however, a small subset of patients develop a hyperinflammatory process similar to Kawasaki disease and toxic shock syndrome. This disease was termed multisystem inflammatory syndrome in children (MIS-C). Clinical manifestations are distinct from COVID-19 in adults and include fevers, rash, gastrointestinal complaints (vomiting, diarrhea, abdominal pain), conjunctival injection, and mucosal changes with a lack of prominent pulmonary symptoms. Hematologic abnormalities are common, with lymphopenia, anemia, and thrombocytopenia present in approximately 80%, 70%, and 50% of cases, respectively. Ferritin is elevated in approximately 75% of cases. The pathophysiology of MIS-C is not well understood but presumed to be related to an abnormal immune response to SARS-CoV-2 infection.

CHARACTERISTICS OF THE COMPLETE BLOOD COUNT AND WHITE BLOOD CELL DIFFERENTIAL IN COVID-19

Lymphopenia

Among the most common hematologic abnormalities in patients with COVID-19 is lymphopenia, present in 35% to 83% of patients based on initial reports from Wuhan, China. In a larger United States based study, a lymphocyte count less than 1.0×10^9/L was observed in 60% of patients.[20] The etiology behind this lymphopenia is not known, although several mechanisms have been postulated. Some studies have reported that lymphocytes express angiotensin-converting enzyme-2 (ACE-2), the receptor for SARS-CoV-2, thus suggesting direct infection with the virus. However, several studies have not confirmed this finding and have suggested a separate mechanism whereby SARS-CoV-2 infects and destroys lymphatic organs (though it should be noted that evidence of ACE2 expression in lymph nodes, thymus, or spleen is currently lacking). A more plausible explanation for lymphopenia may be that proinflammatory cytokines, such as TNFα and IL-6, lead to decreased production and increased apoptosis of lymphocytes. Functional studies have also demonstrated that SARS-CoV-2 may promote excessive activation of CD8+ T cells, possibly leading to exhaustion and impaired functioning of CD4+ T cells. It should be noted that many viral infections cause lymphopenia, such as respiratory syncytial virus, severe measles, and H1N1 influenza. Thus, the novelty of lymphopenia in COVID-19 compared with other viral infections may be somewhat overstated.

The degree and trend of lymphopenia appear to be at least somewhat prognostic, although its independent associations have not been fully evaluated. In a preliminary series from Wuhan, China, COVID-19 non-survivors developed more persistent and marked lymphopenia as compared with survivors. In another report from China, baseline lymphocyte count was significantly higher in survivors as compared with non-survivors (1.1×10^9/L vs. 0.6×10^9/L, $P < .0001$). However, it remains unclear if lymphopenia is independently associated with mortality. Further studies are needed to establish the mechanisms and risk associated with lymphopenia in COVID-19.

Thrombocytopenia

Thrombocytopenia is less prevalent than lymphopenia in acute COVID-19 infections. A large early series from China estimated the prevalence of thrombocytopenia to be less than 150×10^9/L at 36.2%, with a higher prevalence in severe disease (57.7%) versus non-severe disease (31.6%).[21] In a separate study, the platelet nadir was prognostically important, with an in-hospital mortality of 92.1% in patients with a platelet count of 0 to 50×10^9/L compared with 4.7% in patients with platelet count above 150×10^9/L. Several mechanisms of thrombocytopenia in COVID-19 have been proposed. SARS-CoV-2 has been postulated to directly infect CD13 positive cells in the bone marrow, as has been documented with other coronaviruses. The cytokine storm associated with COVID-19 infection may also decrease hematopoietic progenitor cell numbers. Immune-mediated thrombocytopenia with COVID-19 has also been reported, suggesting peripheral destruction of platelets. Finally, increased consumption due to systemic thrombosis and/or low level DIC may be occurring in a small subset of patients, although as above, the thrombotic state of COVID-19 is distinct from DIC.[22] It is likely that the mechanisms behind COVID-19 induced thrombocytopenia are multifactorial. Even with severe thrombocytopenia, bleeding does not appear to be a major feature of COVID-19.

Other Complete Blood Count Abnormalities

In contrast to thrombocytopenia and lymphopenia, anemia is not a prominent feature of COVID-19 infection. In preliminary studies from Wuhan, China, the median hemoglobin level was 13.4 g/dL.[21]

In addition, the percentage of patients requiring red blood cell (RBC) transfusions appears to be low, with one study estimating that only 1.6% of hospitalized COVID-19 patients required an RBC transfusion. There has been some reporting of COVID-19-associated hemolysis; however, this has been limited to a few small case series. There is some evidence from a single-center retrospective study that even mild anemia may be predictive for the need for mechanical ventilation and death; however, the clinical implications of this observation are unclear. An elevated red cell distribution width (RDW), even in nonanemic patients, has also been shown to be a negative predictor for mortality in COVID-19 patients, but as with many of the presented observations, rigorous data in this regard are limited.

VACCINATION

The United States Food and Drug Administration (FDA) granted an Emergency Use Authorization (EUA) to the first COVID-19 vaccine by Pfizer-BioNTech on December 11, 2020. One week later, a second vaccine produced by Moderna was granted an EUA. Both Moderna and Pfizer-BioNTech are messenger RNA (mRNA) vaccines, which deliver mRNA in a lipid nanoparticle that expresses the full length spike protein to elicit an immune response. Advantages of this technology include a completely in vitro manufacturing process that facilitates rapid production. Other vaccines utilizing a recombinant protein nanoparticle or adenovirus vector that express the spike protein are in development and will likely gain approval in the near future. The Pfizer-BioNTech and Moderna mRNA vaccines have demonstrated extraordinary effectiveness in preventing infection, with 95% and 94% efficacy respectively against symptomatic COVID-19. Even more impressive, the rates of severe COVID-19 were reduced to nearly zero in the large phase III clinical trials, which led to the approval of these vaccines.[23,24] Notable adverse events include myalgias at the site of injection, headaches, chills, and fatigue, particularly after the second dose. Anaphylaxis is extraordinarily rare, with a rate of 5 and 2.8 events per one million doses for the Pfizer-BioNTech and Moderna mRNA vaccines, respectively. Shortly before this writing (March 01, 2021) an adenoviral vector vaccine (Janssen COVID-19 vaccine, also referred to as the Johnson & Johnson vaccine) was granted EUA. This viral vector vaccine is based on an adenovirus modified to contain the gene for expression of the SARS-CoV-2 spike protein. Phase III trials have demonstrated that 28 days after a completed single vaccination, the vaccine had an efficacy of 66% in preventing symptomatic COVID-19, 85% efficacy in preventing severe COVID-19, and 100% efficacy in preventing COVID-19-related hospitalization or death.

Of note, clinical trials did not include immunocompromised subjects. In particular, patients with hematologic malignancies have been excluded from the clinical testing of COVID-19 vaccines. The immunogenicity of SARS-CoV-2 vaccines in patients with hematologic malignancies is therefore unknown. Many hematologic malignancies are characterized by perturbations in the bone marrow resident cells and microenvironment that may impact the generation and preservation of plasma cells necessary for durable immunity. The immune response to the COVID-19 vaccine will likely be a function of the nature and status of the underlying hematologic malignancy.[25] In addition, immune dysfunction as a result of cancer-directed therapy, such as B-cell depletion or hematopoietic stem cell transplantation, is also a concern. The European Hematology Association has released guidance that recommends COVID-19 vaccinations for all patients with hematologic malignancies. In patients who have received B-cell-depleting therapy or hematopoietic stem cell transplantation, an interval of 3 to 6 months prior to vaccination should be observed.[26] When vaccination is more widely available, efforts should be made to provide the vaccine at least 2 to 4 weeks prior to planned immunosuppressive therapy, transplant, or splenectomy.

In February of 2021, reports emerged of thrombocytopenia that developed after the administration of the COVID-19 vaccine.[27,28] The most extensive description of this phenomenon at the time of this writing comes from a case series of 20 patients collected from the Centers for Disease Control (CDC), US FDA, and Vaccine Adverse Events Reporting System (VAERS). Nine patients received the Pfizer-BioNTech and 11 received the Moderna vaccine. The median onset after vaccination was 5 days and the majority had a platelet count of less than 10×10^9/L. Of note, out of the 20 patients identified in this report, one had a known history of ITP in remission, another had baseline thrombocytopenia with positive anti-platelet antibodies, and a third had inherited thrombocytopenia with a baseline platelet count of around 40 to 60×10^9/L. Three other patients had autoimmune conditions. Fifteen of the 20 patients received ITP (immune thrombocytopenic purpura)-directed treatment including steroids in 14, intravenous immune globulin (IVIG) in 12, rituximab in 2, romiplastim in 1, vincristine in 1, and aminocaproic acid in 1. Eight patients received platelet transfusions. Improvement in platelet counts were described in 14 patients after treatment.[29]

The favorable response to ITP-directed treatment suggests that antibody-mediate platelet clearance is the mechanism in the majority of these cases. However, at the time of this report, over 20 million people had been vaccinated, making the case rate of ITP related to the vaccine as less than 1 case per million vaccinated persons. The authors extrapolated the number of cases reported during this monitoring period and found that it correlated with 80,000 cases per year. There are 50,000 cases of secondary ITP diagnosed annually; thus, the rate is just slightly above expected from the normal population, with an increase incidence perhaps explained by amplified surveillance post-vaccination for COVID-19. Other vaccines are known to lead to secondary ITP, such as the measles-mumps-rubella vaccine.

While it possible that the mRNA COVID-19 vaccine may have triggered a small number of cases of secondary ITP, this complication appears to be extraordinarily rare. Given the morbidity and mortality associated with COVID-19 infection, the benefits far outweigh the risks of vaccination. Clinicians should be mindful of these reports and check platelet counts in patients who are post-vaccination and complaining of excessive bleeding/bruising. In those who develop extreme thrombocytopenia, treatment for ITP should be rapidly implemented (see Chapter 129).

At the time of this writing, reports are emerging describing cases of thrombosis with thrombocytopenia following administration of the Johnson & Johnson COVID-19 vaccine and the AstraZeneca COVID-19 vaccine (another adenovirus vector vaccine presently available in Europe, though not in the United States). Some among these cases have demonstrated the presence of autoantibodies to the platelet factor 4 (PF4) antigen (similar to what is found in heparin-induced thrombocytopenia and thrombosis [HITT]). Although notable, such complications following vaccination remain profoundly rare, particularly following the Johnson & Johnson vaccine wherein (at the time of this writing) less than one case per one million vaccinated patients has been reported. The six reported cases following the Johnson & Johnson vaccine have presented as cerebral venous sinus thromboses (CVST), among females aged 18 to 48 years, with onset 6 to 13 days after vaccination. Such events have been noted somewhat more commonly following the AstraZeneca vaccine; however, because of the rarity of these events and the potential severity of COVID-19, the European Medicines Agency (EMA) continues to advise that the overall benefits of the vaccine outweigh the risk. A causal relationship between these adenovirus vector vaccines and these thrombotic/thrombocytopenic events has not yet been confirmed. Importantly, there does not appear to be any association between these vaccines (or any COVID-19 vaccines) and thromboembolic events overall. A history of thrombosis, thrombophilia, and/or HIT (heparin-induced thrombocytopenia) does not represent a contraindication to vaccination, and patients with such histories should continue to be encouraged to pursue vaccination.

MONOCLONAL ANTIBODIES

Another recent treatment advance for COVID-19 is the development of monoclonal neutralizing antibodies against the spike protein. Several such agents have been evaluated (largely in the outpatient setting), and two have obtained an EUA by the FDA. Bamlanivimab-etesevimab is a combination of two monoclonal antibodies derived from two separate patients convalescing from COVID-19 infection that bind two different epitopes of the spike protein. In a phase II/III clinical trial, the combination of bamlanivimab and etesevimab led to a small, statistically significant reduction in emergency department (ED) visits or hospitalization.[30] A phase III trial, which has not been published at the time of this writing, evaluated 1035 non-hospitalized patients with COVID-19 demonstrated the combined outcome of hospitalization and death was lower (2% vs. 7%) in the bamlanivimab-etesevimab as compared to placebo.[31] A second monoclonal antibody product, casirivimab-imdevimab, has also obtained EUA from the FDA based on a preliminary report showing that these agents reduce viral load, particularly in patients who were SARS-CoV-2 antibody–negative. Among these antibody-negative patients, fewer patients treated with casirivimab-imdevimab required a medical visit within the subsequent month compared with those receiving placebo (6% vs. 15%).[32] If these agents are employed in clinical practice, they should be given as a single infusion as soon as possible after the diagnosis is confirmed and no longer than 10 days after symptom onset.

CHAPTER 154

HEMATOLOGIC ASPECTS OF PARASITIC DISEASES

David J. Roberts

Parasitic diseases are not common in medical, let alone hematologic, practice in North America or Europe. However, much of the world's population is infected by and becomes symptomatic as a result of a plethora of parasites, and many of these infections represent global public health problems.

Although, some significant parasitic diseases are transmitted in temperate climates, the majority of parasites of significance to human health are endemic in the tropical world. This reflects not only socioeconomic circumstances but also the origin of our species in tropical Africa, where the human host, parasites, and also vectors have established complex relationships over evolutionary timescales.[1,2] Notwithstanding such geographic variation in the incidence of parasitic disease, both travelers and recent immigrants now present to hematology clinics and laboratories all over the world with increasing frequency. Even in those circumstances, there are marked variations in practice in North America as well as in Europe, where the United Kingdom reports more cases of imported malaria than the United States and indeed has a 10-fold greater incidence of malaria per capita, reflecting the increased frequency of travel to and from endemic areas compared with North American populations.

Patients with malaria, leishmaniasis, trypanosomiasis, and babesiosis may present directly or indirectly to hematologists. This chapter is concentrated on the biologic, clinical, and hematologic features of these infections and the hematologic aspects or complications of their treatment. Comprehensive accounts of the general medical aspects of these diseases are provided in many other recent textbooks.[3–5]

MALARIA

Malaria is a major public health problem in tropical areas, and it is estimated that it is responsible for approximately 400,000 deaths annually and 150 to 300 million infections.[5a] The vast majority of morbidity and mortality caused by malaria is caused by infection with *Plasmodium falciparum*, although *Plasmodium vivax, Plasmodium ovale*, and *Plasmodium malariae* are also responsible for human infections. A fifth species, *Plasmodium knowlesi*, has been shown to cause human infection in some parts of Southeast Asia (for review, see the article by Jeyaprakasam et al.[6]). In endemic areas, a significant proportion of the mortality and morbidity is from anemia. In Europe and North America, malaria is not infrequently a clinical problem in travelers or recent arrivals from malaria-endemic areas, and hematologists may be involved in the diagnosis and management of the disease. Moreover, in nonendemic areas, malaria may cause a fatal transfusion-transmitted infection, and detection of blood donors who may be carrying the disease represents a major challenge for blood services.

Epidemiology

Approximately 1 billion people live in areas of endemic or epidemic malaria. The global mortality and morbidity were revised to 350 million cases and 1 million deaths per year, respectively, following an evaluation of the prevalence of infection in Southeast Asia in 2005 (Fig. 154.1). There is, however, substantial evidence that the incidence of severe disease has fallen considerably across the world in the last 15 years, following the widespread introduction of artemisinin combination treatment, impregnated bed nets, and residual spraying because the resources available for malaria control have increased substantially through the Global Fund, the World Health Organization's Global Malaria Programme, and the Roll Back Malaria Partnership to End Malaria (https://endmalaria.org/). The current estimated annual death total from malaria in Africa has fallen from 700,000 in 2004 to 386,000 in 2019.[5]

The distribution of malaria is determined by features of host, vector, and parasite. In summary, the global distribution of autochthonous or endogenous malaria is limited by the lower temperature limits for development of the parasite in the mosquito (sporogony) of 20°C for *P. falciparum* and 15°C for other human malarias. Within these limits, transmission does not occur above 1500 m in arid regions or in the Central and South Pacific (because of the absence of suitable vectors). In addition, *P. vivax* malaria is rare in Africa, where the population frequency of the blood group Duffy negative (Fya^-Fyb^-) is high. *P. ovale* requires a lengthy period of sporogony and is confined to areas of Africa and Southeast Asia with a high density of susceptible *Anopheles* spp. *P. knowlesi* is transmitted from macaque monkeys in forest areas of Borneo, Malaysia, Thailand, and Vietnam.[6]

In some malarious areas the seasonal pattern of clinical malaria is determined by the increase in vector density after rainfall, leading to an increase in new infections as transmission increases. In naive individuals, parasites can cause chronic infection lasting many months.

The intensity of transmission determines the distribution of clinical symptoms in different age groups.[7] In general, in areas of high transmission, younger children experience severe disease. Where transmission is less intense, older children experience severe disease. Finally, if the rate of transmission is very low, few cases of malaria are seen in any age group, and such populations would have little natural immunity. In such areas, a sudden increase in vectorial capacity (through the accidental introduction of efficient vectors or higher density, biting, or survival of the resident vectors), more rapid parasite sporogony, or migration of infected or nonimmune populations can result in epidemics where large numbers fall ill in all age groups. The transition from high to low transmission has been classified by holoendemicity, hyperendemicity, mesoendemicity, and hypoendemicity. These categories can be related epidemiologically to age-specific rates of parasite prevalence or splenomegaly and theoretically to the reproductive ratio of malarial infection.[8]

Malaria exerts a substantial selection for human traits that protect from infection. About a third of the variability in the risk of severe and complicated malaria is now explained by additive host genetic effects.[9] Substantial protection from malaria is derived from sickle cell trait and thalassemia traits which are truly polymorphic characteristics in many parts of the world. Other red cell traits conferring resistance to severe disease include the ABO blood groups and polymorphisms of ATPas4 (the major calcium pump on red cells) and polymorphisms of the glycophorins, including the Dantu blood group antigen.[10] Understanding genetic epidemiology has provided the foundation of population genetics and has provided classic examples of principles of genetic selection in vivo—for example, balancing selection for sickle cell trait and negative epistasis for sickle cell trait and α-thalassemia. The homozygous forms of these characteristics cause significant clinical disease, such as sickle cell disease, β-thalassemia, and glucose-6-phosphate dehydrogenase (G6PDH) deficiency. In endemic areas these genetic diseases represent major public health problems (for review, see Williams[11] and Luzzatto et al.[12]).

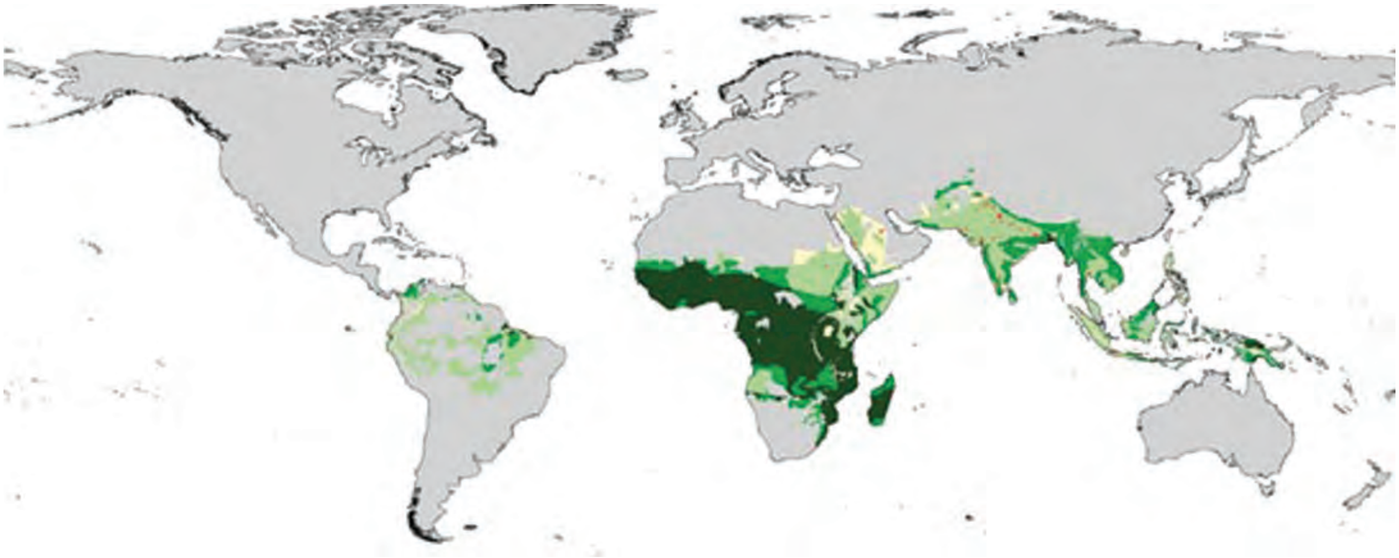

Figure 154.1 GLOBAL MALARIA ENDEMICITY. Areas are colored according to malaria endemicity (prevalence): *light green*, hypoendemic (areas in which childhood infection prevalence is less than 10%); *medium green*, mesoendemic (areas with infection prevalence between 11% and 50%); *dark green*, hyperendemic and holoendemic (areas with an infection prevalence of 50% or more); unclassified areas *(yellow)* represent only 6% of the global population at risk and are caused by discrepancies in recent data. *Gray* areas are a combined mask of areas outside the transmission limits and areas of population density less than 1 person/km^2. *(Data from Snow RW, Guerra CA, Noor AM, et al. The global distribution of clinical episodes of Plasmodium falciparum malaria. Nature. 2005;434:214.)*

Parasitology

In *P. falciparum* (see later for a discussion of the other human parasites) the infective sporozoite forms are inoculated into the bloodstream from the salivary glands of a female *Anopheles* mosquito (Fig. 154.2). These thin, needle-shaped cells, 10 to 12 µm in length, circulate briefly with a half-life of approximately 30 minutes before traversing macrophages and several hepatocytes and ultimately residing in a single hepatocyte.[13] Here rapid multiplication takes place over 5 to 8 days to produce a liver schizont, 80 µm in diameter and containing 30,000 ± 10,000 merozoites that are released into the bloodstream, where they infect erythrocytes.[13] When ready to leave hepatocytes, the parasite induces cell death in the hepatocytes and causes the release of merozoites in membrane-enclosed structures or merosomes that are extruded from the infected cell, thereby avoiding host cell defense mechanisms.[14]

The merozoites bind and then invade red blood cells (RBCs; for review of RBC and merozoite interactions, see Satchwell[15]). The host plasma membrane is invaginated to form the parasitophorous vacuole. For the first 10 hours the developing parasites appear as fine "ring forms." Between 10 and 15 hours the cytoplasm thickens, and 16 hours after invasion, granules of the black pigment hematin, the end product of hemoglobin (Hb) digestion, begin to appear. Ligands are expressed at the surface of the infected RBC that mediate adhesion to host receptors on venular endothelium. These trophozoites no longer circulate throughout the body but are sequestered in the peripheral circulation. Nuclear division begins, at approximately 30 hours, to form schizonts containing up to 32 merozoites. At 48 hours the RBC is ruptured to release the merozoites into the circulation to continue further cycles of asexual multiplication.

The erythrocytic cycle of schizogony may achieve a 10-fold increase in parasitemia in vivo and a patent or microscopically detectable infection 6 days after the liver stage is completed. After two or more cycles the infection becomes clinically apparent by the paroxysms of fever that accompany the release of merozoites. Cycles of schizogony continue until the rate of parasite multiplication is reduced by chemotherapy, specific or nonspecific defense mechanisms, or occasionally the demise of the host.

Some merozoites do not multiply but become committed during the previous erythrocytic cycle to form male or female gametocytes.[16]

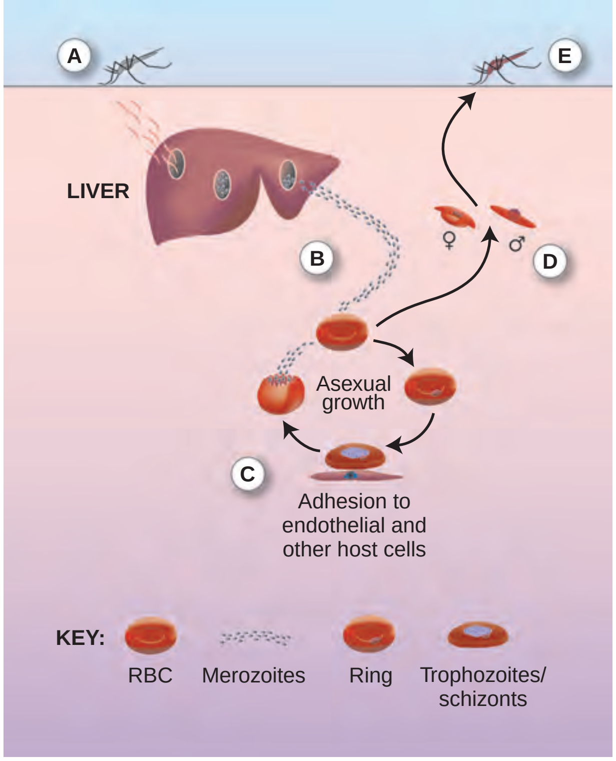

Figure 154.2 *PLASMODIUM* LIFE CYCLE. (A) The asexual life cycle begins when sporozoites from a female mosquito taking a blood meal enter the circulation and invade hepatocytes. (B) Up to 10,000 merozoites are formed. Following rupture of the hepatocyte, infective merozoites are released and invade erythrocytes (red blood cells [RBCs]). (C) Within RBCs, the parasite develops through the stages of rings, trophozoites, and schizonts. Mature schizonts burst to release erythrocytic merozoites that invade new RBCs. (D) A small proportion of merozoites in RBCs transform into male and female gametocytes that are ingested by the mosquito. (E) The male and female gametes fuse and transform into an oocyst, which divides asexually into many sporozoites that migrate to the salivary gland from where they are released during the next blood meal.

Gametocytes are distinguished by dispersed pigment in a single nucleus, in a fully grown parasite, and are sequestered for the first 5 days of their development in the peripheral circulation. Thus 8 to 10 days after the start of clinical infection, mature, crescent-shaped gametocytes appear in the blood.

The sexual phase (or sporogony) of the parasite life cycle begins after a male and female gametocyte are ingested by a feeding female *Anopheles* mosquito. In the midgut of the mosquito the gametocytes shed the RBC membrane. This change is apparently precipitated by the drop in temperature. A female gametocyte forms a single macrogamete, but male gametocytes undergo several rounds of nuclear division to produce flagellated microgametes. These microgametes are motile and migrate to fertilize a macrogamete. The resulting zygote enlarges to form a mobile ookinete and migrates through the epithelial wall of the mosquito midgut to rest finally on the external surface. The oocyst divides repeatedly to form up to 10,000 sporozoites, which travel up through the hemolymph to enter the acinar cells of the salivary glands. Once there, they are infective when injected into the host.

Major differences exist in the life cycles of other human *Plasmodium* spp. First, in *P. vivax* and *P. ovale* infections, some sporozoites entering the liver form dormant hypnozoites that begin to divide only after a variable period of some months to cause further blood-stage infections or relapses. Second, the cycle of erythrocytic development in *P. malariae* takes 72 hours and thus causes quartan fever (i.e., on days 1 and 4).

Pathophysiology of Malarial Anemia

Malaria gives ample reasons for both increased RBC destruction and reduced RBC production (see Fig. 154.3 for overview).

Loss of Infected Erythrocytes

Destruction of RBCs is inevitable as parasites complete their 48-hour growth cycle and lyse their temporary host cell. Some parasites may be removed from erythrocytes as immature ring forms by phagocytic cells, leaving the RBCs with residual parasite antigens to continue to circulate, albeit with reduced survival.[17] Infected erythrocytes may also be phagocytosed by macrophages following opsonization by immunoglobulins and/or complement components.[18,19] Other signals for recognition of infected erythrocytes by macrophages include abnormally rigid membranes and exposure of phosphatidylserine and other altered host antigens and, in animal models of malaria, antiphosphatidylserine antibodies.[20–23]

Loss of Uninfected Erythrocytes

The activity and the number of macrophages are increased in malarial infection, and increased removal of uninfected cells may occur. Moreover, the signals for recognition of uninfected erythrocytes for removal by macrophages are enhanced. Uninfected erythrocytes bind increased amounts of immunoglobulin and/or complement as detected in the direct antiglobulin test (DAT or Coombs test).[21] These antibodies do not have a particular specificity but are more likely to represent immune complexes absorbed onto the surface of RBCs.[21] Furthermore, hemozoin may activate complement directly and cause deposition of C3b on uninfected RBCs.[24] However, an association between positive DAT results and severe anemia has not been established.[25] More recent studies have shown not only that RBCs from patients with malaria were more susceptible to phagocytosis but also that RBCs from children with acute malaria had increased surface immunoglobulin G (IgG) and low levels of RBC CR1 and CD55 compared with control subjects.[26]

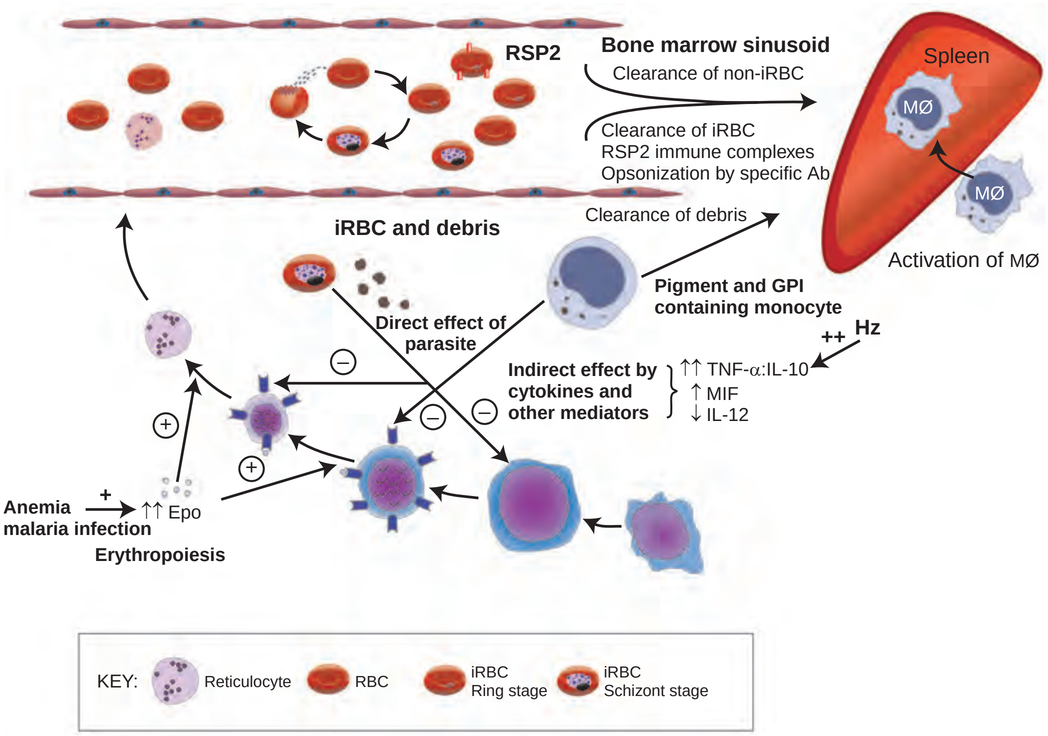

Figure 154.3 PATHOGENESIS OF MALARIAL ANEMIA. Severe malarial anemia is characterized by destruction of infected red blood cells (iRBCs) following schizogony and clearance of both iRBC and uninfected RBCs. During malarial infection, changes in membrane protein composition occur, and the resultant immune complexes of RBC, Ag, and immunoglobulin (e.g., RBC-RSP2-Ig) are cleared by MØ to the spleen, where they become activated. Pigment-containing MØ may release inflammatory cytokines and other biologically active mediators such as 4-hydroxynonenal. MIF may be released by MØ, or a plasmodial homologue may suppress erythropoiesis. Malarial pigment or other parasite products may have a direct inhibitory effect on erythropoiesis. Inhibition of erythropoiesis may occur at one or more sites in the growth and differentiation of hematopoietic progenitors. Both indirect and direct effects may cause suppression of the bone marrow and spleen, resulting in inadequate reticulocyte counts for the degree of anemia. *Ab*, Antibody; *Ag*, antigen; *Epo*, erythropoietin; *GPI*, glycosylphosphatidylinositol anchors of merozoite proteins; *Hz*, hemozoin; *Ig*, immunoglobulin; *IL*, interleukin; *MIF*, macrophage inhibitory factor; *MØ*, macrophages; *RSP2*, ring surface protein-2; *TNF*-α, tumor necrosis factor-α.

Role of the Spleen

Some degree of splenomegaly is a normal feature of malarial infection, and the prevalence of splenomegaly in regions of malarial transmission is used as a major indicator of the level of malarial endemicity. The importance of the spleen in host defense against malaria has been demonstrated in experimental systems, and individuals whose spleens have been surgically removed are thought to be more susceptible to severe infection. Indeed, the phenomenon of parasitic sequestration is thought to have evolved primarily as an immune evasion strategy so the mature parasite can avoid passing through the spleen.[27]

Active erythrophagocytosis is a conspicuous feature within the bone marrow during *P. vivax* and *P. falciparum* malaria,[28,29] and it is highly probable that this also occurs within the spleen. Cytokines may be responsible for activating macrophages during malarial infection. Children with acute *P. falciparum* malaria have high circulating levels of interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α),[30] a synergistic combination of cytokines that activates macrophages.

Researchers in several studies have attempted to define the pathophysiologic changes in the spleen during acute malaria. In animal models, malaria is accompanied by increased intravascular clearance of infected or rigid, heat-treated cells by the spleen,[31] as well as alterations in the splenic microcirculation.[32] In studies of human malaria, it has been found that increased splenic clearance of heated RBCs occurs during acute attacks.[33] Ex vivo models of splenic function suggest that the spleen removes not only mature infected RBCs but also uninfected cells marked for clearance by low deformability, aggregated band 3, complement deposition, or phosphatidylserine exposure. Moreover, "pitting" of ring-stage infected cells may remove the parasite and leave the RBC marked with parasite antigen to return to the circulation (reviewed by White[34]).

Changes to the uninfected RBCs during infection also contribute to their own enhanced clearance by phagocytes. Uninfected RBCs in children and adults with severe disease are less deformable, and this is a significant predictor of the severity of anemia and indeed outcome, consistent with the notion that these cells are being removed by the spleen.[20] It has also been found that IgG-sensitized RBCs are rapidly removed from the circulation by the spleen and that unusually rapid clearance persists well into the convalescent phase.[35]

Thus, all the available evidence points to increased reticuloendothelial clearance in *P. falciparum* malaria, persisting long after recovery. These changes are presumably a host defense mechanism, maximizing the clearance of parasitized erythrocytes. Nevertheless, the contribution of clearance of uninfected erythrocytes to anemia during acute malaria is substantial and it has been estimated that loss of unparasitized erythrocytes accounts for approximately 90% of the drop in Hb resulting from a single infection. The severity and duration of anemia is determined not only by red cell clearance but also by dyserythropoiesis and reticulocytopenia.

Role of Ineffective Erythropoiesis in Severe Malarial Anemia

Reticulocytopenia has been confirmed in numerous clinical studies of malarial anemia.[36–38] The histopathologic study of the bone marrow of children with malarial anemia shows erythroid hyperplasia with increased numbers of erythroid precursors (Fig. 154.4). However, the maturation is abnormal by light and electron microscopy. Abdalla et al.[39,40] described the hallmark characteristics of such abnormal maturation, namely cytoplasmic and nuclear bridging and irregular nuclear outline. They later confirmed that the distribution of the erythroid progenitors through the cell cycle is abnormal in malarial anemia, with an increased proportion of cells in the G_2 phase compared with healthy control subjects.[41] Dörmer et al.[38] confirmed these findings using the same criteria as Abdalla et al.; they studied six patients with falciparum malaria before and after treatment.

Bone marrow dyserythropoiesis persists for many weeks following the start of malaria treatment in acute malaria and reticulocyte counts are therefore low when patients are symptomatic. In such settings, Hb concentration in acute falciparum malaria is lowest around 1 week after presentation with fever,[42] while in acute vivax malaria the nadir in Hb is a few days after presentation.[43] In acute uncomplicated malaria, anemia is worse in younger children and those with protracted infections. In high transmission areas, where previous infections may confer some protection from the effects of infection, Hb concentrations often increase soon after treatment.[44]

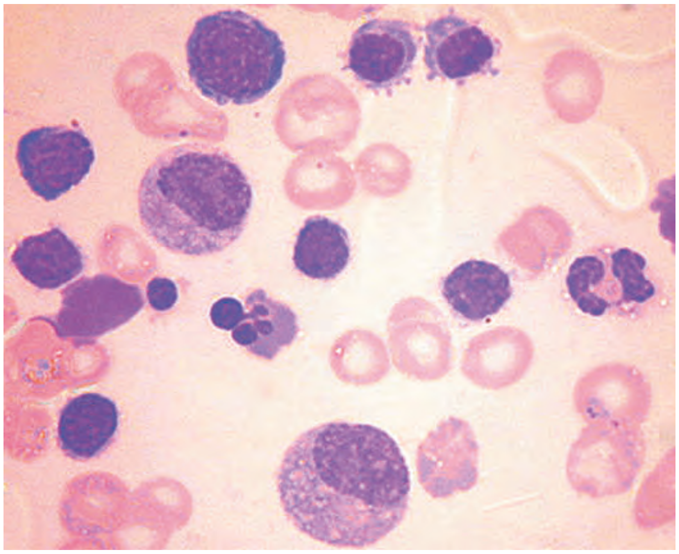

Figure 154.4 BONE MARROW ASPIRATE IN MALARIA. Although erythropoiesis is usually normoblastic in individuals with acute or chronic malaria, the examination of bone marrow frequently shows changes reflecting dyserythropoiesis, such as the irregular nuclei and cytoplasmic bridges in erythroblasts seen in this figure. Two young rings of *Plasmodium falciparum* can be seen in an erythrocyte. *(Courtesy Dr. Saad H. Abdalla.)*

Modulation of Erythropoiesis by Cytokines

Given the importance of erythropoietin (Epo) to erythropoiesis, attention has been focused on the levels of this crucial cytokine in malarial infection. Serum Epo was appropriately raised in studies of African children with malarial anemia, and high levels of this cytokine have been associated with better outcomes of disease.[45,46] African children with severe malaria, particularly young children, were shown to have supraphysiologic levels of Epo compared with age-matched community control subjects with nonmalarial anemia.[47,48] Evidence from some observational clinical studies suggested that these high levels of Epo in children with malarial anemia were associated with a cytoprotective effect and so reduce the risk for neurologic sequelae or death in children with cerebral malaria.[49] Other studies in children over 18 months old with cerebral malaria, showed that high Epo levels were associated with prolonged coma duration and increased mortality.[50] Moreover, clinical studies using Epo as an adjuvant in other neurological diseases have shown that although Epo was associated with some neurological benefits, treatment with Epo increased mortality from other causes. There have been no large-scale trials of recombinant Epo in malaria.

The prime candidates for the host factors mediating dyserythropoiesis are imbalances of TNF-α, IFN-γ, and interleukin-10 (IL-10). The concentrations of TNF-α and IFN-γ have been correlated with the severity of the disease.[51–53] Whereas low concentrations of TNF-α (<1 ng/mL) stimulate erythropoiesis, higher levels of TNF-α have been shown to suppress erythropoiesis.[53] Furthermore, it is possible that high levels of these inflammatory cytokines may contribute to reduced and abnormal production of erythrocytes and also to increased erythrophagocytosis.

Recent evidence has suggested that the release of hepcidin is associated with malarial infection and that high levels of hepcidin could contribute to the sequestration of iron and impair erythropoiesis.[54,55] The stimulus for hepcidin secretion may be proinflammatory cytokines such as IL-6, but malaria-infected erythrocytes may also enhance hepcidin production by peripheral blood mononuclear cells. Intriguingly, hepcidin released during blood-stage parasitemia may be a key regulator of *P. falciparum* liver-stage development.[56] These data now support suggestions from large-scale studies of iron supplementation that iron may be unhelpful and possibly even harmful when given during acute malarial infection. Indeed, there are both clinical and experimental evidence that iron deficiency may confer protection from severe malaria. Malaria parasites show reduced growth in RBCs from subjects with iron deficiency, and infection is augmented during the phase of iron supplementation after severe iron deficiency.[57]

High levels of the T-helper cell type 2 (Th2)-type cytokine, IL-10, might prevent the development of severe malarial anemia. Low levels of IL-10 have been described in African children with severe malarial anemia.[51] Similarly, defective IL-12 production has been shown experimentally to be associated with increased severity of malaria in a rodent model, and low IL-12 levels have been associated with severe malaria in African children.[58] The role of IL-12 in clinical malaria appears complex, but IL-12 and other cytokines may activate adaptive natural killer (NK) cells to reduce parasitemia by antibody-dependent cytotoxicity.[59]

Modulation of Erythropoiesis by Infected Erythrocytes

There is also substantial evidence that lysate of infected erythrocytes may directly modulate the function of host cells. During its blood stage, the malaria parasite proteolyzes host Hb in an acidic vacuole to obtain amino acids, releasing heme as a byproduct, which is auto-oxidized to potentially toxic hematin (aquaferriprotoporphyrin IX [$H_2O\text{–}Fe_{III}PPIX$]). β-Hematin forms as a crystalline cyclic dimer of $Fe_{III}PPIX$ and is complexed with protein and lipid products as malarial pigment or hemozoin. Schwarzer et al.[60,61] showed that the function of monocytes and of monocyte-derived macrophages is severely inhibited after ingestion of malaria pigment or hemozoin.[62,63]

The hemozoin polymer of heme moieties may be complexed with biologically active compounds. The oxidation of membrane lipids catalyzed by the ferric heme produces the lipoperoxides.[61,63] There is accumulating evidence that 4-hydroxynonenal (HNE) and other lipoperoxides, including 15-hydroxyarachidonic acid [15-(*R*,*S*)-HETE], may play a role in the pathophysiology of malaria. It has been shown that HNE and HETE are generated in parasitized erythrocytes and that HNE and endoperoxides produced in pigment-containing monocytes or macrophages may cause cell-cycle arrest and impair erythroid growth.[63,64] Hemozoin may also directly inhibit erythroid development in vitro and cause apoptosis of erythroid precursors.[65] Furthermore, increased levels of plasma hemozoin and pigment in monocytes have been associated with anemia.[49]

Modulation of Erythropoiesis by Infection

In children presenting with acute malaria, bacteremia is associated not only with anemia but also with excess mortality.[66] Malaria infection is particularly associated with non-typhi salmonella bacteriemia, due at least in part to impaired neutrophil function.[67]

Parvovirus B19 may cause a transient reticulocytopenia and thus severe and sudden anemia in those with a hemolytic anemia or fetal anemia and intrauterine death. Most children in Africa have serologic evidence of infection early in life. However, acute infection with this virus is uncommon in those presenting with severe malarial anemia,[46] and a recent parvovirus B19 infection and falciparum malaria appear to be independent risk factors for anemia in children in Africa.[68]

Prevalence and Etiology of Anemia in Low-Income Countries

In endemic areas the etiology of anemia is complex. Acute or chronic malarial infection is a major precipitating factor in children with severe anemia causing admission to hospital.[47]

Longitudinal studies from The Gambia have shown that whereas the mean Hb levels in children vary significantly through the year, anemia is much more common in the rainy season, when malaria transmission is at its highest.[69] However, the rains are also associated with an increase in waterborne diarrheal disease and poor food supplies. So the seasonal increase in anemia in malaria-endemic areas arises on a background of low or frankly deficient stores of hematinics and/or other micronutrients. Iron deficiency, which affects at least 20% of the world's population, is a major factor in the seasonal surge of anemia in the tropical rainy season. Low iron stores at birth and dietary iron deficiency may be exacerbated by hookworm or schistosomal infection. It is now also clear that malarial infection is associated with reduced uptake of available iron and reduced incorporation of iron into developing erythroid cells.[54,55] Folate deficiencies and/or increased requirements may occur in many populations, although frank folate deficiency is uncommon.

A low baseline Hb level at the start of the season for malaria transmission is a major risk factor for developing severe malarial anemia and has encouraged studies aimed at preventing the development of anemia by hematinic supplementation with or without antimalarial prophylaxis or surveillance.[70]

Quantifying the contribution of these individual factors to anemia reliably requires intervention studies. In Tanzania, Menendez et al.[71] and Schellenberg et al.[72] have shown that iron supplementation and antimalarial prophylaxis prevented 30% and 60%, respectively, of all cases of moderate anemia presenting during the malaria transmission season in children and in infants.

Translating the results of these studies from well-defined and carefully controlled study areas has not been easy. Considerable concerns about iron supplementation programs for children have been raised in sub-Saharan Africa and in areas of high malaria endemicity. One large trial of iron supplementation was stopped because of increased hospital admission and death in the group receiving iron. However, meta-analysis of iron supplementation in malaria-endemic areas has shown that iron alone or with antimalarial treatment does not increase the risk for clinical malaria or death when regular malaria surveillance and treatment services are provided.[73] It is increasingly clear that iron supplementation in these areas must be based on either defining iron-deficient children or combining iron administration with effective infection control and treatment strategies.[73,74]

Features of Malarial Anemia

Spectrum of Disease Caused by Malarial Infection

The signs and symptoms of malarial infection in humans are caused by the asexual blood stage of the parasite. Infection with blood-stage parasites may result in a wide range of outcomes and pathologic conditions. Indeed, the spectrum of severity ranges from asymptomatic infection to rapidly progressive, fatal illness. The clinical presentation of malarial infection is also wide and influenced by age, immune status, and pregnancy, as well as by the species, genotype, and perhaps the geographic origin of the parasite. In endemic areas, many infections present as an uncomplicated febrile illness. In more severe forms of the disease, children may present with prostration or inability to take oral fluids, or in younger children an inability to suckle. Alternatively, these children may exhibit a number of syndromes of severe disease, including anemia, coma, respiratory distress, and hypoglycemia and may also have a high rate of bacteremia.[66,75]

In most age groups, anemia is frequently accompanied by more than one syndrome of severe disease, and the already substantial case fatality rate of 15% to 20% for severe malaria in African children rises significantly when multiple syndromes of severe disease are present.[75] The age distribution of anemia and other syndromes of severe disease is a consistent but puzzling feature of the epidemiology of clinical malaria. Children born in endemic areas are protected from severe malaria in the first 6 months of life by the passive transfer of maternal immunoglobulins and by fetal Hb. Beyond infancy, the most common form of presentation of severe disease changes from anemia in children aged 1 to 3 years old, in areas of high transmission, to cerebral malaria in older children, in areas of lower transmission.[44,76] As transmission intensity declines further, severe malaria is most frequently found in older age groups.

Clinical Features of Malarial Anemia

The blood stage of falciparum malaria may cause life-threatening anemia; an Hb level of less than 5 g/dL is considered to represent severe disease. Children with anemia may present with malaise, fatigue, and dyspnea or respiratory distress, which usually represents metabolic acidosis, but in an ill child acute respiratory infection must be carefully excluded.[75,77]

Acidosis is due largely to excessive lactic acid and other anions. Salicylate toxicity and dehydration may also play a role. However, the majority of children presenting with respiratory distress are severely anemic, have a metabolic acidosis secondary to reduced oxygen-carrying capacity, and respond to rapid transfusion of fresh blood.[78]

A minority of those with respiratory distress do not respond to appropriate resuscitation. They probably represent a heterogeneous clinical group and may have renal failure, systemic bacterial infection, or a more profound syndrome of systemic disturbance caused by malarial parasites.

Resuscitation of children with anemia and/or severe metabolic problems must be conducted carefully. Fluid boluses given to African children with shock and life-threatening infections showed somewhat surprisingly that rapid infusion of crystalloids or albumin (20 to 40 mL/kg) significantly increased 48-hour mortality in these critically ill children with impaired perfusion.[79] The TRACT trial has recently provided additional evidence for management of severe anemia and shown that conservative management of uncomplicated severe anemia (Hb 40 to 60 g/L) is safe, if children are reviewed regularly. The trial showed that severely anemic children without fever can be safely transfused with 30 mL/kg of blood but a blood infusion of 20 mL/kg is needed for safe transfusion of febrile children with severe anemia (see box on Transfusion Management of Severe Anemia in African Children.).[80,81] Fluid resuscitation and blood transfusion must be carefully supervised, and it may be relevant that after transfusion in children with acute malarial anemia, BNP levels are high in children with severe malarial anemia suggesting that cardiac function may be compromised and should be carefully monitored during fluid and blood therapy for acute malaria.[82]

Hemolytic Syndromes, Including Blackwater Fever

The sudden appearance of Hb in the urine, indicating severe intravascular hemolysis leading to hemoglobinemia and hemoglobinuria or blackwater fever, received particular attention in early studies of anemia in expatriates living in endemic areas. There was an association between blackwater fever and the irregular use of quinine for chemoprophylaxis. This drug can act as a hapten and stimulate production of a drug-dependent, complement-fixing antibody. Recent studies of sudden intravascular hemolysis have shown that it is rare in Africa but more common in Southeast Asia and Papua New Guinea, where some cases are associated with G6PD deficiency and treatment with a variety of drugs, including quinine, mefloquine, and artesunate.[83] Treatment with artesunate frequently induces anemia without induction of antibodies. Post-artesunate delayed hemolysis (PADH) occurs in 40% of returning travelers with severe malaria treated with artesunate, occurring more commonly in patients of European than of African origin.[84] Hemolysis is largely, but not entirely, due to clearance by splenic macrophages of once-infected cells that may circulate for many days after removal of the ring-stage parasite from red cells. The once-infected cells retain several parasite proteins, including histidine-rich protein-2. Post-artesunate hemolysis is associated with increased levels of this protein, which can be detected by testing at 1:500 dilution of blood with the rapid diagnostic dipsticks for HRP-2 antigen.[85]

TRANSFUSION MANAGEMENT OF SEVERE ANEMIA IN AFRICAN CHILDREN

The Phase III Transfusion and Treatment of severe anemia in African Children Trial (TRACT) showed:

- conservative management of uncomplicated severe anemia [hemoglobin (Hb) 40–60 g/L] was safe
- transfusion volume (20 vs. 30 mL/kg whole blood equivalent) for children with severe anemia (Hb <60 g/L) had strong but opposing effects on mortality, depending on fever status (>37.5°C).

In 2020 a stakeholder meeting of pediatric and blood transfusion groups from Africa reviewed the results and additional analyses and concluded:

- the definition of severe anemia can be standardized as Hb <60 g/L
- children with uncomplicated severe anemia do not require immediate transfusion, but do require monitoring because ~50% will develop severe and life-threatening anemia requiring subsequent transfusion
- clinical and Hb monitoring reviews are needed in a child with severe anemia (both uncomplicated and complicated) to identify those needing transfusion
- the most effective and safest volume of blood for transfusion depends on the axillary temperature when a blood transfusion is ordered
  - if temperature is equal to or <37.5°C then transfuse 30 mL/kg whole blood or 15 mL/kg red cell concentrate
  - if temperature is >37.5°C then transfuse 20 mL/kg whole blood or 10 mL/kg red cell concentrate
- there is no need for separate recommendations for children with malaria (even those with high parasite burdens)
- optimal transfusion of SCD patients or of children with poor nutritional status may need further specific studies.

Hematologic Features of Malarial Infection

The anemia of falciparum malaria is typically normocytic and normochromic, with a notable absence of reticulocytes, although microcytosis and hypochromia may be present because of the very high frequency of α- and β-thalassemia traits and/or iron deficiency in many endemic areas.[47,69]

The anemia of malaria may be accompanied by changes in the white cell and platelet counts and in clotting parameters, but these changes are not in themselves diagnostic, nor do they guide management. Malaria is accompanied by a modest leukocytosis, although leukopenia may also occur. Occasionally, leukemoid reactions have been observed. Leukocytosis has been associated with severe disease.[86] A high neutrophil count may also suggest intercurrent bacterial infection. Monocytosis and increased numbers of circulating lymphocytes are also seen in acute infection, although the significance of these changes is not established. However, malarial pigment is often seen in neutrophils and in monocytes and has been associated with severe disease and unfavorable outcome.[87,88]

Thrombocytopenia is almost invariable in malaria and so may be helpful as a sensitive but nonspecific marker of active infection. However, severe thrombocytopenia (platelet count $<50 \times 10^9$/L) is rare. Increased removal of platelets may follow absorption of immune complexes or platelet activation, but there is no evidence for platelet-specific alloantibodies. Thrombocytopenia has not generally been associated with disease severity, although platelets have been shown to contribute to disease pathology in both animal and human malaria.[89] Moreover, in human infections, platelets may form clumps with infected erythrocytes.[90] One explanation of inconsistent relationships reported between the severity of malaria and the thrombocytopenia may be that findings of low levels of platelets might not only be a marker of parasite burden but also be protective from severe disease as parasite growth is inhibited by physiological concentrations of platelets.[91,92] Platelet factor 4 may bind to and enter malaria-infected RBCs and induce cell death of intra-erythrocytic parasites.[93]

Disordered coagulation and clinical evidence of bleeding are not infrequent in nonimmune adults contracting malaria and presenting with severe disease. Patients may present with bleeding at injection sites, gums, or epistaxis. Abnormal results of laboratory tests for hemostasis, suggesting activation of the coagulation cascade, occur in acute infection. However, histologic evidence of intravascular fibrin deposition is notably absent in adults dying as a result of severe malaria.[94] Factor XIII, normally responsible for cross-linking fibrin, is inactivated during malarial infection, and these data may explain low levels of fibrin deposition in the face of increased procoagulant activity.[95]

During acute disease the levels of a disintegrin and metalloproteinase with thrombospondin motif 13 (ADAMTS13) protease are moderately reduced, and the concentration of high-molecular-weight von Willebrand multimers is increased, but the role of this adhesive pathway in the etiology of severe and cerebral malaria has not been established. Infected RBCs from different isolates or clones may variously bind to a series of endothelial receptors including CD36 and ICAM-1. Adhesion of infected RBCs to the endothelial receptor for protein C is associated with cerebral malaria and may induce endothelial activation and brain swelling.[96]

The bone marrow is typically hypercellular. The most striking findings are of grossly abnormal development of erythroid precursors or dyserythropoiesis. The developing erythroid cells typically demonstrate cytoplasmic and nuclear bridging and irregular nuclear outline.[39,40] These changes are probably central to the pathophysiology of malarial anemia and are discussed in detail later. The proportion of abnormal erythroid precursors and the degree of dyserythropoiesis are markedly greater in chronic compared with acute infection, suggesting that the inhibition and abnormal maturation of erythroid precursors may have somewhat differing etiologies in acute and chronic infection.[39]

The role of hematinic deficiency in children presenting with malaria and anemia may be difficult to assess. The relative importance of absolute and functional iron deficiency have not been defined. Iron will not be absorbed during acute infection, because hepcidin levels are raised.[54,55] Nevertheless, many hospitals give a course of iron supplementation after an episode of acute malaria, although no general guidelines have been established. Chronic hemolysis may increase folate requirements, but frank deficiency is uncommon in children presenting with acute malaria, at least in East Africa.[47] Folate deficiency may be more common in West Africa, and protocols for folate supplementation after malaria must reflect local experience.

Malarial Anemia in Pregnancy

Pregnancy is accompanied by a series of physiologic changes that predispose not only to anemia but also to malaria. Hemodilution causes a physiologic decrease in Hb. Moreover, the demand for both iron and folate increases as the fetus grows and often precipitates frank folate or iron deficiency, particularly in multigravid women.

Occult malarial infection, often without fever, may cause anemia and placental dysfunction. This effect is greatest in primigravidas and has been attributed to the adhesion of parasitized erythrocytes to chondroitin sulfate A and hyaluronic acid in the placenta[97,98] (for review, see Rogerson et al.[99]). Fetal growth is impaired, and babies born to women with placental malaria are, on average, 100 g lighter than those born to women without malaria. The subsequent contribution of malaria to infant mortality is substantial.[100] Furthermore, the increase in hematopoiesis demanded by hemolysis during malarial infection may precipitate frank folate deficiency. Finally, women who are not immune to malaria are more likely to develop hypoglycemia and pulmonary edema during pregnancy. The increase in maternal and fetal morbidity and mortality secondary to malaria may be prevented by routine hematinic supplementation, implementation of insecticide-impregnated bed-nets, and by intermittent treatment with antimalarials during the second and third trimesters with sulfadoxine-pyrimethamine (Fansidar) where parasites remain sensitive to this combination, dihydroartemisinin-piperaquine in Africa and areas of drug resistance to sulphadoxine-primethamine.[101]

Hyperreactive Malarial Splenomegaly

Although splenomegaly secondary to malarial infection usually regresses as immunity is acquired, some people living in endemic areas develop progressive, massive splenomegaly.[102] The pathophysiology of such hyperreactive malarial splenomegaly (HMS) is poorly understood but certainly results in B-cell hyperplasia with high levels of polyclonal IgM, reaching a level greater than two standard deviations (SDs) above the local reference mean. The specific antimalarial antibody titer is high, although only a small proportion of the polyclonal IgM response is directed at malarial antigens. B-cell hyperplasia may provoke proliferation of both T cells and macrophages, and IgM levels may cause cryoglobulinemia and stimulate erythrophagocytosis.

Patients may present typically between 20 and 40 years old, with massive splenomegaly without lymphadenopathy, anemia that may be severe, neutropenia, and thrombocytopenia. The anemia may cause life-threatening hemolytic crises and/or neutropenia associated with severe bacterial infection. Thrombocytopenia is rarely symptomatic. The bone marrow shows hypercellularity, with a lymphocytosis in marrow and peripheral blood. The high IgM levels distinguish HMS from chronic lymphocytic leukemia or other lymphoproliferative disorders. However, the polyclonal proliferation of B cells may transform to a true clonal lymphoproliferative disorder. This appears to be derived from a naive B cell, although the exact classification of such lymphoproliferative disorders is poorly defined[103]; however, there is a single report of a high incidence of B prolymphocytic leukemia in one population.

Treatment for HMS is lifelong antimalarial prophylaxis. Signs and symptoms usually subside over 1 to 2 years, but relapse may occur if antimalarial therapy ceases. Splenectomy is contraindicated because it is technically difficult, with considerable intra-operative mortality, and it may predispose to severe infection (for review see Leoni et al.[104]).

Anemia and *P. vivax*, *P. ovale*, and *P. malariae* Infection

In *P. vivax* and *P. ovale* malaria, high parasitemias are rare because invasion of erythrocytes is limited to reticulocytes. However, there is an emerging consensus that *P. vivax* monoinfection may cause severe disease with cerebral malaria and/or anemia (for review, see Price et al.[105]). The vivax-infected RBC can adhere to host cells, but sequestration in the peripheral circulation and organ-specific syndromes of disease are much less common than in falciparum malaria.

P. vivax malaria has been associated with anemia during pregnancy and with low birth weight of children of affected mothers. Here cytokines or other inflammatory mediators appear to cause placental dysfunction.[99,105] *P. malariae* infection is also rarely fatal but is distinguished by the persistence of blood-stage parasites for up to 40 years. It can, however, cause a progressive and fatal nephrotic syndrome.[106]

Malaria Diagnosis

The diagnosis of malaria is based on the identification of circulating blood-stage parasites. The standard methods of preparing thick and thin films are straightforward and allow a simple method to diagnose infection (Table 154.1).[107–110] However, malaria diagnosis poses particular problems for inexperienced staff. The main biologic problem is that the level of circulating parasites is only weakly associated with the overall parasite burden because falciparum-infected erythrocytes

TABLE 154.1 Malaria Diagnosis

- Thick and thin films should be prepared for cases of suspected malaria.
- Immunochromatographic tests lack sensitivity to detect low levels of parasites that may be highly clinically significant.
- Routine Giemsa or May-Grünwald-Giemsa stains are unlikely to give satisfactory results because the pH is too low.
- Films can be stained with Giemsa or Leishman stain (thin films) or Field stain (thick films). (For details, see Bailey JW, Williams J, Bain BJ, et al. Guideline: the laboratory diagnosis of malaria. *Br J Haematol*. 2013;163[5]:573. doi: 10.1111/bjh.12572.)
- Two hundred high-power fields (×100 objectives) should be examined in a thick film.
- Asexual parasitemia should be reported after counting 1000 RBCs in a thin film. A graticule or grid may help counting.
- If parasitemia is less than 1:1000 RBCs, parasitemia may be counted in a thick film in relation to the number of WBCs.
- During active infection, a daily parasite count should be obtained.
- Counting and species determination of malaria parasites should be verified by a second observer.
- Reports on negative films despite a strong clinical suspicion of malaria should be qualified that negative films do not exclude a diagnosis of malaria. Repeat films should be requested if clinically appropriate. Thrombocytopenia may heighten suspicion of malaria.

RBC, Red blood cell; *WBC*, white blood cell.

are sequestered in capillary venules; thus the parasitemia is not a reliable guide to the severity of disease. Second, missing or delaying the diagnosis of falciparum malaria may result in serious morbidity and mortality. Finally, the most sensitive methods for diagnosis of infection, namely microscopy, require both skill and time.

In endemic areas, laboratory staff are skilled at the examination of thick films and routinely are able to detect 1 parasite in 100 high-power fields of a thick film, which corresponds to a sensitivity of approximately 5 to 50 parasites/μL.[107,111] Thin films are used for determining the species of the parasites, and the circulating asexual forms of the four main malaria species can be readily identified, whereas the sexual forms (gametocytes) of the species require some skill and regular practice (Figs. 154.5 and 154.6).

Nevertheless, diagnosis of malaria by microscopy in nonendemic countries has proven problematic. Routine laboratories may only achieve sensitivities of the order of 500 parasites/μL using thick films.[111,112] Quality assurance schemes show that performance of routine hematology laboratories in the recognition of and species determination of malaria parasites is poor.[109,112]

There has therefore been a strong drive to use nonmicroscopic methods for malaria diagnosis. Until recently, it has been the received wisdom that these methods are not sufficiently sensitive for clinical diagnosis but may have a role in detecting parasites of more than 500 parasites/μL when experienced staff are not available and/or as part of an out-of-hours service. However, advances in rapid antigen tests and in loop-mediated isothermal amplification (LAMP) amplification of deoxyribonucleic acid (DNA) have brought modern technology closer to an established role in the laboratory service and have enabled a significant change in practice where resources are limited.[113,114] Operationally, this means that hematology laboratories need to make the diagnosis of malaria and must maintain the skills needed for reliable examination of thick films.

A number of methods based on the fluorescent staining of parasite DNA and/or ribonucleic acid (RNA) and the concentration of parasites have been devised. However attractive these methods may appear, their sensitivity is limited by background staining of cellular debris, and the limit of their sensitivity is approximately 100 parasites/μL The time taken in preparing samples and the specialized equipment and skills needed to use these methods limit their effectiveness in routine practice (for review see Amir[115]).

Detection of circulating malarial antigens by rapid diagnostic tests (RDTs) is another potentially attractive alternative to the laborious method of screening blood films. There are over 200 different RDT brands that utilize three antigens, namely, Plasmodium histidine-rich protein 2 (PfHRP-2), Plasmodium lactate dehydrogenase (pLDH), and Plasmodium aldolase (pALDO). pfHRP-2 is produced exclusively by *P. falciparum* and the assay is very Pf sensitive, but an alternative antigen(s) is needed in areas where *P. vivax* is more common. The sensitivity of these immunochromatographic tests decreases with low parasitemia (<100 parasites/μL), genetic variability of the antigen(s) including deletion of PfHRP-2, and prozone effect when the parasitemia is over 4%.[113] The formulation of the tests using dipstick antigens allows rapid testing to be performed by laboratory staff. However, the sensitivity is variable and may range from 100 to 1000 parasites/μL, and this is comparable to the sensitivity achieved by inexperienced microscopists and may approach that achieved by experienced microscopists.

In lower- and middle-income countries, RDTs have allowed change in strategy from empiric treatment of a febrile child for malaria to parasitological diagnosis before therapy, with guidance to confirm RDT diagnoses with microscopy. WHO malaria treatment guidelines now recommend against routine presumptive treatment unless strong clinical suspicion of a severe disease without the opportunity for a timely laboratory diagnosis. The current recommendations for malaria diagnosis in the United Kingdom emphasize that the optimum diagnostic procedure is examination of thick and thin blood films by an expert to detect and speciate the malarial parasites. The sensitivity of RDTs is highest for *P. falciparum* and *P. vivax* malaria. However, RDTs for other *Plasmodium* species are not as reliable.[116]

Amplification of circulating parasite DNA using the repeated ribosomal RNA (rRNA) genes is an extremely sensitive method of malaria diagnosis.[117] The sensitivity may be as low as 0.005 parasites/μL or 5 parasites/mL.[118,119] Undoubtedly, this is a useful tool for reference laboratories and epidemiologic surveys. LAMP amplification of parasite DNA is more sensitive than RDTs but less sensitive than conventional polymerase chain reaction (PCR) at low-level parasitemia. LAMP tests require DNA extraction and some basic molecular techniques and so are unlikely to replace RDTs and microscopy in the point-of-care diagnosis for suspected cases of malaria but may be suitable for epidemiological surveys of asymptomatic infection.[114]

Management of Malaria

Malaria requires urgent effective chemotherapy to prevent progression of disease and may be the most crucial public health intervention to reduce global mortality from malaria. The drug treatment of malaria must take account of the expected pattern of drug resistance in the area where infection was contracted, the severity of clinical disease, and the species of parasite. The spread of drug-resistant parasites and the optimal use of affordable, effective drugs are of continual concern, and these have recently been reviewed (Table 154.2).[117,120,121]

Artemisinin-based combination treatments have been the mainstay of treatment for falciparum malaria in Southeast Asia for more than 15 years and are now recommended as first-line treatment throughout the rest of the world.[122] However, resistance to these drugs is emerging, and very young children (particularly those underweight for age), patients with high parasitemias, and patients in very low transmission intensity areas with emerging parasite resistance are at risk for treatment failure and should be monitored closely.[120,121] The hematologic side effects of antimalarial drugs in use today are few. Amodiaquine is associated with neutropenia and agranulocytosis. Artemisinin-based treatments may cause reticulocytopenia and hemolysis in approximately 10% to 15% of patients following intravenous artesunate treatment (see above).[84,85] High levels of circulating PfHRP-2 predict late hemolysis and memoglobin concentrations should be checked approximately 14 days following treatment in those treated with intravenous artemisinins.[85,117]

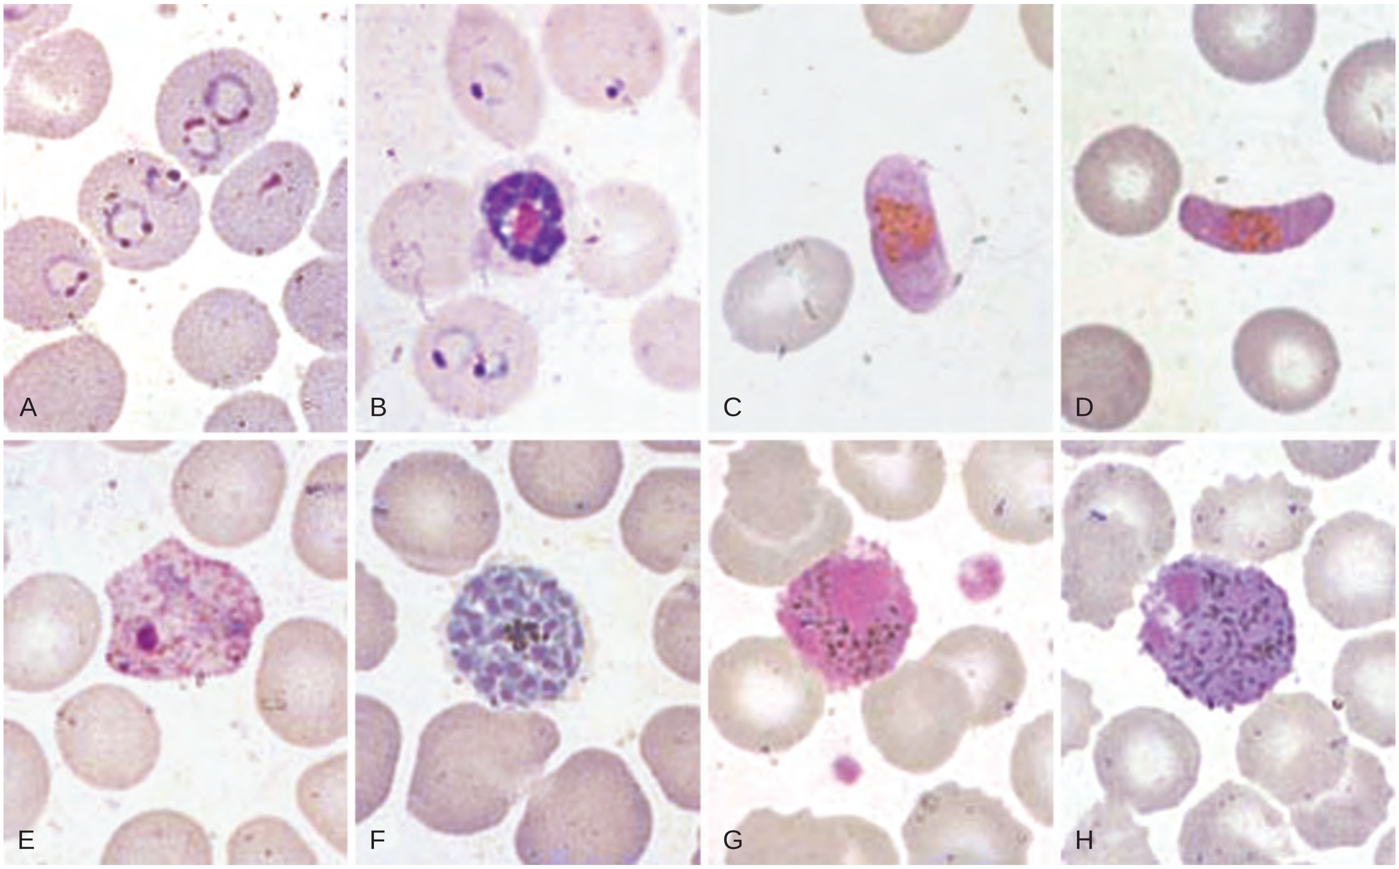

Figure 154.5 BLOOD-STAGE MALARIA (THIN BLOOD FILMS). *Plasmodium falciparum:* Fine rings (A) predominate, with mature trophozoites and schizonts (B) appearing uncommonly in the peripheral circulation because infected cells adhere to postcapillary venules. Host cells are not enlarged. Basophilic clefts and spots of irregular shape and size (Maurer clefts and dots) may be seen in erythrocytes containing more mature parasites. They are thought to be aggregates of parasite proteins that are being exported from the parasite to the surface of the red cell. Crescent-shaped male (C) and female (D) gametocytes are diagnostic. *Plasmodium vivax:* All stages of asexual parasites, from young trophozoites (E) to schizonts, appear in the peripheral circulation in vivax malaria together with gametocytes. The parasites are large and ameboid and produce schizonts with approximately 16 daughter cells (merozoites) (F). Pigment is well developed. Host red cells are enlarged and uniformly covered with fine eosinophilic stippling (Schüffner dots). Gametocytes are round, with the male (microgametocytes; G) being approximately 7 μm and the female (macrogametocytes; H) being 10 μm or more in diameter. *Continued*

In severely ill patients, good nursing care is vital. Monitoring and treatment of fits and hypoglycemia are essential, and antipyretics should be given. Certainly, blood transfusion is required for the treatment of severe malarial anemia,

A consensus has emerged following the TRACT trial (see box on Transfusion Management of Severe Anemia in African Children).[80,81] Children with uncomplicated severe anemia do not require immediate transfusion and should be monitored as half these children will develop severe and life-threatening anemia requiring subsequent transfusion. The most effective and safest volume of blood for transfusion for afebrile children is 30 mL/kg whole blood and for febrile children is 20 mL/kg whole blood. Longer-storage RBC units are not inferior to shorter-storage RBC units for tissue oxygenation as measured by reduction in blood lactate levels and improvement in cerebral tissue oxygen saturation among children with severe anemia.[82]

Whatever clinical guidelines emerge, in reality blood transfusion in the heartland of malaria-endemic areas is beset by many practical and theoretic problems. First, the absence of well-characterized donor panels (and thus systematic blood collection) frequently jeopardizes the supply of blood. Second, even when standard screening for human immunodeficiency virus (HIV) is in place, the residual risk for viral transmission in the serologic window of infectivity varies from country to country but recent estimates are that the risks remain for HIV at 1 in 3000 to 1 in 16,000, for hepatitis C 1:200 to 1:5000, and hepatitis B 1:400 to 1:2000.[123] At a practical level, positive indirect antiglobulin test results in the setting of acute infection may make the exclusion of alloantibodies difficult. Depending on the clinical urgency and transfusion history, the least serologically incompatible blood may have to be given.

One therapeutic option available in North America and in Europe for the urgent treatment of nonimmune patients with severe disease would be an exchange blood transfusion. This procedure removes non-sequestered, infected erythrocytes but there are no randomized trials supporting the use of exchange transfusion in malaria. Some experts have suggested that this treatment could be given for hyperparasitemia (>20%) in severely ill nonimmune patients, but there is doubt whether this rationale is still relevant when artesunate kills circulating, non-sequestered ring-stage infected erythrocytes.[44,124] The salient features that make this clinical problem a major public health concern are the very large numbers of children affected and the difficulty of satisfactory treatment by blood transfusion outside specialist centers.

Malaria as a Transfusion-Transmitted Infection

Malaria is undoubtedly the most common transfusion-transmitted infection in the world. In endemic areas a large proportion of adult donors will be parasitemic, perhaps 20% to 80%, depending on the rate of transmission. Here donor deferral is impractical, and treatment of recipients with a course of effective antimalarials is the most

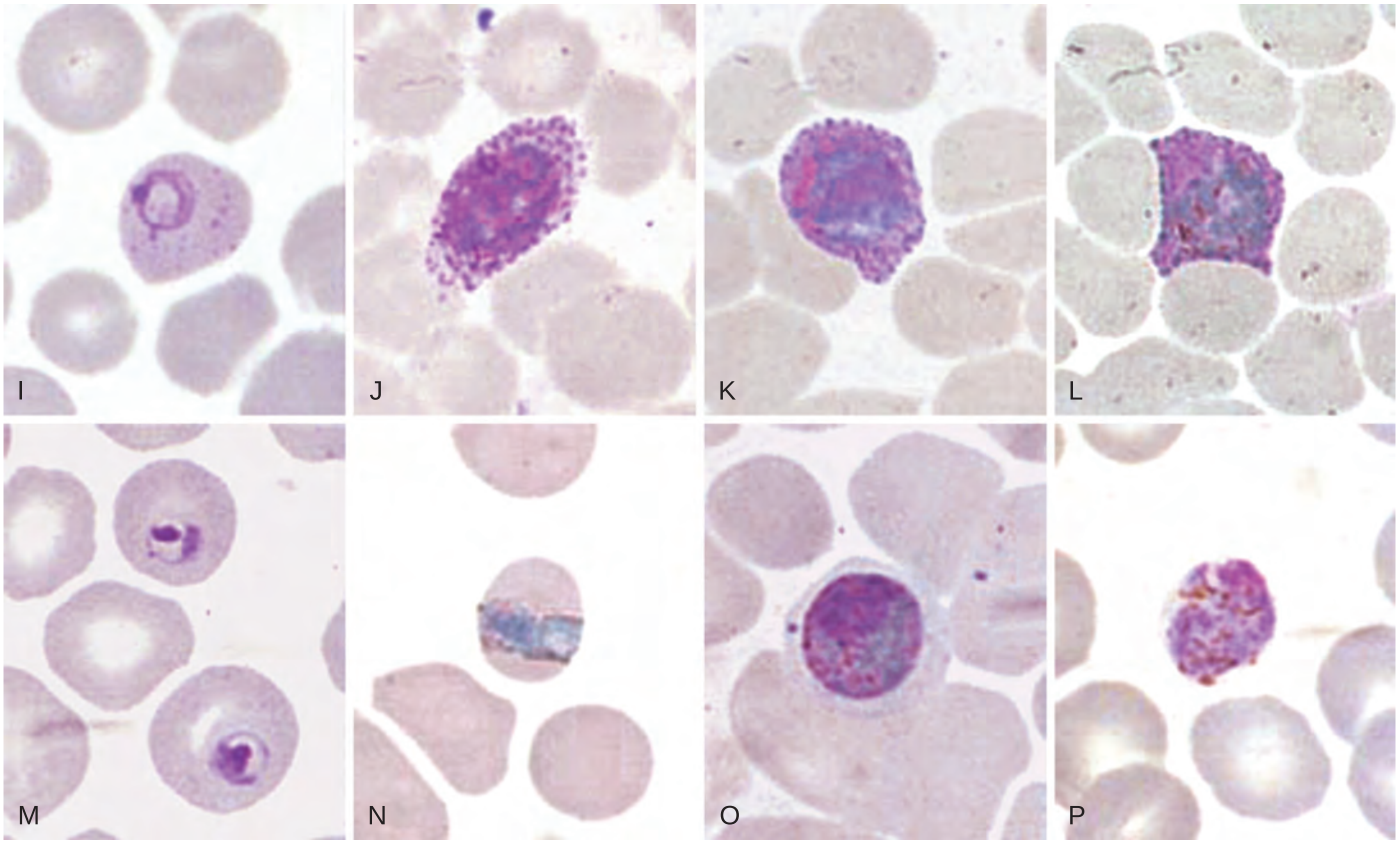

Figure 154.5 cont'd *Plasmodium ovale:* Intraerythrocytic ring forms (I) have a prominent nucleus. The older parasites (J) differ from *P. vivax* in being more compact and producing about eight merozoites at schizogony. Like *P. vivax*, the host red cells contain Schüffner dots and tend to be ovoid and fimbriated. Male (microgametocytes) and female (macrogametocytes) gametocytes (K and L) are smaller than those of *P. vivax. Plasmodium malariae:* All intraerythrocytic stages may appear in the peripheral circulation, from young trophozoites (M) to compact schizonts with eight merozoites. Band forms (N) stretching across the red cell are common. With special staining, a very fine stippling (Ziemann dots) is sometimes seen. Host red cells are not enlarged. Gametocytes, no larger than their host cells, are round and compact with distinct blackish pigment, being finer in the males (O), in which the nucleus is more diffuse and the cytoplasm somewhat mauvish, whereas the granules are fewer and larger in the female (P), which stains a bluer color.

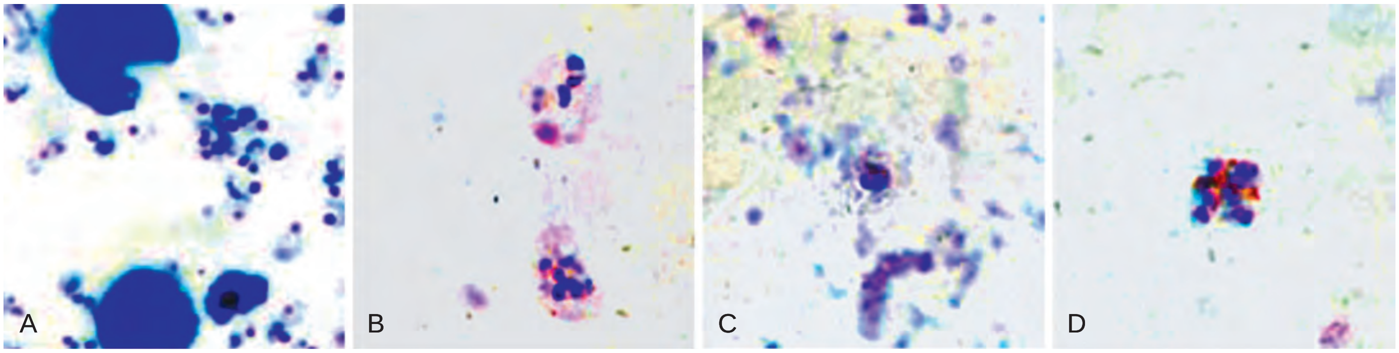

Figure 154.6 BLOOD-STAGE MALARIA (THICK BLOOD FILMS). *Plasmodium falciparum:* Usually only young rings (A) are seen in acute infections, although sometimes in very large numbers. *Plasmodium vivax:* All stages may be present; here two young trophozoites are seen (B), with Schüffner dots seen as "ghost cells" in the thinner parts of the film where the host cell has been hemolyzed. *Plasmodium ovale:* The Schüffner dots of *P. ovale* also may show up in a thick film as a ghost cell, but the parasite can be distinguished from *P. vivax* by the solid appearance and heavy pigment even of young trophozoites (C). *Plasmodium malariae:* Younger parasites can be recognized by their heavy pigment, but this may be so heavy that it obscures the other inner structures. Schizonts containing up to eight merozoites with a central mass of pigment (D) are characteristic. *P. malariae* is difficult to differentiate from *P. ovale* in thick films, in which the parasites are easily confused. However, unlike *P. malariae, P. ovale* may be seen in ghost cells (C).

practical alternative. In nonendemic areas, transmission of malaria is an occasional but potentially devastating complication of blood transfusion, and considerable thought and resources are required to combat the problem effectively.

The first case of transfusion-transmitted malaria (TTM) was in 1911.[125] Between 1911 and the mid-1970s the incidence of TTM rose to more than 140 cases per year, with *P. vivax* the most common species causing infection, although the proportion of cases from *P. falciparum* has steadily increased, perhaps reflecting the speed and destination of international travel. It is striking that the background problem, namely malaria in returned travelers, is much more common in the United Kingdom than in the United States, with the per

TABLE 154.2 **Commonly Used Antimalarial Drugs and Their Side Effects**

	Oral Dose	Parenteral Dose	Side Effects
Sulfadoxine-pyrimethamine	Sulfadoxine 25 mg/kg Pyrimethamine 1.25 mg/kg as a single dose (maximum 1500 mg sulfadoxine and 75 mg pyrimethamine)	For IM injection, doses as for oral	Use with caution in first trimester Causes kernicterus in neonates Skin rashes, fatal Stevens–Johnson syndrome
Artemether	3.2 mg/kg day 1 1.6 mg/kg days 2–7	3.2 mg/kg IM day 1, then 1.6 mg/kg for 3 days, then oral	Reticulocytopenia
Artesunate	4 mg/kg once daily for 7 days	2.4 mg/kg IM day 1, then 1.2 mg/kg for 3 days, then oral	Reticulocytopenia
Artemether/lumefantrine	Fixed-dose combination: artemether (20 mg) with lumefantrine (120 mg), adults give 4 tablets initially, followed by 5 further doses of 4 tablets each given at 8, 24, 36, 48, and 60 h (total 24 tablets over 60 h) If 5–15 kg, then 1 tablet initially followed by 5 further doses of 1 tablet each, given at 8, 24, 36, 48, and 60 h (total 6 tablets over 60 h); 15–25 kg, then 2 tablets initially, followed by 5 further doses of 2 tablets each given at 8, 24, 36, 48, and 60 h (total 12 tablets over 60 h); body weight 25–35 kg, 3 tablets initially, followed by 5 further doses of 3 tablets each given at 8, 24, 36, 48, and 60 h (total 18 tablets over 60 h)		
Quinine	10 mg/kg of salt (maximum 600 mg) every 8 h for 7 days, together with or followed by either doxycycline 200 mg once daily for 7 days or clindamycin 450 mg every 8 h for 7 days [unlicensed indication]	20 mg/kg in 10 mL/kg isotonic fluid over 4 h, then 10 mg/kg over 2 h given every 12 h in children and every 8 h in adults, together with or followed by either doxycycline 200 mg once daily for 7 days or clindamycin 450 mg every 8 h for 7 days [unlicensed indication]	Thrombocytopenia, intravascular hemolysis (blackwater fever) when used prophylactically, nausea, tinnitus, deafness

IM, Intramuscular.

capita incidence differing by nearly a factor of 10 and a higher proportion of cases from *P. falciparum* in Europe and the United Kingdom compared with the United States.

Recent experience in the United Kingdom and the United States has emphasized the seriousness of TTM. Two of the last five cases of malaria owing to blood transfusion in the United Kingdom were fatal.[126–128] In the United States, 14 cases of TTM were reported between 1990 and 1999, but only 5 cases were reported between 2000 and 2009.[129–131] Detecting these cases after transfusion is frequently delayed because malarial infection acquired in nonendemic countries rarely figures in immediate differential diagnosis and requires careful examination of the blood film.

The mainstay of preventing TTM in the United Kingdom is donor deferral backed up by detection of circulating antibodies to malaria antigens. The guidelines for donor deferral have recently been revised (Table 154.3).[132] These criteria recognize that malaria in the nonimmune patient is likely to present within four months of return from an endemic area and that significant immunity to falciparum malaria may be acquired by residence after 6 months in a malarious area.

The criteria also require that residents, as well as those having had malaria or an undiagnosed febrile illness, may be reinstated, after four months without malaria or a fever that could have been due to malaria or three years after treatment for an episode of malaria, if antimalarial antibodies cannot be detected. The importance of antimalarial antibody testing rests on the fact that it is a very sensitive method to detect chronic infection, whereas the identification of circulating malarial antigens or nucleic acids or microscopy would fail to detect a level of 1 parasite/mL, which would still give a highly infectious dose in a unit of blood.

TABLE 154.3 **UK Donor Selection Guidelines for Donors at Risk of Transmitting Malaria**

Donor Risk Category	Guidelines
Resident	Defined as having lived in sub-Saharan Africa (except South Africa) or Papua New Guinea for a continuous period of 6 months at any time of life Permanent deferral unless malaria antibody test results are negative at least 4 months after returning from a malarious area Any subsequent visits to any malarious area each require a 4-month deferral period and negative antibody test results before reinstatement
History of malaria	Permanent deferral unless malarial antibody test results are negative at least 3 years after cessation of treatment or last negative test results
Undiagnosed febrile illness	While abroad or within 4 weeks of return Deferral for 12 months or 4 months if malarial antibody test results are negative
All other risks	Deferral for 12 months or 4 months if malarial antibody test results are negative

The assays for antimalarial antibodies previously used indirect immunofluorescence antibody tests (IFATs) to detect reactivity to a crude parasite lysate as a target antigen. However, several enzyme-linked immunosorbent assays (ELISAs) using recombinant malarial antigens have proved to be a more practical if slightly less sensitive alternative to IFATs.[128,133,134] These tests detect antimalarial antibodies in less than 2% of donors who have visited endemic areas. It has been calculated that the return of 90% of malarial antibody–positive visitors to the donor pool releases an extra 50,000 units per year in the United Kingdom, and this is a highly cost-effective process to reduce the attrition of eligible blood donors. In the United States, over 200,000 donors per year are deferred after travel to malaria-endemic areas.

Donor deferral is based on the potential of a donor to carry malaria and is therefore based on the area of travel, length of stay or residence, elapsed time since leaving the endemic area, and history of malaria. It has been repeatedly shown that application of even the most thorough donor questionnaires allows some of those carrying malaria to give blood because guidelines are frequently incorrectly applied or questions are answered inaccurately in routine practice.[130]

In Canada donors reporting diagnosis or treatment of malaria defer permanently, and in the United States donors are deferred for 3 years after treatment.[130] These criteria and the respective regulations of other major international blood services will inevitably cause unnecessary deferral of those who never actually had malaria but also may permit some individuals with low-level chronic infection to donate because malaria may very occasionally present more than 3 years after travelers return from endemic areas.[129,130,135] The last case of malaria transmitted in the United Kingdom was by someone who had left a malarious area 8 years previously, and the longest recorded case of recrudescence of malarial infection is 44 years for *P. malariae*.

Permanent deferral of all those visiting malaria-endemic areas is unlikely to be a viable strategy to prevent TTM because donor bases are declining. Preventing malaria transmission through blood transfusion requires comprehensive, regularly reviewed, and effectively implemented guidelines for donor deferral and laboratory testing. Even the best strategy is a compromise, and medical laboratory staff should be aware of the rare but potentially serious possibility of fever after transfusion that could be caused by malaria.

VISCERAL LEISHMANIASIS

Leishmaniasis is a generic term for infection by 30 or so species of the obligate intracellular parasites from the genus *Leishmania*, and different species may cause systemic or visceral, mucocutaneous or cutaneous infection. Visceral leishmaniasis (VL), or kala-azar, presents with a wide spectrum of systemic and hematologic features.

Epidemiology

VL occurs in all countries bordering the Mediterranean Sea and across the Middle East, including Saudi Arabia and Yemen. Indian VL occurs in the eastern regions of India (particularly Assam, Bengal, Bihar, Uttar Pradesh, Tamil Nadu, and Sikkim) and in Nepal and Bangladesh. African kala-azar is endemic in Kenya, Ethiopia, and the Sudan and sporadically elsewhere in tropical Africa. In the Americas, VL occurs in foci across Mexico, Central America, Colombia, Venezuela, Guyana, Brazil, Bolivia, and northern Argentina (Fig. 154.7).

The total burden of disease is difficult to estimate but significant. Leishmaniasis burden is endemic in 88 countries, with 15,000 to 40,000 new cases of VL per year, with the vast majority occurring in India, Bangladesh, Nepal, Northern Sudan, and northeastern Brazil.[136] VL is associated with poverty and undernutrition in endemic areas, particularly in the hyperendemic foci of the southern part of the Sudan and the Ganges river basin. In the Mediterranean area, it is increasingly seen in association with HIV infection, where infection rates in HIV-infected people may be as high as 10%.

VL is caused by a number of species of the *Leishmania donovani* complex.[137,138] In the Mediterranean region and areas in the Middle East and Central Asia through to China, *Leishmania infantum* predominates, whereas *L. donovani* is more prevalent in India. *Leishmania tropica* is a less common cause of VL in these areas. Throughout their range in the Old World, parasites are transmitted by the female sandfly of the *Phlebotomus* genus. Leishmaniasis is caused by different

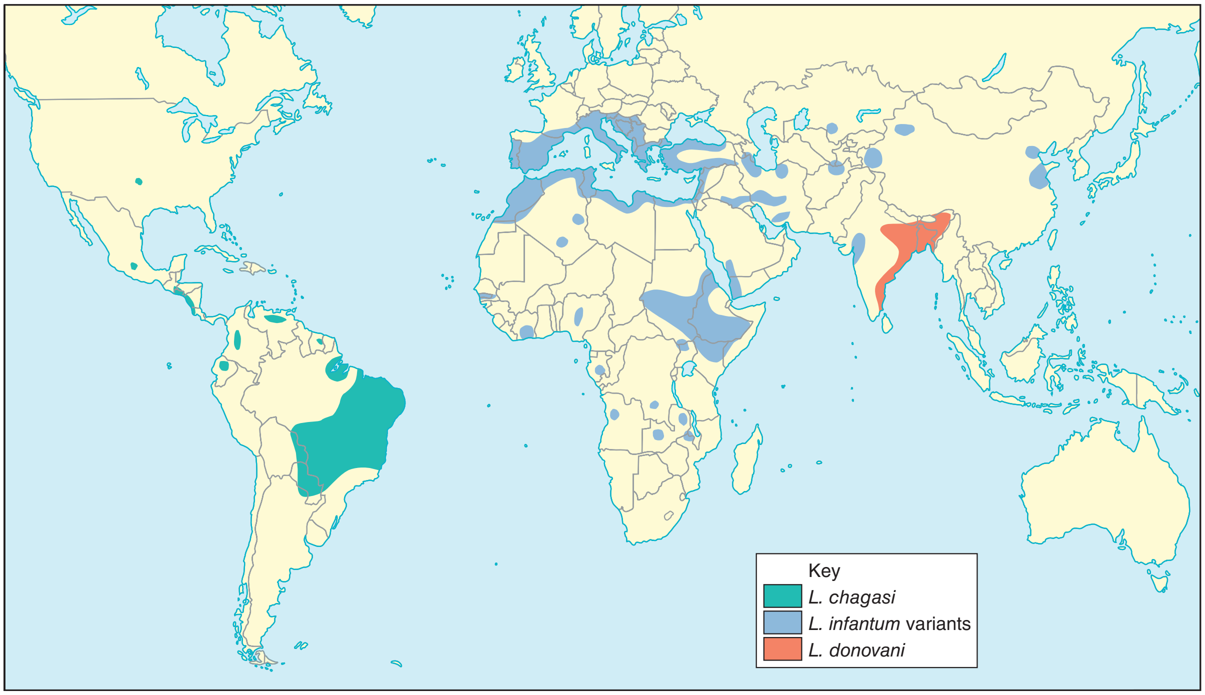

Figure 154.7 EPIDEMIOLOGY OF VISCERAL LEISHMANIASIS (VL). VL caused by parasites of the *Leishmania donovani–Leishmania infantum* complex occurs in the Mediterranean littorals, the Middle East, and adjacent parts of the former Soviet Union, the Sudan, East Africa, the Indian subcontinent and China, and South America *(Leishmania chagasi)*. An arid, warm environment provides ideal ecologic conditions for the breeding of many species of sandfly. Zoonotic kala-azar from *L. infantum* and *L. chagasi* is commonly associated with dry, rocky, hill country, where cases are typically scattered. In India, *L. donovani* is essentially an anthroponosis. This type of kala-azar may occur in severe epidemic fashion, as can kala-azar in the Sudan.

parasites and vectors in the New World, where *Leishmania chagasi* and *Leishmania amazonensis* are transmitted by the *Lutzomyia* genus of sandfly.

Leishmania organisms are present in blood, and so the disease can be transmitted by blood transfusion, as a sexually transmitted disease, as a congenital infection, by needle sharing for intravenous drug abuse, or within a laboratory by intradermal inoculation of *L. donovani* promastigotes.[139,140] Very few cases of leishmaniasis have occurred as transfusion-transmitted infections in Europe or North America, with under 10 cases in infants or immunocompromised patients reported over the past 50 years. In endemic areas, this problem represents a much greater but unquantifie risk.

Parasitology

Leishmania amastigotes live and multiply within macrophages by binary fission. They are round or ovoid bodies, approximately 2 to 3 µm in diameter. Occasional rupture of cells allows invasion of uninfected monocytes and macrophages by free forms. Sandflies ingest amastigotes within macrophages from blood or skin. In the insect's stomach, free amastigotes multiply and divide asexually, becoming elongated and developing flagella as metacyclic promastigotes. Within 2 weeks, such infective forms migrate through the lining of the stomach and enter the proboscis of the sandfly, allowing them to be inoculated in the human host while the sandfly takes a blood meal. Promastigotes are taken up by macrophages, where they become amastigotes by simple fission.

The large, elongated, fusiform promastigote measures 15 to 20 µm in length and 0.5 to 3.5 µm in width. Cultured promastigotes may also demonstrate rounded forms 4 to 5 µm in diameter. In Giemsa or other Romanowsky stains, a large nucleus and smaller, distinct rodlike kinetoplast are obvious. The organisms must be distinguished from *Histoplasma capsulatum*.

Pathology

Parasites spread within macrophages to local lymph nodes and then to the liver, spleen, and bone marrow. They are also present more widely, in particular in the gastrointestinal tract and epidermis. In the subclinical cases, a cellularly mediated immune response causes a granulomatous lesion and resolution of the infection. However, in clinical VL little if any inflammatory response to the rapidly extensive and expanding parasite-laden macrophages is seen. Where it shows, a granuloma develops at the site of the initial inoculation but may not be apparent at the time of presentation.

Features of Visceral Leishmaniasis

Clinical Features

The spectrum of clinical disease is wide, ranging from asymptomatic infection to acute or chronic illness. Perhaps only 1% to 3% of all infections are symptomatic, with an incubation period of 10 days to 10 years but typically between 3 and 6 months.

The high number of seropositive individuals in relation to clinical cases suggests that spontaneous cure without symptoms or with mild systemic symptoms and hepatosplenomegaly occurs in the majority of individuals. In a large series of children with VL in Brazil, the overall case fatality rate was 10%, and mucosal bleeding, jaundice, dyspnea, bacterial infections, and low neutrophil count of less than 500/mm^3 or low platelet count of less than 50,000/mm^3 were associated with a poor outcome.[141]

In endemic areas, a significant number of seropositive children, who do not develop classic VL, have a subclinical form of disease with malaise, fever, poor weight gain, intermittent cough, diarrhea, hepatomegaly, and variable splenomegaly. In these cases, leishmania were neither cultured nor seen in bone marrow aspirates.[142] There are also reports of VL presenting as mild, nonspecific illness with fever, fatigue, cough, and abdominal pain in army personnel returning from the Middle East. In these cases, *L. tropica* was isolated from bone marrow or lymph nodes.[143]

Patients with typical chronic VL often present with malaise and considerable fatigue and the slow onset of low-grade fever, anorexia, and weight loss. They usually have anemia, progressive and occasionally massive splenomegaly, hepatomegaly, lymphadenopathy, and hypergammaglobulinemia, with increasing skin pigmentation (hence the name *kala-azar* from the Hindi for "black sickness"). Patients may have jaundice, petechia, or purpura; heart murmurs; and edema. The size of the spleen is related to the length of infection and severity of the pancytopenia. In Africa, patients may have diffuse polymorphic papular lesions at presentation. Oral, nasal, nasopharyngeal, and laryngeal ulcers may occur during active disease or after treatment. The large spleen, often extending to the right iliac fossa, may be painful. Other features of acute disease include cough, epistaxis, and in some severe cases concurrent infection of the respiratory or gastrointestinal tracts and/or tuberculosis.

The typical features of VL may be preceded by bacteremia, bacterial infection, acute hepatitis, or Guillain-Barré syndrome. VL may be associated with hepatic necrosis, cholecystitis, or neuropathy. Occasionally, lymphadenopathy may occur without systemic features of the disease. Here histology shows noncaseating granulomas and amastigotes within macrophages. A more acute presentation in recent immigrants and visitors to endemic areas may include a high periodic fever similar to classic malaria, with malnutrition, bleeding, hepatitis, and/or acute renal failure (for review see Torres-Guerrero et al.[144]).

Immunocompromised Hosts

Coinfection with HIV and VL is now a well-recognized clinical entity in the Mediterranean region and undoubtedly occurs more widely[145–147] (for review, see van Griensven et al.[148] and Lindoso et al.[149]). VL occurs in the setting of late-stage acquired immunodeficiency syndrome (AIDS) with CD4$^+$ lymphocyte counts of less than 200×10^6/L. Patients present with fever, splenomegaly, and pancytopenia with frequent and sometimes atypical involvement of the gastrointestinal and respiratory systems and skin. The typical hematologic features of VL are sometimes absent, and serologic tests are often negative, although antibodies to 14- and 16-kDa *Leishmania* antigens may be detected by Western blot analysis.[150] However, organisms are plentiful in bone marrow and even in buffy coat preparations. Some patients may have few symptoms, and the diagnosis of VL in immunocompromised patients requires a high index of suspicion. Treatment is difficult, with poor responses to pentavalent antimony. Liposomal amphotericin is the drug of choice. However, relapses are common, and maintenance treatment is required.[148]

VL may also occur after transplant and after immunosuppressive treatments, including chemotherapy, rituximab, or other immunodeficiency states.[151] Although patients present with a typical combination of fever, pancytopenia, and splenomegaly, the diagnosis may be missed if not considered.

Hematologic Features

VL causes a moderate normocytic, normochromic anemia.[152] The pathogenesis of anemia is multifactorial and includes hemodilution, shortened RBC survival, and reduced erythropoiesis.[153,154] The plasma iron is low, with plentiful stored iron typical of the anemia of chronic disease.[155] One report has suggested that Epo levels are reduced compared with what would be expected for the degree of anemia.[156] Occasionally, folate deficiency secondary to malabsorption and/or increased cell turnover or coexistent iron deficiency are associated with macrocytic or microcytic anemia, respectively.[157]

The direct Coombs test results are usually positive for C3 components, and IgG and anti-I agglutinins may be present, but the presence and strength of the test is not correlated with the severity of the anemia. The positive direct Coombs test results appear to be caused

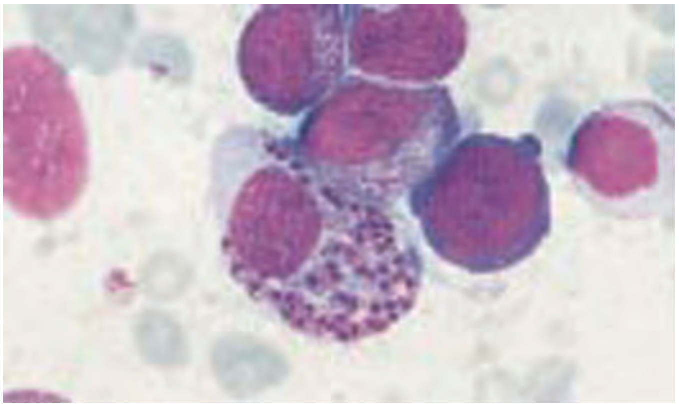

Figure 154.8 *LEISHMANIA INFANTUM* IN MACROPHAGE FROM BONE MARROW. Although typically found in macrophages as shown here, isolated extracellular amastigotes from disrupted host cells are commonly seen in such preparations.

by absorbed immune complexes onto erythrocytes.[158] The neutrophil survival is reduced, and the differential white blood cell count shows neutropenia, relative lymphocytosis, and low eosinophil levels, with a white blood cell count typically in the range 2 to 4 × 10^9 L.

Neutrophil function may be impaired.[159] Pancytopenia is more severe in those with concurrent HIV infection. A leukemoid reaction to infection has been reported.

Typically, the platelet count is reduced to 50 to 200 × 10^9/L as platelet survival is reduced. Mucosal bleeding may occur, but extensive purpura is uncommon.

The prothrombin time is usually mildly prolonged to 2 to 4 seconds longer than in control subjects, secondary to impaired liver function. Fibrinolytic activity is increased, and in advanced cases, fibrinogen levels may be reduced. Disseminated intravascular coagulation or vasculitis may occur.[152,159] Full coagulation screening is advisable if a splenic aspirate or bone marrow biopsy is planned.

The bone marrow is usually hypercellular, with increased erythroid, myeloid, and platelet precursors. Lymphocytes may be increased, and macrophages contain Leishman-Donovan bodies (Fig. 154.8).[160] If weight loss and malabsorption are extensive, the marrow may undergo gelatinous transformation.

The mechanisms of leukopenia and thrombocytopenia are multifactorial. There is evidence for reduced bone marrow production of granulocytes and platelets and also for their autoimmune destruction and/or increased splenic clearance. After treatment, hematologic recovery is slow, and full recovery may take many months.[155]

Laboratory Features

The epidemiologic context and clinical features can suggest a diagnosis of leishmaniasis. Hematologic and biochemical tests are nonspecific; biochemical tests may show mild elevation of bilirubin and transaminase levels and more commonly a raised level of alkaline phosphatase. Previously the nonspecific formol-gel test was used to indicate hypergammaglobulinemia. Diagnosis is confirmed by direct examination of parasites by microscopy, culture, or PCR (for detailed review, see Boelaert et al.[161] and Thakur et al.[162]).

Morphology

The pathognomonic amastigotes of *Leishmania* spp. can be found in a variety of sources. The diagnosis is often made by splenic puncture or by bone marrow aspiration where large numbers of amastigotes may be seen within macrophages. Amastigotes are stained using Giemsa or other Romanowsky stains and demonstrate a purple nucleus and the large anterior kinetoplast (see Fig. 154.8).

In non-immunocompromised patients with VL, splenic aspirates are positive in more than 95%, bone marrow aspirates positive in more than 85%, buffy coat macrophages positive in more than 70%, and lymph nodes positive in more than 60%. In practice, samples are taken from the least invasive sites first, although lymphadenopathy is not invariable.

Where coinfection of HIV and leishmania occurs, amastigotes are more reliably found in bone marrow than in peripheral blood and may also be demonstrated in biopsy specimens from a wide variety of sites. Biopsy material can be stained with polyclonal anti-*Leishmania* serum and indirect immunofluorescence. However, direct demonstration of parasites is less sensitive than culture or PCR.

Splenic Aspiration

Splenic aspiration is rarely performed in North America and Europe but is a common diagnostic procedure in endemic areas. Aspiration is contraindicated in the presence of a bleeding tendency, portal hypertension, or a splenic hydatid cyst. Splenic aspirates are obtained from the middle of the long axis of the spleen. After the skin is cleaned, a 21-gauge needle attached to a 5-mL syringe is inserted subcutaneously in line with the long axis of the spleen. The needle should be swiftly inserted to a depth of approximately 2 or 3 cm at an angle of roughly 45 degrees to the skin, applying negative pressure. The needle should be withdrawn immediately while maintaining negative pressure and taking only a few seconds for the entire procedure. The splenic tissue may be expelled from the needle using a small amount of air and by fixing the stain using standard procedures.

Culture

Amastigotes may be grown as motile promastigotes from aspirates on the classic Novy-MacNeal-Nicolle (NNN) medium or other suitable media at 22°C to 24°C, and populations double only every 2 to 3 days.[163,164] Inoculation of material into the susceptible golden hamster is no longer used to grow parasites.

Molecular Methods

The PCR may detect low levels of infection and has been used for diagnosis and monitoring of treatment as well as to determine the genotype of the parasites.[162,165] Blood from filter paper can be used to prepare DNA, but as for direct morphology, PCR from bone marrow samples is a more sensitive method to demonstrate parasites. Quantitative PCR may be particularly useful for monitoring treatment and relapse in HIV- and *Leishmania*-infected patients.[166,167] Isothermal DNA amplification methods are being applied to develop tests to be used where sophisticated equipment is not available.[168]

Serologic Tests

Serologic tests have to be interpreted in light of the clinical findings. The tests are useful to screen suspected cases or populations for VL. However, they are unreliable in immunocompromised patients, who frequently are seronegative in spite of patent infection. Conversely, those harboring a subclinical infection may be seropositive, but samples may fail to yield evidence of parasites. Finally, serologic findings are positive many years after treatment or self-cure.

An indirect IFAT or ELISA using freeze-dried *Leishmania* antigen has sensitivity and specificity greater than 95%. A DAT is also available with purified, freeze-dried antigen and is a highly sensitive and specific test.[169] The freeze-dried antigen is very stable even when stored in extreme conditions.

The ELISA and immunochromatographic tests using *Leishmania* recombinant K39 antigen are 100% sensitive and more than 98% specific in Asia.[169] The sensitivity and specificity of the DAT and K39 immunochromatographic test are broadly similar, although the K39 test was less sensitive in the Sudan than in Asia.[170,171] Alternative target antigens are being developed for rapid, point-of-care tests although PCR, qPCR, and LAMP may provide inexpensive and sensitive tests for the parasite.[167,172]

Treatment in patients without HIV coinfection may be monitored using urine antigen tests for detection of the K39 and K26 *Leishmania* antigens or by DNA-based methods.[167] These test results become negative 3 weeks after commencing treatment.

Management

General supportive care is important and includes correction of nutritional and hematinic deficiencies, blood transfusion in severe anemia, and antibiotics for secondary infections (for review of diagnosis, therapy, and management, see report from the World Health Organization[172]).

Specific chemotherapy for VL uses a number of potentially toxic drugs. Intercurrent infections must be identified and treated, and general measures include improvement of nutritional status (for review of treatment, see Copeland et al.[173] and Sundar et al.[174]). Use of pentavalent antimonials, including sodium stibogluconate (Pentostam) and meglumine antimonate (Glucantime), are now limited, especially in South Asia, by increasing drug resistance, but they remain effective in East Africa. There is concern that drug resistance will develop to the alternative therapies, and combination treatment aiming at short courses that also delay the development of drug resistance are in progress.

Amphotericin B is effective against *Leishmania* and is used in endemic areas where high levels of resistance to pentavalent antimonials are present. It may be given as a slow intravenous infusion in 5% dextrose over 4 to 6 hours, beginning at 250 μg/kg/day, increasing to 1 mg/kg/day until a total dose of 20 mg/kg/day has been given. Side effects include anaphylaxis, anemia, fever, bone chills, bone pain, and thrombophlebitis. Hypokalemia and hypomagnesemia are significant problems, and potassium loss and supplementation may be reduced by the concurrent use of amiloride to prevent renal tubular potassium leakage.[175]

Reduced toxicity from amphotericin is achieved using a liposomal amphotericin preparation (AmBisome), which has been made more widely available through preferential pricing in endemic areas. It is an effective and safe treatment and is used when affordable. A test dose of 1 mg should be given, and then the recommended dose is 1 to 3 mg/kg daily for 10 to 21 days to a cumulative dose of 21 to 30 mg/kg, alternatively 3 mg/kg for 5 consecutive days, followed by 3 mg/kg after 6 days for 1 dose. In patients with HIV, a dose of liposomal amphotericin at 4 mg/kg/day on days 1 to 5 followed by 4 mg/kg/day on days 10, 17, 24, 31, and 38 is recommended. The relapse rate is high, and close monitoring of patients is required.

Miltefosine was developed in India and is effective orally against VL in India and Africa.[176,177] The current regime is 2.5 mg/kg/day for adults and children older than 2 years for 4 weeks. Higher than 95% cure rates have been achieved. Gastrointestinal upset occurs frequently. Miltefosine is teratogenic and may reduce fertility. It has a long half-life and has a low therapeutic index, which may contribute to the development of resistance, and so combination chemotherapy is being investigated to combat development of resistance.

Intramuscular paromomycin has been used at a dose of 20 mg/kg/day for 21 days. It has been shown to be equivalent to amphotericin B for the treatment of VL in India.[178] Moreover, patients treated for VL in Africa with sodium stibogluconate and paromomycin have an improved outcome compared with therapy with sodium stibogluconate alone.[179]

Post–kala-azar dermal leishmaniasis may occur in up to 10% of patients after treatment for VL. It is seen mainly in India and is common in Africa. It occurs after treatment of VL and may appear up to 10 years after treatment. It presents as a maculopapular rash spreading around the mouth, trunk, and limbs. These nodules and papules contain amastigotes. Prolonged treatment may be required to eliminate infection.

Leishmaniasis as a Transfusion-Transmitted Infection

Leishmaniasis poses problems as a potential transfusion-transmitted infection in endemic areas. The disease can be transmitted by blood and platelet concentrates, although leukodepletion by filtration reduces organisms by many orders of magnitude and so probably also the risk for transmission. In Europe, given the low absolute risk for transmission, donor deferral is used to reduce the risk for donation by anyone who is parasitemic.[180] However, surveys of blood donors in areas where the parasite is transmitted suggest parasite DNA can be detected in 0.3% to 1.75% of donors. It has been noted that service personnel returning from the Eastern Mediterranean represent a group of potential donors who may have been exposed to infection.[181]

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is caused by the flagellate protozoa *Trypanosoma brucei* spp., named after David Bruce, a Scottish parasitologist who first demonstrated the parasite in the blood of cattle affected by nagana. In humans, Aldo Castellani demonstrated trypanosomes in the cerebrospinal fluid (CSF) of patients with sleeping sickness. Bruce was able to show the protozoa in blood and demonstrated that they were transmitted from antelopes to cattle by the tsetse fly and blood of patients with sleeping sickness.

Epidemiology

Trypanosomes are transmitted by some species of the large and distinctive tsetse flies (*Glossina* spp.) in a sporadic distribution south of the Sahara and north of the Zambezi River. Of the three subspecies, *Trypanosoma brucei brucei* infects animals, whereas *Trypanosoma brucei gambiense* causes infection and sleeping sickness in Central and West Africa, and *Trypanosoma brucei rhodesiense* causes disease in East and Central Africa.[182] *T. b. gambiense* is transmitted mainly between humans by the *Glossina palpalis* group (tsetse fly) in foci along watercourses in West and Central Africa. *T. b. rhodesiense* is transmitted by the *Glossina morsitans* groups widely distributed in the East African savannah. Here the disease is clearly a zoonosis, with antelopes and domestic cattle as reservoir hosts; it afflicts mainly hunters, guides, and game wardens and may occasionally occur in tourists on safari in the game parks of East Africa (Fig. 154.9).

Historically the disease has caused major epidemics, causing hundreds of thousands of deaths, and has prevented human settlement in large areas of Africa. Over 50 million people are now at risk for trypanosomiasis, and it has been estimated that the disease causes over 50,000 deaths each year. At present, over 90% of clinical cases in Africa are caused by *T. b. gambiense*.

Most cases are reported in the Democratic Republic of the Congo and northwestern Uganda, with a few hundred or fewer each year reported in neighboring East African countries.

Case-finding and control measures have substantially reduced the risk for epidemics. Epidemics of disease have been associated with a breakdown in health services, for example, in villages in the areas of Lake Victoria in Uganda and more recently in the Democratic Republic of the Congo, Angola, and southern Sudan (for review of current epidemiologic and clinical aspects of this disease, see Simarro et al.[182] and Kennedy and Rogers[183]).

Parasitology

The small, mobile trypomastigotes circulate and may be seen in peripheral blood. These flattened, fusiform organisms are pleomorphic but are typically of a size similar to an RBC, approximately 20 μm long, and have an undulating membrane, attached to the protruding flagellum, extending from the anterior pole of the elongated body

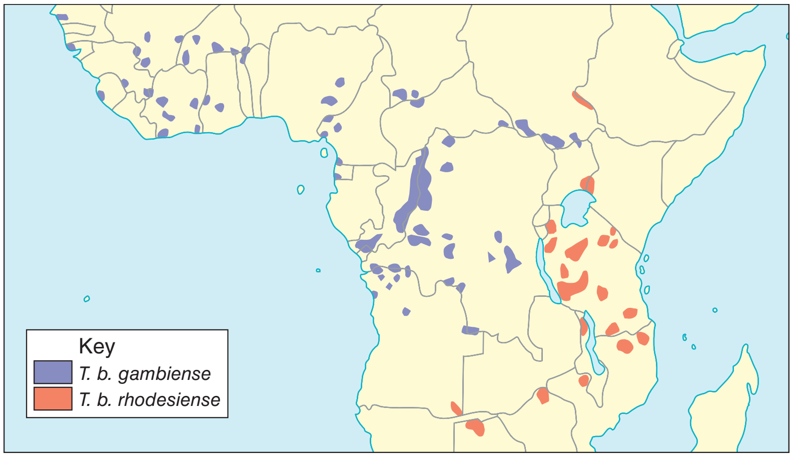

Figure 154.9 DISTRIBUTION OF *TRYPANOSOMA BRUCEI* INFECTION IN HUMANS. African trypanosomiasis is confined to equatorial Africa, with a patchy distribution depending on detailed topographic conditions. It is caused by two subspecies of *T. brucei*: *T. b. gambiense* infection is widespread in West and Central Africa, transmitted mainly by riverine species of tsetse fly *(Glossina)*, but *T. b. rhodesiense*, transmitted mostly by savannah species, is restricted to the eastern and east-central areas of Africa, with some overlap between the two. Although domestic pigs form an important reservoir for *T. b. gambiense* infection, various wild ruminants are the major sources for *T. b. rhodesiense*. The epidemic reemergence of African trypanosomiasis in recent years is exemplified by the death of at least 96 people in Angola in 2003, when 3115 cases were confirmed among a suspected 270,000 new cases in that country. In the same year it was estimated that some 500,000 people across Africa had trypanosomiasis, which was likely to have a mortality rate of approximately 80%. Recent reports indicate a spread of transmission from the northern toward the southern parts of Angola. *(Modified from World Health Organization Map No. 98005.)*

(Fig. 154.10). Parasites multiply by binary fission and may cause chronic parasitemia and evade humoral immune responses by clonal antigenic variations of the major surface glycoprotein.[184]

When trypomastigotes are taken up in a blood meal by the tsetse fly, they multiply in the midgut by simple fission. Later they penetrate the wall of the gut and migrate to the salivary glands. There, as morphologically distinct epimastigotes, they become infective (or metacyclic) trypomastigotes 15 to 30 days after first infecting the fly. In endemic areas, up to 1% to 5% of flies may be infected. Flies remain infective until they die, several months later.

Pathology

The lymphatic, cardiac, and central nervous systems (CNSs) are involved by the disease. Initially, proliferation of trypanosomes within lymph nodes and the spleen is accompanied by expansion of the lymphocytes, macrophages, and erythrophagocytosis. Polyclonal activation of lymphocytes results in high production of IgM and rheumatoid factor, and anti-DNA antibodies may appear. Later fibrosis and endarteritis supervene with proliferation of endothelial cells and perivascular infiltration of plasma cells and lymphocytes. The liver shows infiltration of the portal tracts and fatty degeneration. In *T. b. rhodesiense*, cardiac involvement may be extensive, with endocarditis, myocarditis, and pericarditis leading to extensive damage and death.

In the second stage of the disease, trypanosomes multiply within the CNS and cause a chronic meningoencephalitis. Edema, hemorrhages, granulomatous lesions, and thrombosis contribute to cerebral degeneration. Lymphocytosis and plasma cells with large eosinophilic inclusions (Mott cells) may be found in the CNS.

Intriguingly, nonpathogenic species of African trypanosomes may be killed by the human high-density lipoprotein particles astonishingly subverting a parasite pathway for heme uptake. The complex of haptoglobin-related protein and apolipoprotein L1 (ApoL1) are taken up into the parasite by a parasite glycoprotein receptor, which binds the haptoglobin–Hb complex.[185,186] *T. b. rhodesiense* is resistant to killing by human sera because the ApoL1, which induces parasite apoptosis, is neutralized in the lysosome by serum resistance–associated

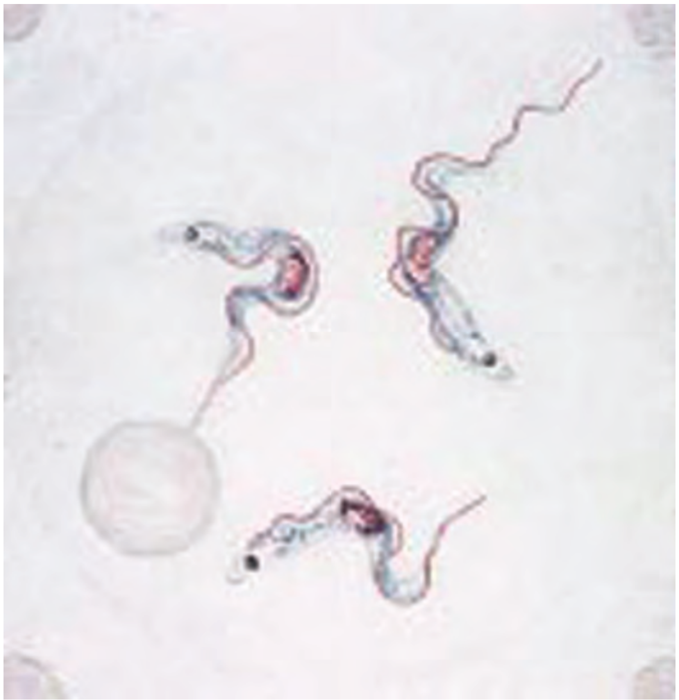

Figure 154.10 ORIGINAL MICRO-PHOTOGRAPH OF *TRYPANOSOMA (TRYPANOZOON) BRUCEI GAMBIENSE* IN HUMAN BLOOD BY J. EVERETT DUTTON. Polymorphic trypanosomes were first discovered more than a century ago, in 1895, by David Bruce in the blood of domestic cattle with the wasting disease nagana in South Africa. The first observation of these protozoa in humans was made by R. M. Forde, who noted, in 1902, "small worm-like, extremely active bodies" in the blood of a sick European seaman in The Gambia. The parasites seen here in a Romanowsky-stained thin blood film, which were described and named by Dutton in 1902, are responsible for sleeping sickness in West Africa. *(Reproduced by kind permission of the Director, Liverpool School of Tropical Medicine.)*

protein, which binds to a specific ApoL1 domain.[187] The selection of trypanolytic ApoL1 variants have a cost. In African Americans, focal segmental glomerulosclerosis and hypertension-attributed end-stage kidney disease are associated with two independent sequence variants in the *APOL1* gene.[188]

Features of African Trypanosomiasis

Clinical Features

Trypanosoma brucei gambiense

Local inflammation at the site of inoculation causes a distinctive chancre or painful, indurated ulcer appearing 2 to 3 days after an infective bite and lasting for up to 1 month. Trypanosomes multiply in the lymphatic system for 6 to 14 days before causing patent infection in the blood, characterized by waves of parasitemia and fever. Later, invasion of the CNS may occur by transit of organisms through the choroid plexus and/or endothelial cells.

In the blood stage of infection, fever, headache, and arthralgia are prominent. Lymphadenopathy is common, particularly in the posterior triangle of the neck (Winterbottom sign). There may be intermittent rashes (often circinate erythema), pruritus, or edema. Moderate splenomegaly occurs in 10% to 20% of patients. A few infected patients are asymptomatic.

This early stage of infection may last for up to 2 years or more before CNS involvement, although rapidly progressive disease may occur. The CNS phase of disease is marked by the progressive onset of headache; disinhibited behavior changes; and mood, thought, and sleep disturbances. Wasting is prominent. Signs of diffuse CNS damage in the last phases of the disease include dementia, extrapyramidal and cerebellar dysfunction, and hyperesthesia. Tendon reflexes are increased, and signs of upper motor neuron lesions are widespread. Death usually occurs by intercurrent infection.

Trypanosoma brucei rhodesiense

T. b. rhodesiense is more virulent, causing a more serious acute disease, with systemic features including serous effusions; hepatocellular jaundice; and a mild, normocytic, normochromic anemia. Hepatosplenomegaly and lymphadenopathy are common, but involvement of cervical lymph nodes is less typical. Myocarditis is rare but may cause death before CNS involvement. Here CNS disease occurs sooner and is more rapidly progressive than *T. b. gambiense* infection and is fatal within 1 to 3 months.

Infection with *T. b. gambiense* may resolve in the vast majority of cases. Where infection persists, there is typically a long asymptomatic phase. Numerous lymph nodes are enlarged to 1 to 2 cm in diameter and are soft, mobile, and painless.

The differential diagnosis of trypanosomiasis includes malaria, typhoid, fever, and viral hepatitis in the acute phase, whereas lymphadenopathy may suggest infectious mononucleosis or tuberculosis. In the cerebral phase of the disease, syphilis, tuberculosis, HIV-associated cryptococcal meningitis, or chronic viral encephalitis must be considered.

Children

Those affected in utero may be born with CNS abnormalities. In children the disease is more rapidly progressive, and epileptic seizures and psychomotor retardation are the principal features of the disease.

HIV Infection and Other Immunosuppressed Patients

The frequency of HIV seropositivity has been reported to show no significant differences between those presenting with trypanosomiasis and age-matched control subjects.[189] However, there are case reports of human African trypanosomiasis presenting in immunocompromised patients in America, many years after possible initial infection in Africa.[190,191] These cases suggest that a long phase of tolerance to trypanosomes, lasting over 20 years, may be followed by clinical relapse during immunosuppressive therapy or disease.

Hematologic and Laboratory Features

The main hematologic features are a normocytic, normochromic anemia and moderate thrombocytopenia.[192] The anemia of trypanosomiasis is multifactorial. Hemodilution, hemolysis, and dyserythropoiesis or ineffective erythropoiesis all contribute to the pathogenesis. Hemolysis may be caused directly by lytic factors released by trypanosomes or indirectly by deposition of immune complexes and subsequent clearance of coated erythrocytes. In vitro studies have suggested that the variant surface glycoprotein from trypanosomes may be shed and taken up onto the erythrocyte membrane, where antibody and complement deposition could contribute to hemolysis. Bone marrow response is inadequate, and although the nature of the defect is unclear, there is failure in incorporation of iron into erythroid precursors, as is seen in many forms of the anemia of chronic disease. In mice infected with human trypanosomiasis, TNF-α contributes to bone marrow suppression, but detailed studies of the pathogenesis of anemia in human infections have not been reported. Serum IgM levels may be elevated to four times normal and with raised IgG levels may cause an increased erythrocyte sedimentation rate.

The white blood cell count may be elevated with monocytosis, lymphocytosis, and circulating plasma cells, but eosinophilia is absent. Plasma cells with eosinophilic inclusion or Mott morular cells may occasionally be seen.

Petechia and purpura may be secondary to vascular injury, thrombocytopenia, and a complex but poorly defined coagulopathy. Abnormal liver function may cause prolonged clotting times. Functionally, both thrombosis and fibrinolysis are increased, and fibrin degradation products (D-dimers) are raised in acute disease; in *T. b. rhodesiense*, a frank disseminated intravascular coagulation may become evident.[193]

Examination of the bone marrow shows hypercellularity. Gelatinous degeneration may be seen in patients with wasting.

Mononuclear cells are present in the CSF late in the disease, and the cell count corresponds to the degree of neurologic involvement and may reach more than 300/μL in severely ill patients. The CSF protein levels are elevated (0.4 to 1.0 g/L).

As disease progresses, the circulating parasites become scarce. However, anemia and endocrine dysfunction, including amenorrhea, reduced libido, and impotence, becomes apparent.

Parasitologic Assays

Direct detection of the parasite is particularly important in light of the toxicity of the treatment. Trypanosomes may be detected in lymph node aspirates and in wet and thick blood smears (Fig. 154.11). An aspirate may be taken from enlarged nodes. Aspirated fluid can be examined under a coverslip, and motile trypanosomes are typically seen at the edges of the coverslip.

Trypanosomes can be seen in wet smears, where a drop of blood is placed on a slide and examined under a coverslip. Alternatively, thick or thin Giemsa-stained blood films are made as for malaria diagnosis. The sensitivity may be increased by microcentrifugation.[194]

More recent methods used to detect the low levels of parasitemia seen in *T. b. gambiense* include quantitative examination of the buffy coat using acridine orange[195] and small-scale ion-anion exchange chromatography.[196] Erythrocytes are retained in the column, whereas trypanosomes are eluted and are visible after concentration by centrifugation. The sensitivity of detection with these methods ranges from 10^4/mL for wet smears to 10^2/mL for ion-exchange columns and centrifugation. In *T. b. rhodesiense*, examination of the blood is more likely than aspiration of lymph nodes to yield a positive result (for a review of diagnostic methods using microscopy, see Chappuis et al.[197]).

Inoculation of the aspirate or samples into susceptible animals or in vitro culture has been used to detect low-level parasitemia. Mice and rats were used to detect *T. b. rhodesiense*, whereas the multimammate

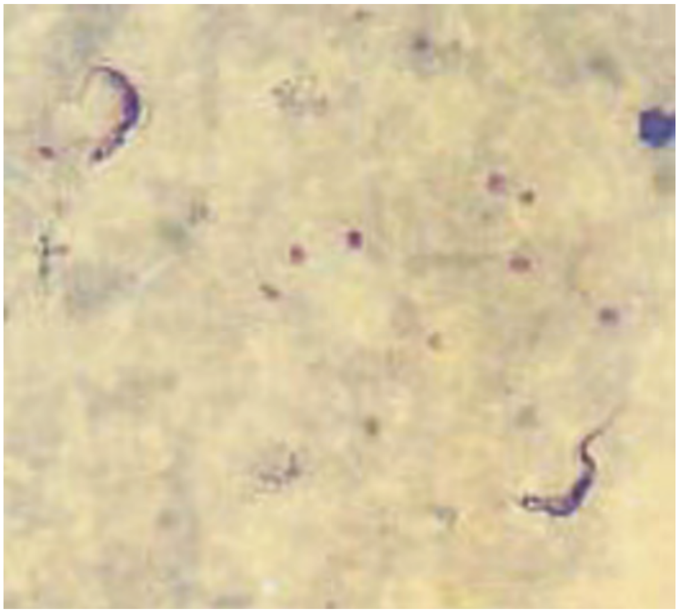

Figure 154.11 *TRYPANOSOMA BRUCEI RHODESIENSE* IN HUMAN BLOOD. *T. brucei brucei* parasitizes wild and domestic animals but does not infect humans. The different subspecies can be distinguished with certainty only by biochemical techniques, such as electrophoretic typing of their isoenzymes or by the use of DNA probes. *T. brucei gambiense* and *T. b. rhodesiense* (and *T. b. brucei* of animals) are virtually indistinguishable in blood films. Note the small kinetoplast and free flagellum. Both subspecies from humans will infect guinea pigs, but only *T. b. rhodesiense* is infective to rats, in which the parasites are polymorphic—that is, long, thin, intermediate, and short, stumpy forms of trypomastigotes may coincide.

rat *(Mastomys natalensis)* and guinea pigs were used for *T. b. gambiense*. PCR of the 18 S rRNA gene can detect parasites with sensitivity similar to that of parasitologic and serologic methods.[198,199]

Cerebrospinal Fluid

Trypanosomes may be found in the CSF as disease progresses, although a double-centrifugation technique may be required to demonstrate organisms. In this technique, 5 to 10 mL of CSF is centrifuged, and the sediment is taken up into a capillary tube and recentrifuged before the capillary tube is examined under a coverslip (Fig. 154.12).[200] Specific molecular markers for this stage of CNS disease are being sought by proteomic analysis of the CSF.

Serology

Serologic tests are used for passive population screening in control programs (for review, see Chappuis et al.[197]). A Card Agglutination Test for Trypanosomiasis (CATT) is robust and can be used without extensive laboratory facilities.[201,202] The test contains freeze-dried trypanosomes with the LiTat 1.3 variant antigens and can be obtained from the Institute of Tropical Medicine Antwerp (www.itg.be). It is quite sensitive (>95%), but it lacks specificity, owing to cross-reactivities with animal *Trypanosoma* spp. Although useful as a patient screening test in a hospital for suspected cases of trypanosomiasis, the predictive value for positive test results falls when screening populations for active cases. It has nevertheless been reported to double the number of active cases found. Some patients may have false-negative results for this test if they are infected by parasites that do not express this variant antigen. Further versions of this assay have been developed to use dried blood on filter paper, namely the micro-CATT and macro-CATT, but these are less sensitive than the whole-blood assay.

In *T. b. gambiense*, serologic tests are not widely available, and direct examination of blood and CSF for parasites is the first line of investigation. The card indirect agglutination trypanosomiasis test (*Tryp*Tect CIATT) can detect circulating antigens in *T. b. gambiense* and *T. b. rhodesiense* infection by latex agglutination. The sensitivities of the test are 95.8% for *T. b. gambiense* and 97.7% for *T. b. rhodesiense*, and therefore significantly higher than that of lymph node puncture, microhematocrit centrifugation, and CSF examination after single- and double-centrifugation.[203]

A rapid latex agglutination test (LATEX/*T. b. gambiense*) contains a mixture of three variable surface antigens of the bloodstream form of trypanosomes and has been used to detect antibodies in patients infected with *T. b. gambiense*. At 1:16 serum dilution, test specificity was 99%, whereas sensitivity ranged from 83.8% to 100%, depending on the geographic origin of the samples. The test sensitivity falls to 66% for CSF samples from second-stage patients.[204] A rapid latex agglutination test, LATEX/IgM, for the semiquantitative detection of IgM in CSF is available.[205] Finally, immunofluorescence assays and ELISA tests for antibodies using whole parasites are highly sensitive and specific, although they are less practical for mass screening. A series of new approaches is being evaluated for control and elimination of trypanosomiasis, including tiny targets for tsetse fly control, use of RDTs, and oral treatment with fexinidazole or oxaboroles.[206]

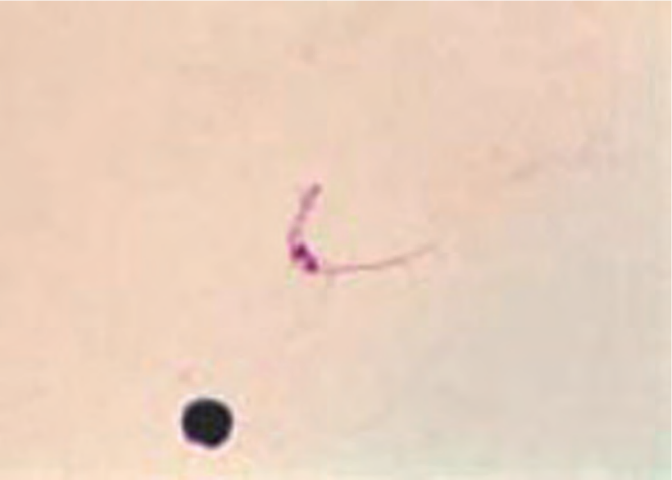

Figure 154.12 TRYPOMASTIGOTE OF *TRYPANOSOMA BRUCEI BRUCEI* IN CEREBROSPINAL FLUID. A single organism is seen in this sample taken from cerebrospinal fluid filtered in a “minicolumn.”

Management

Treatment of trypanosomiasis depends on the subspecies of trypanosome present. The drugs may be difficult to source and are toxic, so treatment requires expert help.

Early-stage (stage 1) *T. b. gambiense* may be treated with pentamidine for 7 days (more usually intramuscularly, 4 mg/kg/day). Hematologic side effects include neutropenia, and more general side effects include hypotension, hypercalcemia, hyperkalemia, renal failure, and hyperglycemia. Pentamidine will not cure CNS disease, and so examination of the CSF is required after initial treatment of the blood-stage disease.

Stage 2 *T. b. gambiense* is treated with a combination of intravenous eflornithine (α-difluoromethylornithine) and oral nifurtimox (NECT) given as 200 mg/kg of eflornithine as an intravenous infusion over 1 to 2 hours every 12 hours for 7 days combined with nifurtimox at 5 mg/kg orally every 8 hours for 10 days.[207] This combination caused less neutropenia, is less toxic, and has fewer relapses than monotherapy with eflornithine.

Melarsoprol is a trivalent organic arsenical compound and is more toxic but cheaper than eflornithine. It is used in Africa for the treatment of late-stage CNS trypanosomiasis. It is given by slow intravenous bolus injections at a dose of 2.2 mg/kg/ day for 10 days.[208]

Melarsoprol causes a secondary encephalopathy in 5% to 10% of treated cases and is fatal in half of these.[209] The incidence and severity of encephalopathy may be reduced by concurrent administration of prednisolone (1 mg/kg/day up to 40 mg) started 1 to 2 days before melarsoprol treatment.[210] When steroids are used, it is necessary to give patients antimalarial and antihelminthic therapy, especially if *Strongyloides stercoralis* is present.

Prior treatment of blood-stage disease with pentamidine may reduce antigen levels and possibly adverse events. Promethazine, anticonvulsants, and antiemetics are important adjunctive treatments before commencing CNS therapy.

Polyneuropathy occurs in 10% of cases treated with melarsoprol and may be severe, causing quadriplegia. If neuropathy is suspected, melarsoprol should be stopped immediately and thiamine (100 mg, three times daily) given until symptoms subside.

Patients require prolonged specialist follow-up over 2 years, including blood and CSF examination for parasites. A rising CSF leukocyte count is a good guide to CSF relapse even in the absence of a demonstration of parasites.[211]

Suramin is effective against the first stage of both forms of the disease. It is generally used for treatment of *T. b. rhodesiense* because it is active against onchocerciasis which is more prevalent in *gambiense* HAT endemic areas and it can cause severe immunological reactions in co-infected patients.[212] In treatment for early-stage *T. b. rhodesiense*, suramin is given as five intravenous injections (20 mg/kg, up to 1.5 g) on days 1, 3, 6, 14, and 21. Adverse effects include fever, proteinuria, paresthesia, pruritus, and urticaria. Hemolytic anemia, agranulocytosis, and thrombocytopenia have been reported as side effects (for review of treatment for trypanosomiasis, see WHO Expert Report).[213]

African Trypanosomiasis as a Transfusion-Transmitted Infection

Trypanosomiasis is a transfusion-transmitted infection. Asymptomatic or early-stage patients with trypanosomiasis are clearly a threat to the blood supply. Patients are excluded in the United Kingdom, Europe, and North America by the general donor queries relating to fever and constitutional symptoms. In endemic areas, exclusion of infected donors with early-stage *T. b. gambiense* is clearly a more complex problem because patients may be asymptomatic for long periods if the degree of risk is unknown and no specific screening procedures are in place. In summary, hematologic involvement in trypanosomiasis is peripheral to the main two features of the disease, but examination of lymph node aspirates, blood, and CSF is essential for diagnosis and management of the disease. Occasionally, patients may become severely ill and have complex hematologic abnormalities. In endemic areas, trypanosomiasis may pose a risk to the blood supply.

AMERICAN TRYPANOSOMIASIS

American trypanosomiasis (or *Chagas disease*, named after the Brazilian parasitologist Carlos Chagas) is caused by infection with *Trypanosoma cruzi*. This flagellated protozoan is transmitted by the triatomine insects, the reduviid bugs. The acute phase of infection is characterized by fever and high parasitemia, followed by a chronic phase with positive serologic results and low parasitemia but with end-organ damage to the heart, peripheral nervous system, and gastrointestinal tract, causing a chronic cardiomyopathy, neuropathy, megaesophagus, and megacolon.

Epidemiology

Chagas disease may occur in the Americas from the southern United States to Chile, but the highest prevalence is in Bolivia and Brazil (Fig. 154.13). There are approximately 10 million seropositive people in Latin America, and the number of people infected and the incidence of new infection are falling rapidly.[214] Infections are found not only in rural areas but also in recent immigrants to urban areas in North and South America and to Europe.[215] It is estimated that approximately 100,000 seropositive individuals are living in the United States. True, endogenous (autochthonous) infection in the United States is vanishingly rare, but human infections have been reported in Texas, California, Tennessee, and Louisiana. Visitors to endemic areas are only rarely infected, with only a handful of cases being recorded in intrepid travelers spending time in traditional housing in rural areas. The range of reservoir hosts and species of triatomine bugs transmitting infection is wide.

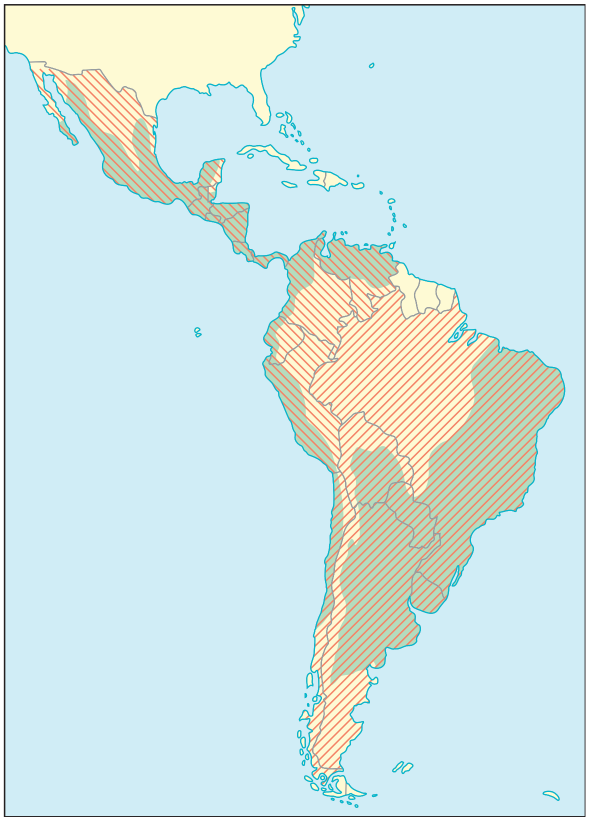

Figure 154.13 DISTRIBUTION OF CHAGAS DISEASE. Human infection is endemic in parts of Central and South America from the Andes to the Atlantic coast and as far south as the latitude of the River Plate (Río de la Plata), shown here in *green*. Two major intergovernmental programs were started in 1991 to eliminate domestic vectors by a combination of spraying residual insecticides in houses, the use of insecticidal paints, and the deployment of fumigant canisters. The countries covered in the two initiatives, the second of which started in 1997, are shown in the figure (hatched red). The latter program instituted universal blood screening to avoid transmission from infected blood donors. Remarkable progress has been made. Transmission (by the major vector *Triatoma infestans*) was eliminated in Uruguay by 1997 and in Chile by 1999. Major reductions in transmission but, to date, not complete control have also been reported in other endemic countries. (Southern Cone Initiative; Andean and American Initiative areas.)

Parasites may also be transmitted by blood transfusion (see later), vertically from mother to child by breastfeeding, organ transplant, and rarely by sexual transmission. Several outbreaks in Brazil have been reported after contamination of food by triatomine bugs and their feces. Laboratory infection by accidental ingestion or inoculation of parasites is well recorded.

Parasitology

T. cruzi parasites are from the order Kinetoplastida and family Trypanosomatidae, existing as infective trypomastigotes in the bloodstream of vertebrate hosts. These organisms are fusiform cells, 10 to 20 μm in length, with a distinctive large posterior kinetoplast containing mitochondrial DNA. They can enter phagocytes, muscle, and nerve cells, and a wide variety of other cell types and here transform to oval amastigotes 2 to 5 μm in diameter. They multiply by fission, and amastigotes develop into mature trypomastigotes released on rupture of the cell to begin a new cycle of invasion and multiplication.

Slender, highly motile and broader, less motile trypomastigotes have been distinguished, which may be relatively more infective for host cells and insects, respectively. The species of triatomine bugs that commonly transmits disease is able to cause extensive infestation of simple mud-and-wattle thatched houses in rural Latin America, where Chagas disease is a disease of poverty associated with poor housing. These bugs are infected by circulating trypomastigotes after taking a blood meal on sleeping victims. In the midgut, trypomastigotes transform into epimastigotes and multiply by fission before migrating to the hindgut, where they develop into metacyclic trypomastigotes, adherent to the epithelium of the rectum. These infective forms are excreted into the feces, and people are infected by rubbing this infected material from the bug into the skin or conjunctival membranes. In the human host, multiplication into macrophages is followed by rapid dissemination of trypomastigotes into the blood and hence to tissues. The genome sequence of *T. cruzi* has stimulated a plethora of comparative and genomic approaches to the study of the parasite.[216–218]

Trypanosoma rangeli Infections

The nonpathogenic trypanosomes can be transmitted directly to people by the bite of the triatomine bugs, and they exist only as circulating trypomastigotes. No tissue amastigotes exist. Circulating organisms are sparse, but sometimes diagnosis can be made by careful microscopic examination of the distinctive morphology of these organisms in blood smears. The anterior position of the nucleus and small kinetoplast distinguish it from *T. cruzi* (Fig. 154.14). The antibodies produced to *T. rangeli* cross-react with those from *T. cruzi* and hence cause false-positive serologic test results for *T. cruzi*. However, the species may be differentiated by xenodiagnosis or molecular genetics in specialized laboratories.[219] The importance of recognizing this nonpathogenic infection is to avoid unnecessary treatment for *T. cruzi*.

Pathology

There is a wide variation in the pathogenicity of isolates and some regional variation in the clinical spectrum of acute and chronic illness.

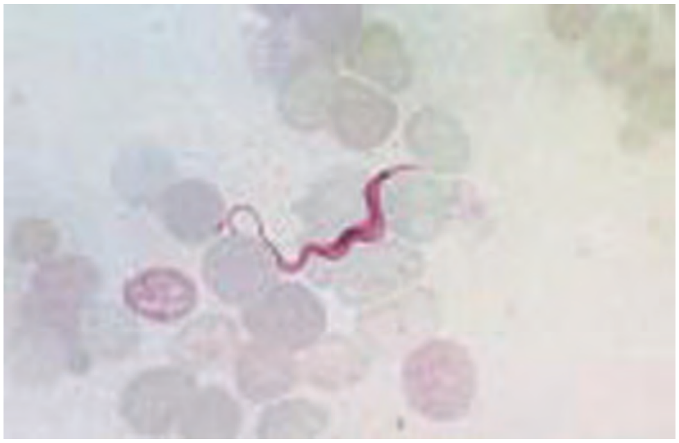

Figure 154.14 *TRYPANOSOMA RANGELI. T. rangeli* is a long, slender trypanosome also transmitted by reduviid bugs from wild animals to humans. It is readily distinguished by its shape from *Trypanosoma cruzi* in blood films and appears to be nonpathogenic to humans.

Molecular typing has demonstrated considerable heterogeneity of *T. cruzi* isolates, although the association between strains of parasite and the outcome of infection are unclear. Clearly the organism must have many mechanisms of the immune evasion to cause chronic infections in a high proportion of individuals. Some of these have been elegantly defined, including resistance to activation of the alternate pathway of complement, specific mechanisms of entering the host cells, and evasion of intracellular killing by the oxidative burst and lysozymes. Both CD4$^+$ and CD8$^+$ T cells are important for killing *T. cruzi*–infected cells, and IFN-γ has shown to be important to controlling disease, whereas transforming growth factor-β and IL-10 enhance parasite replication (for review, see Rios et al.[220]).

End-organ damage occurs after tissues have been infected by *T. cruzi* amastigotes, but the mechanisms leading to extensive cell damage are not clear. After multiplication, tissue amastigotes form pseudocysts in the heart with little or no inflammatory reaction, although occasionally acute myocarditis with focal hemorrhage and inflammation may lead to heart failure. As the disease progresses, the inflammatory response is increased and is associated with increased tissue damage. There may be an autoimmune component to this inflammatory response, but the precise pathogenesis is poorly understood.[221] In the heart, chronic myocarditis leads to a decline in cardiac function. In late-stage disease, amastigotes can be found in almost all organs. Acute myocarditis with focal hemorrhage and inflammation may also lead to heart failure. Involvement of the brain, meninges, liver, lymph nodes, and spleen is common. Damage to the muscle walls and intramural nerve plexus in the esophagus and colon leads to dilation of these structures in the later phases of the disease.

Features of American Trypanosomiasis

Clinical Features

In about half the patients, a granuloma (or chagoma) occurs where parasites have been inoculated. The tender erythematous papule becomes keratotic and later heals, forming a hyperpigmented scar. When the conjunctiva are inoculated, the extensive unilateral periorbital edema may be prolonged (Romaña sign).

The severity of the acute illness is variable and ranges from asymptomatic infection or a mild febrile illness to a severe, potentially fatal illness with cardiac failure and meningoencephalitis in a minority of cases. Myalgia, generalized lymphadenopathy, hepatosplenomegaly, headaches, facial or generalized edema, vomiting, diarrhea, and anorexia are common features of the acute disease. The disease may be worse in children. The acute illness typically resolves in 4 to 8 weeks. Chagas disease must be distinguished from typhoid fever, VL, brucellosis, toxoplasmosis, and malaria in cases of chronic, febrile illness in endemic areas.

Chronic Disease

The acute phase of *T. cruzi* infection is followed by a variable latent or indeterminate phase with no clinical symptoms. Indeed, patients may never present with signs of end-organ damage. However, up to one-third of clinically infected patients may develop cardiac involvement and show right bundle branch block, atrioventricular conduction abnormalities, and/or abnormal T and Q waves. The patient may experience palpitations, chest pain, edema, and dizziness or syncope or dyspnea. The heart is enlarged, and intramural thrombus may cause sudden death.

In a further minority of chronically infected patients, the gastrointestinal tract is infected with abnormal motility of the esophagus and colon, leading to dysphagia and/or severe constipation. Occasionally, other hollow organ systems may be affected.

Pregnancy and Congenital Infection

In pregnant women, Chagas disease can cause spontaneous abortion, premature birth, intrauterine growth retardation, and stillbirth.

Congenital infection occurs in 1% to 2% of women with chronic infection. Prompt diagnosis of circulating parasites in neonates at risk for congenital Chagas disease is essential to beginning early treatment. It is recognized that infection can also be transmitted by breastfeeding. Most children are asymptomatic, but 10% to 20% of children have a mild systemic illness with hepatosplenomegaly. More severely affected newborn children have pneumonitis, meningoencephalitis, and diffuse dermal granulomas. Petechiae, purpura, and a generalized bleeding tendency may occur.[222]

Immunocompromised Patients and Organ Transplantation

The disease may recrudesce after chemotherapy for malignant disease, immunosuppressive therapy, or after organ transplant. The clinical disease may be fulminating with obvious parasitemia. Patients may present with acute myocarditis and congested cardiac failure. Irregular erythematous indurated lesions have been described during *T. cruzi* recrudescence after solid-organ transplant. Here tissue amastigotes can be demonstrated by fine-needle aspiration.

In the United States, screening of solid-organ donors is based on the assessment of risk; donors born in or with significant periods of residence in Latin America, born of women from Latin America, and/or noted to have clinical findings such as cardiomegaly consistent with Chagas disease should be screened by serology. As screening of donors has become more frequent, most donor-derived infections have been detected by PCR testing before symptoms arise and treated quickly and effectively with anti-trypanosomal chemotherapy. Current recommendations suggest monitoring the recipient of an organ from an infected donor for at least 6 months, before decreasing surveillance.[223]

Human Immunodeficiency Virus

Coinfection with *T. cruzi* and HIV has been reported from urban centers in Brazil. *T. cruzi* develops in end-stage disease with CD4$^+$ T-cell counts of less than 400/µL. Patients may be severely ill, the majority with meningoencephalitis and often with a space-occupying lesion. Typically, the CSF shows a mild lymphocytosis (<100 cells/µL). Parasites may be seen in the blood and occasionally the CSF. Cardiac involvement and heart failure are common.

Hematologic and Laboratory Features

A mild, normocytic, normochromic anemia is typical of acute illness. The pathogenesis of the anemia and contributions of hemolysis and bone marrow depression have not been studied in humans, but in experimental infections in mice, uncontrolled infection and TNF-α can be shown to contribute to depressed hematopoiesis. A modest lymphocytosis and increases in liver and muscle enzymes may be present. Nonspecific electrocardiographic changes, first-degree heart block, and cardiomegaly suggest early myocardial involvement.

Hematologic abnormalities are not usually found in the late stage of disease, in which cardiomyopathy with cardiac failure, rhythm disturbance, and angina and systemic emboli from intramural thrombus may occur. Trials of systemic anticoagulation have not been conducted.

Diagnosis

Microscopy

During the acute phase of the disease, motile trypanosomes can be identified in wet preparations or buffy coat preparations using concentration methods and detailed morphologic examination, including Giemsa-stained, gently prepared thick and thin films to avoid damage to parasites (Fig. 154.15). Trypanosomes can be aspirated from the chagoma in the acute phase of disease and visualized in a wet preparation of needle aspirates. Parasites may occasionally be found in lachrymal fluid.

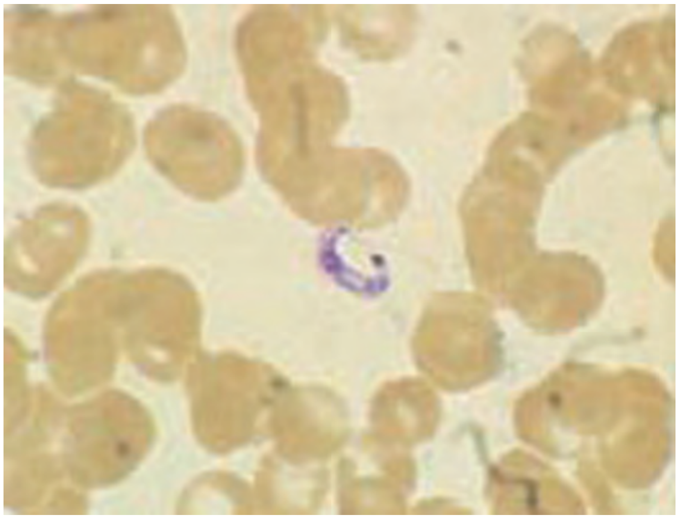

Figure 154.15 *TRYPANOSOMA CRUZI* IN HUMAN BLOOD FILM. The causative agent occurs in blood films, characteristically as short C-shaped or S-shaped trypomastigotes with a prominent kinetoplast. It is otherwise monomorphic.

Sensitivity is increased by the concentration methods described for *T. brucei* earlier. Organisms may also be sought in centrifuged serum after blood has clotted or by centrifugation after lysis of RBCs with 0.8% ammonium chloride. Trypomastigotes can also be detected in other specimens, including CSF, bone marrow, pericardiac fluid, and tissue biopsy specimens. Organisms must be distinguished from the morphologically similar nonpathogenic *T. rangeli* (see Fig. 154.14 and earlier).

After the acute phase, circulating parasites are not visible, although inoculation of blood into susceptible animals (xenodiagnosis), in vitro culture, or molecular methods may demonstrate patent infection. Parasitemia may be obvious in immunocompromised patients in the chronic phase of disease.

Xenodiagnosis

Infection of laboratory triatomine bugs by a seropositive patient is more sensitive than morphologic examination in chronically infected patients. It is also possible to infect susceptible laboratory animals. However, these techniques are available only in specialized centers in Latin America.

In Vitro Culture

Epimastigotes can be cultured using blood agar (NNN) medium or other media such as Schneider insect medium. After 4 weeks or more of culture at 26°C, epimastigotes may be detected.[224]

Serology

Serologic testing is a sensitive method of detecting infection after the acute phase. In Latin America, a number of commercial assays are available using crude epimastigote lysates in a variety of different formats. Serologic tests have used IFAT and ELISA using crude antigen prepared from in vitro cultures of epimastigotes. These tests must be carefully controlled with appropriate positive or negative sera. Chronically infected patients usually give a positive test result if titers are greater than 1:80. These have a sensitivity and specificity of more than 95%. These antibodies may cross-react with antibodies to malaria, leishmaniasis, syphilis, and some autoimmune conditions. ELISA should be used in conjunction with a confirmatory test such as Western blot using parasite lysate.[225]

In South and North America, a number of companies market ELISA-based assays using recombinant antigens, synthetic peptides, or a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuen strain *T. cruzi* trypomastigotes (total trypomastigote excretory-secretory antigens [TESAs]). These assays may provide more rapidly available and cheaper tests without loss of sensitivity and specificity (see Trypanosomiasis as a Transfusion-Transmitted Infection section for further discussion).

Serologic testing may be useful in the evaluation of people who may have been exposed to Chagas disease, pregnant women, and patients about to undergo immunosuppressive treatment or to receive chemotherapy or who have been diagnosed with HIV or other immunosuppressive illness. Children born to seropositive women will have maternally derived IgG anti-*T. cruzi* antibodies but demonstrate IgM anti-*T. cruzi* antibodies if congenitally infected.[226]

Molecular Diagnosis

Amplification of *T. cruzi*-specific sequences by PCR is the most widely applicable, sensitive, and specific method for detecting parasites. A number of assays have been developed, based on the application of repetitive sequences in kinetoplast DNA. A meta-analysis has suggested that PCR is not more sensitive than ELISA for detection of *T. cruzi* in chagasic patients. The recommendation is to use two serologic tests, which may be supplemented by PCR-based assays in the immunocompromised patient, in whom seroconversion may not occur in patent infection.[227]

Treatment

The detailed treatment of Chagas disease is beyond the scope of this chapter. Treatment of the acute, intermediate, and chronic phases requires expert supervision because parasitologic cure is achieved in only half the cases and monitoring progress requires specialist testing and evaluation and where necessary treatment of end-organ damage. The current and potential future chemotherapy have recently been reviewed.[228–230]

Nifurtimox is a synthetic nitrofuran that inhibits pyruvic acid synthesis by inhibition of lactic dehydrogenase. It is given for 30 to 120 days at 3 to 5 mg/kg three times per day. The most serious side effects are peripheral neuropathy, mental disturbance (including psychosis), and hemolytic anemia associated with G6PD.

Benznidazole is widely available in Latin America and is given at 5 mg/kg of body weight per day for 60 days. Severe hematologic complications are common, and bone marrow depression is a serious side effect. Thrombocytopenia may be severe, and neutropenia may progress to agranulocytosis. Other serious complications include photosensitivity, neuropathy, and weight loss.[230]

Supportive therapy is required for heart failure and acute meningoencephalitis.[228] Surgery may be required for alleviation of esophageal and chronic dysfunction. In the absence of effective or simple therapy, control of triatomine bugs and an improvement in the housing stock are essential to prevent and control disease.

American Trypanosomiasis as a Transfusion-Transmitted Infection

Chagas disease may occur as a transfusion-transmitted infection and represents a real threat to the safety of the blood supply in endemic areas. In endemic areas, seropositivity is high, reaching 50% in some areas of Bolivia and 1% to 2% in major areas in Brazil. Control of blood transfusion–transmitted infection is part of the World Health Organization strategy for control of Chagas disease.[231] Outside Latin America, Chagas disease has been an occasional cause of transfusion-transmitted infection, mainly in immunosuppressed patients. It is possible that minor infections are not recognized in healthy individuals. Clearly the high rates of seropositivity in individuals from endemic areas suggest that recent immigrants may easily transmit the disease.

Before blood donor screening, seven transfusion-associated *T. cruzi* infections were documented in the United States between 1988 and 2006.[232,233] These infections were manifested in patients with malignancy and associated with platelet transfusions. In Europe, transfusion-transmitted Chagas disease has been less common, but has occurred after a red cell transfusion.[234] These cases have allowed an estimate of the risk of infection in a recipient associated with an infective platelet unit of 13.3% (95% confidence interval 5.6 to 25.7) but is likely to be less than 1% for RBCs and plasma components. Infection may cause severe acute disease in recipients.

Transmission of Chagas disease has been reduced by donor screening using the Ortho ELISA or the Abbott PRISM chemiluminescent immunoassay (ChLIA) as a primary screening test and the radioimmunoprecipitation assay (RIPA) or the Abbott enzyme strip assay (ESA) as the confirmatory test.[235]

All blood donors were tested between 2007 and 2017 and no incident cases representing local or autochthonous transmission were detected. After 2017, the FDA has recommended screening donors once. Widespread donor screening has shown an overall seroprevalence of 1:27,500, with the highest rates in Florida (1:3800), followed by California (1:8300). Of these 104 *T. cruzi*-infected donors 28% were born in Mexico, 26% in the United States, 16% in El Salvador, and 11% in Bolivia. The other 20 donors were born in nine other countries of Central and South America, illustrating widespread distribution of endogenous infection in South and Central America.[236]

The United Kingdom has implemented systematic screening of at-risk blood donations for *T. cruzi* infection since 1999, testing blood donors born in endemic areas, or donors born to mothers native of endemic areas, or recipients of blood transfusions in endemic areas,[237] and similar measures have been implemented by an increasing number of countries including Spain, France, and Switzerland. It is possible to treat blood with gentian violet (0.25 g/L for 24 hours at 4°C) or with methylene blue to kill circulating organisms. It has also been shown that amotosalen or riboflavin plus ultraviolet A photochemical inactivation technology is effective in inactivating *T. cruzi* in platelet concentrates and plasma.[238] In addition, prophylactic benznidazole can be given to immunosuppressed patients receiving blood products in endemic areas.

It is only to be hoped that sensitive screening tests are consistently applied to reduce transmission of Chagas disease by blood products in endemic and nonendemic countries. On a more general note, it is encouraging that the initiatives to control *T. cruzi* infection across Latin America are showing real evidence of success.[239,240]

BABESIOSIS

Babesiosis is an intraerythrocytic infection caused by parasites from the order Piroplasmida and the family Babesiidae. It was first observed as causing parasitic inclusions in erythrocytes of cattle in Romania by Victor Babes at the end of the 19th century.[241] The infection is zoonotic and is transmitted by hard-bodied ticks and causes fever and hemolytic anemia. Several distinct *Babesia* spp. cause disease in different geographic areas.[242,243]

There are two well-defined *Babesia* species that cause human infection. *Babesia microti* is a parasite of small rodents in the northeastern United States and is spread by nymphs, larvae, and adult forms of the hard-bodied ixodid ticks (*Ixodes dammini*). Infection of the white-tailed deer by ticks allows multiplication and spread of the infected ticks. Infections can be transferred to humans by all forms of the tick after prolonged feeding. The infection is therefore most common in people vacationing or working in forested areas of the northeastern United States. The northeastern US offshore islands of Nantucket, Martha's Vineyard, Block Island, and

Shelter Island are foci of the disease, but it also occurs in eastern states, particularly Connecticut, Rhode Island, Delaware, and New York State, as well as upper Midwestern states. Hundreds of cases have been recorded since the first identified case in 1969. Visitors and workers in endemic areas should avoid tick bites by using appropriate clothing and repellents.

In Europe, *Babesia divergens* and the morphologically indistinguishable parasite *Babesia bovis* are transmitted to humans by ticks (*Ixodes ricinus*) from cattle. Fewer than 50 cases have been recorded. European cases of *B. microti* and *Babesia canis* infection have also been reported.

A handful of cases of infections with *Babesia duncani* in the western United States have been reported. These organisms are morphologically indistinguishable from *B. microti* but are distinguished by molecular methods. The MO1-type piroplasm caused illness in an index case in Missouri in 1992, and the WA1-2 and CA1-5 piroplasms caused disease in eight cases reported in Washington State and California.[244,245] A further *B. microti*-like organism, *B. venatorum*, has caused infection in a small series of older men who had undergone splenectomy for a lymphoproliferative disease.[246] The same organism has been isolated in a much larger series of patients from China.[247]

B. microti and *B. duncani* have been transmitted by red cell and platelet components in over 260 documented cases of transfusion-transmitted infection.[248,249] Transplacental infection by *B. microti* has also been reported.

Parasitology

Parasites appear to be introduced into the bloodstream, where they invade erythrocytes. There they multiply by asexual fission to produce two to four merozoites. These infective forms are released after lysis of the erythrocyte and begin another cycle of invasion multiplication. Parasites are cleared by macrophages. The contribution of antibodies and cell-mediated immune response has not been defined, although *B. bovis* expresses clonally variant antigens on the surface of infected erythrocytes.[27]

Clinical Features

The North American *B. microti* infections have an incubation period of several weeks, and after infection by blood transfusion, clinical symptoms have taken from 17 days to many months to become manifest.[250–252] The spectrum of clinical disease is wide. *B. microti* may cause asymptomatic infection or present with a mild flulike illness in most cases in people with normal immune and splenic function.[253] The cardinal manifestations are fever and hemolytic anemia. Splenectomy, old age, and immunosuppression, including HIV, may increase the risk for more severe clinical disease.[254–256] Hematological features of infection may include not only mild anemia but also severe pancytopenia, splenic rupture, disseminated intravascular coagulopathy (DIC), or even hemophagocytic lymphohistiocytosis (HLH).[252] Patients who have had a splenectomy should avoid exposure to ticks in forested areas where the disease is transmitted.

B. divergens in Europe predominantly causes symptomatic infection in people who have had a splenectomy.[257,258] Here, the case fatality rate is on the order of 50%. However, symptomatic disease does also occur in immunocompetent individuals.[259]

Patients present with high fever, often with chills and sweats, jaundice, fatigue, malaise, headache, arthralgia, and myalgia. Gastrointestinal disturbances are common, and people may complain of dark urine secondary to hemoglobinuria. In some cases, the disease progresses with respiratory failure secondary to ARDS, disseminated intravascular coagulation, and renal failure requiring the appropriate supportive care.[260] Such severe cases resemble severe malaria in nonimmune persons, and it has been suggested that the pathophysiology, like in malaria, includes adhesion and sequestration of infected erythrocytes and the release of proinflammatory cytokines. These diseases may be confused with falciparum malaria, leptospirosis, or viral hepatitis. In pregnancy, acute babesiosis may mimic the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count).[260]

Hematologic and Laboratory Features

The hematologic features of the disease are dominated by substantial intravascular hemolysis.[242] Physical examination shows pallor, jaundice, and mild hepatosplenomegaly.

The laboratory findings are those of a compensated intravascular hemolytic anemia and thus feature low Hb and haptoglobin levels, increased reticulocyte count and serum lactate dehydrogenase, and hemoglobinuria and proteinuria. Moderate thrombocytopenia is common.[251,252,261] Electron microscopy suggests uninfected erythrocytes are damaged during infection and so likely to be cleared more rapidly than normally.[262] The white blood cell count is usually decreased with atypical lymphocytosis and occasional evidence of hemophagocytosis.[252] However, leukocytosis may occur, particularly in *B. divergens* infections.

About 5% to 10% of patients with acute babesiosis develop warm-antibody autoimmune hemolytic anemia 2 to 4 weeks after diagnosis, and after treatment and clearance of the parasites.[262–264] Almost all the cases with AIHA after acute babesiosis were asplenic.

Diagnosis

The blood films stained with Giemsa or Romanowsky stain show ring-like intraerythrocytic parasites. Morphology is variable, and ring, rod, and ameboid forms of *Babesia* parasites may be seen (Fig. 154.16).[265–267] Occasionally, multiple intraerythrocytic forms can be seen, linked to form a tetrad or, colloquially, a “Maltese cross.” However, at low parasitemia, *Babesia* parasites may easily be mistaken for ring-stage forms of *P. falciparum*. Moreover, false-positive sightings of *Babesia* spp. may be caused by platelets, nonspecific stain deposit overlying erythrocytes, or indeed other intraerythrocytic inclusions.

Parasitemias are variable, and in *B. microti* infections may be low or transient.[253] In symptomatic infection, parasitemias typically range from less than 1% to 10% and rarely much higher, more than 70%, in severe infections. Low-level parasitemias may be detected by inoculation of the blood into susceptible animals, including the golden hamster (*Mesocricetus auratu*), but this form of testing is not routinely available.

An IFAT using crude antigen is available in the United States through the Division of Parasitic Diseases at the Centers for Disease Control and Prevention.[268] Titers greater than 1:64 are regarded as positive and have been reported to be 88% to 96% sensitive and 90% to 100% specific. However, the degree of cross-reactivity between Babesia species is variable. If the infection is contracted on the West Coast of America, samples should also be tested for antibodies to the *B. duncani*, because of the limited cross-reactivity with *B. microti*.[269]

PCR analysis is the most useful method of detecting or confirming low levels of parasitemia, and it can also be used to monitor treatment. Real-time PCR assays target the *Babesia* 18 S rRNA gene and, with use of a fluorescent probe, can distinguish *B. microti* from *B. duncani*.[270,271] PCR tests may be positive in the absence of positive serology in immunocompromised patients and/or those patients who have received rituximab, whereas serology for *Babesia* spp. may be positive in the absence of positive microscopy or positive PCR tests in asymptomatic individuals who were infected but who have cleared the infection spontaneously.

Treatment

Many *B. microti* infections are self-limiting, and therapy is used for moderate or severe disease.[272–274] The combination of atovaquone and azithromycin is the treatment of choice for mild to moderate illness, whereas clindamycin and quinine and exchange transfusion are indicated for severe disease.

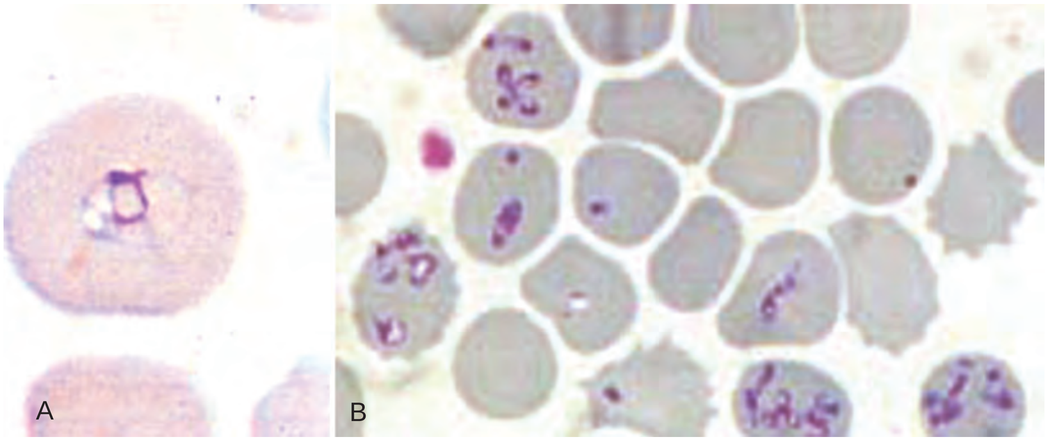

Figure 154.16 *BABESIA* PARASITES. Human infection with species of piroplasm transmitted by the bite of the tick *Ixodes ricinus* infected from cattle is a rare occurrence. Infection in normal people with this piroplasm may give rise to a self-limiting fever and parasitemia, as in the case of infection with the rodent parasite *Babesia microti* on the northeastern seaboard of the United States via the tick *Ixodes scapularis* (A). Heavy red-cell infection may develop, however, in splenectomized patients, leading to fatal hemolytic anemia. This patient died as a result of an infection acquired from the cattle parasite *Babesia divergens* in Scotland (B). Other species of *Babesia* that occasionally infect humans, for example, the WA1, CA1, and MO1 isolates from the United States, are distinguished by molecular means.

B. divergens infections are often fatal in splenectomized patients, and therapy is based on somewhat limited experience. Three cases have been treated successfully with large-volume exchange transfusions (2 to 3 blood volumes) and intravenous clindamycin and oral quinine.[275] This regimen of clindamycin and intravenous and oral quinine gives the best chance of success in the absence of randomized controlled trial evidence.

Exchange transfusion has been suggested as a useful adjunctive treatment if the parasitemia rises to greater than 10% and/or in severely ill patients. *B. divergens* infections can run a rapidly progressive course, and early exchange transfusion should be considered. A prolonged course of treatment may be required in immunocompromised patients.[276] The parasite and Hb levels should be regularly monitored during treatment.

Serologic testing and PCR testing of seropositive cases may be helpful in making a diagnosis. An indirect IFAT is available for *B. divergens* and *B. microti*. The IFAT titer is usually greater than 1:64 in acute infection. The reported sensitivity of the *B. microti* IFAT is 88% to 96%, and its specificity is 90% to 100%. Antimalarial antibodies may cross-react in this test.

Babesiosis as a Transfusion-Transmitted Infection

Babesia infection poses a substantial and increasing threat to the blood supply. Over 150 cases of transfusion-transmitted babesiosis were reported from 1979 to 2015, with 32 recorded deaths.[248,249] Preventing transfusion-transmitted infection by donor screening proved to be very difficult as the questions lacked sensitivity. An arrayed fluorescence immunoassay and PCR test were developed to test for donors with patent babesia infection. Of 89,000 donors from the Northeastern United States (Connecticut, Massachusetts, Minnesota, Wisconsin) 355 or 0.38% were positive by either test, and 69 of these 355 donors were positive by PCR, with 9/69 positive by PCR alone.[277] Infections were detected in donors throughout the year. In 2019, the US FDA issued "Recommendations for reducing the risk of transfusion-transmitted babesiosis" as applied to the collection of blood and blood components, except source plasma.[278] The document instructed blood operators to test each donation using a licensed Babesia NAT on donations collected in the following jurisdictions: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont, Virginia, Wisconsin, and Washington, DC.[278] Subsequent screening of donors and follow-up of recipients suggested that infections in the window period, when the infections could not be detected by immunoassay or PCR, represented 2% of positive donations or 1:15,000 donations.[279] A serology assay(s) using recombinant antigens are under development that may improve the detection of infective donors.[280–283] In the United Kingdom, a conservative approach has been taken, and all donors who have visited the northeastern United States between May and October are excluded, in addition to the standard criteria of screening out febrile and/or anemic donors.[87]

EOSINOPHILIA

Eosinophilia may be caused by a wide variety of systemic diseases and parasitic infections. The association with parasitic disease is through part of the Th2 T-cell response stimulated by helminths (worms), filaria, and cestodes. In general, protozoan infections, such as malaria, amebiasis, and giardiasis, are not associated with eosinophilia. However, case reports do exist suggesting that isosporosis due to infection with *Isospora belli*, toxoplasmosis, and infection with *Dientamoeba fragilis* can cause eosinophilia.

The rise in absolute eosinophil count depends on the degree of tissue invasion and is therefore modest with tapeworms and adult roundworms resident in the bowel but much higher where invasion occurs, for example, with *Toxocara canis* or filaria. Some parasites, such as ascariasis (roundworms) and clonorchiasis, have migratory larval stages.

The differential diagnosis of eosinophilia in those who have lived in tropical areas is therefore wide. Evaluating the patients must begin by establishing the degree of eosinophilia (minimal, $<1 \times 10^9$/L; moderate, 1 to 3×10^9/L; high, $>3 \times 10^9$/L), the relation to travel (where necessary), and the presence of symptoms. A wide range of systemic diseases are associated with eosinophilia, and the eosinophil count may be high in drug allergy, pulmonary infiltrate with eosinophilia, and vasculitides.

Eosinophilia in Travelers

Evaluating the cause of eosinophilia in travelers to tropical areas where many parasitic diseases are endemic requires a systematic approach to narrow down likely possibilities by considering existing systemic diseases that may cause eosinophilia (particularly allergy, drug ingestion, autoimmune disease, vasculitis, or arthritis); the areas visited; duration of stay; and history of exposure to soil-transmitted nematodes, freshwater potentially infected with schistosomiasis, and rural areas where loiasis, onchocerciasis, and hydatid disease may be contracted.

Physical examination may show subcutaneous swellings associated with filaria or hepatosplenomegaly consistent with schistosomiasis, hydatid disease, or toxocara. Laboratory examination requires a stepwise approach, given the breadth of the differential diagnosis (Table 154.4). The details of specific parasitologic tests are beyond the scope of this chapter, and detailed investigation would certainly require consultation with colleagues in infectious diseases (see also further reading, CDC, Laboratory Identification of Parasites of Public Health Concern).

Some parasitic causes of eosinophilia may not be diagnosed during the incubation period, because larval stages of nematode worms may cause eosinophilic drug migration, but eggs will not be excreted in stools for many months. Moreover, filarial infections do not produce detectable parasites in blood or skin for many months after exposure.

In immunocompromised patients or those about to receive a diagnosis, eosinophilia may be crucial, given the risks of giving immunosuppressive therapy such as chemotherapy or hematopoietic stem cell or solid organ transplant to a patient with a chronic parasitologic infection. Patients with undiagnosed eosinophilia and possible exposure to *Strongyloides* should be given an empirical course of treatment.

TABLE 154.4 Approach to Investigation of Eosinophilia in a Returning Traveler

History	Allergy
	Drugs and vitamins (L-tryptophan)
	Regions, localities, and duration of exposure
Physical examination	Skin, subcutaneous tissues
	Liver/spleen
	Signs of other systemic disease
Initial investigations	Full blood count and differential white blood cell count
	Stool examination for ova and parasites (×3)
	Urine analysis
	Examination of midday urine for ova and parasites (×3) (in those who have traveled to Africa or the Middle East)
Further investigations as suggested by travel and exposure from history	As suggested by travel and exposure from history
	Strongyloides culture and serologic testing
	Duodenal aspirate (strongyloidiasis, hookworm)
	Serologic testing (schistosomiasis, filariasis)
	Day/night blood films (filariasis)
Further studies if suggested by history and physical examination	Skin snips (onchocerciasis)
	Chest X-ray examination (hydatid cyst, tropical pulmonary eosinophilia, paragonimiasis)
	Soft tissue X-ray examination (cysticercosis)
	Sputum examination for ova and parasites (paragonimiasis)
	Abdominal ultrasound examination (hydatid cyst)
	Cystoscopy with or without biopsy (schistosomiasis)
	Rectal snips (schistosomiasis)

OTHER PARASITIC DISEASES

Many parasitic diseases cause some minor hematologic disturbance. A few may present with distinct hematologic features or indeed syndromes.

Filariasis

Lymphatic filariasis is caused by *Wuchereria bancrofti* and *Brugia malayi*. Infection with *W. bancrofti* occurs throughout the tropics, but by far the majority of cases are in Asia. The distribution of *B. malayi* is more restricted to China, Southeast Asia, and Southern India. The male and female adult worms live in the lymphatics, and the female worm releases a vast number of microfilariae, each 250 to 300 μm in length. Microfilariae develop but do not appear to multiply in the mosquito.

Infection may present with lymphangitis; often recurrent and unlike bacterial infections, the inflammatory features may spread distally. Over time, lymphatic obstruction may cause hydrocele, lymphedema (if severe elephantiasis), chyluria, and tropical pulmonary eosinophilia. *B. malayi* causes neither hydrocele nor chyluria.

Filariasis is most easily diagnosed by finding microfilariae in peripheral blood in a wet preparation. Motile microfilariae can be seen under low power and may be concentrated by centrifugation or filtration using a 3-μm filter. They are speciated in thin or thick films by their nuclear distribution and sheath characteristics (Fig. 154.17), and the two pathogenic species must be distinguished from the nonpathogenic species *Mansonella perstans* and *Mansonella ozzardi*, which do not have sheaths. Circulating *W. bancrofti* antigens can also be detected in the circulation by ELISA or immunochromatographic methods. Adult worms can sometimes be imaged by ultrasound. Filarial DNA from all species can be detected by PCR. Serologic testing is unhelpful because many people become exposed without developing clinical symptoms.

The worms cause marked or severe eosinophilia (see later) with counts greater than 1×10^9/L. Migration of worms through the lungs may exacerbate the eosinophil count and cause minor respiratory symptoms and fluctuating radiologic signs. Other causes of tropical pulmonary eosinophilia are the worms (helminths) *Ascaris*, *Strongyloides*, *Schistosoma*, and *Toxocara*. Of these organisms causing pulmonary symptoms and signs, filariasis alone is responsive to diethylcarbamazine. Albendazole and ivermectin may also be used against filarial infection.

Toxoplasmosis

Toxoplasmosis may cause a mild illness or a more prolonged course with constitutional symptoms, atypical lymphocytes, and thrombocytopenia. Congenital toxoplasmosis as a result of infection acquired

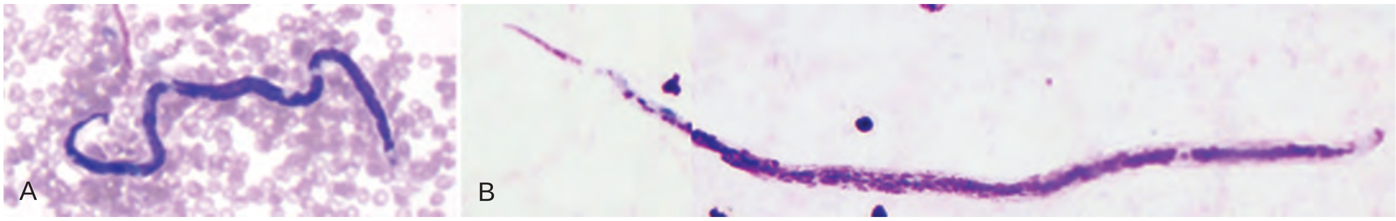

Figure 154.17 MICROFILARIA (*BRUGIA MALAYI*) ON THICK (A) AND THIN FILMS (B). The species is determined by the nuclear distribution and sheath characteristics.

during pregnancy is a cause of neonatal thrombocytopenia, where it may be accompanied by cerebral calcification, hepatitis, and pneumonitis. In immunocompromised patients, new or reactivated toxoplasmosis may cause severe disease, including encephalitis, pneumonitis, and hepatitis. Thrombocytopenia is frequently accompanied by anemia and leukopenia.

Amebiasis

Amebiasis causes hypochromic, microcytic anemia, both as a result of chronic blood loss and as an anemia of chronic disease where the disease progresses to formation of a liver abscess. Neutrophilia accompanies severe tissue damage caused by perforation of the bowel or a liver abscess, or it may be present in a secondary bacterial infection. Sometimes a leukemoid reaction with high white blood cell count and extreme left-shifted myeloid cells can be seen. Prolonged and/or extensive liver damage may cause prolongation of the prothrombin time.

Giardiasis

Acute giardiasis causes folate deficiency through malabsorption of folate in the small intestine. Chronic infection can cause vitamin B_{12} deficiency because ileal absorption of the vitamin is impaired.

Hookworm Infection

Adult hookworms attach themselves to the lining of the small bowel and take blood meals. The accumulated blood loss may be extensive because worms consume 2.0 mL (*Necator americanus*) or 0.5 mL (*Ancylostoma duodenale*) of blood each day. These infections are a common contributing factor to iron deficiency anemia in children, in whom infection is acquired by eating or walking barefoot on larva-infected soil. The disease is usually diagnosed by finding excreted eggs in stool samples, and treatment is with albendazole.

Tapeworm Infection

The fish tapeworm (*Diphyllobothrium latum*) is a rare cause of vitamin B_{12} deficiency. This tapeworm is transmitted in the Far East by eating raw or partially cooked fish. Infection has to be extensive to cause vitamin B_{12} deficiency; however, such cases are rare, even in endemic areas.

Schistosomiasis

Schistosoma haematobium causes blood loss in urine. Infection is acquired by swimming in freshwater, where cercariae from the infected snail host enter the skin and migrate to the blood vessels of the bladder. Chronic blood loss is a cause of iron deficiency anemia in children in endemic areas, but infection is likely to be diagnosed at an early stage in travelers because of the striking symptoms of painless hematuria. Treatment is with praziquantel.

FUTURE DIRECTIONS

Parasitic diseases present many problems for global heath. They cause a wide spectrum of hematologic abnormalities, and in endemic areas, a broad knowledge of the parasitic disease is vital for everyday practice. In nonendemic areas, there are a few situations where the diagnosis or management of these diseases may fall within the remit of hematologists and hematology laboratories, particularly malaria and the diagnosis of anemia, cytopenias, eosinophilia, and hepatosplenomegaly. Here, a high index of suspicion is often needed for the diagnosis to be made. A good travel history is crucial to establishing exposure to parasitic disease and to prompt the search for the appropriate organisms. Several parasitic diseases pose a threat for the safe supply of blood, and the problems of screening of these infections are far from solved. Beyond everyday practice, the pathophysiology and prevention of these diseases pose major challenges for biomedical research and public health.

CHAPTER 155

HEMATOLOGIC PROBLEMS IN THE SURGICAL PATIENT: BLEEDING AND THROMBOSIS

Iqbal H. Jaffer and Jeffrey I. Weitz

The management of hematological issues in surgical patients can be challenging due to myriad factors. Bleeding and thrombotic issues may be present concurrently, and the impact of underlying pathological issues may be masked by the primary pathology warranting surgery. Nevertheless, the role of the hematologist in the management of these patients is to aid patients with a history of bleeding or thrombosis. This chapter will review: (1) the preoperative evaluation of bleeding risk; (2) strategies to promote intraoperative hemostasis; (3) the management of patients with hemostatic abnormalities or those taking anticoagulants or long-acting antiplatelet drugs; and (4) perioperative prevention of venous thromboembolism (VTE).

PREOPERATIVE EVALUATION OF HEMOSTATIC RISK

History

Preoperative evaluation of hemostatic risk begins with a carefully taken history (see Chapter 126). Particular attention should be directed at specific bleeding symptoms and any history of bleeding associated with surgical procedures, including circumcision, tonsillectomy, and dental extractions. For women, it is important to inquire about a history of menorrhagia or excessive bleeding associated with childbirth. Detailed family history and record of medication use, including non-prescription medications, should be obtained.

Obtaining an adequate bleeding history may be complicated by the fact that even in the absence of hemostatic defects, many people consider their bleeding to be excessive. In surveys, healthy individuals frequently report excessive nosebleeds (5% to 39%), gingival bleeding (7% to 51%), easy bruising (12% to 24%), menorrhagia (23% to 44%), postpartum bleeding (6% to 23%), and bleeding following dental extraction (up to 13%) and tonsillectomy (up to 11%).[1–3] The combination of objective evidence and a constellation of symptoms is more helpful than either alone in suggesting the presence and etiology of an underlying bleeding disorder.

Coagulation Testing

The need for routine coagulation testing before surgical or invasive procedures remains controversial. Those in favor of testing point to the asymptomatic nature of some hemostatic abnormalities that may cause surgical bleeding and the occasional failure to obtain a detailed history.[4–6] Given the variety of potential hemostatic defects; however, no simple screening system will identify all patients at increased risk for bleeding. Those against routine laboratory testing[7] point to retrospective studies indicating that they rarely detect unexpected bleeding disorders[8,9] and emphasize the problems associated with the evaluation of false-positive results. A retrospective review of the value of preoperative determination of the platelet count, prothrombin time (PT), and activated partial thromboplastin time (aPTT) in 828 patients undergoing major noncardiac surgery found that only 2% had abnormal results, and most were expected based on history and physical examination.[10] Furthermore, abnormal laboratory test results and intraoperative blood loss or postoperative bleeding complications were not related (see Chapter 126). A number of prospective studies have also concluded that routine laboratory screening tests in asymptomatic patients are not predictive of perioperative or postoperative bleeding.[11–15] Thus, in the absence of historical risk factors or physical examination findings suggestive of an underlying bleeding tendency, the likelihood of an unsuspected, clinically significant, congenital or acquired coagulopathy is low enough that routine laboratory screening is not warranted, particularly for those undergoing low-risk procedures.[16] The British Committee for Standards in Haematology issued guidelines reiterating this position: indiscriminate coagulation testing before surgical or invasive procedures is a poor predictor of bleeding risk, and is not recommended in the absence of a positive personal or family bleeding history.[17]

There are several reasons why routine coagulation tests such as the PT/international normalised ratio (INR) and aPTT may be poorly predictive of underlying coagulopathy and bleeding risk.[17] First, these tests were designed to measure time to clot formation in artificial in vitro assays and do not reliably depict global hemostasis in vivo (see Liver Disease section). More importantly, the PT/INR and aPTT may be insensitive to mild but clinically relevant bleeding disorders such as von Willebrand disease or mild hemophilia (see Chapters 133 and 134). Conversely, they may detect conditions such as factor XII deficiency or a lupus anticoagulant that do not increase the risk for bleeding.

Notwithstanding the controversy about the value of preoperative laboratory screening (see Chapter 127), it is reasonable to personalize the approach to preoperative evaluation depending on the hemostatic risk of the proposed surgery or invasive procedure (Tables 155.1 and 155.2). A hemostatic history should always be obtained, and no laboratory testing is required in patients undergoing procedures at low risk for bleeding. For procedures associated with a high risk of bleeding, screening could include a PT/INR, aPTT, and determination of the platelet count. In practice, hematologists are rarely consulted for routine screening because surgeons have adopted approaches based on their own training and local practice patterns. Instead, consultation is sought because of a history suggestive of a bleeding disorder or because an abnormal test result is found on screening. If a referral is requested because of an abnormal screening test, the abnormality needs to be identified using a focused history and physical exam, and appropriate laboratory testing to further evaluate the issue.

HEMOSTATIC AGENTS

A variety of hemostatic agents are available and may be useful for the prevention or treatment of bleeding in surgical patients. These agents work through a variety of mechanisms to facilitate hemostasis, including enhancement of primary hemostasis, enhancement of thrombin generation and fibrin formation, and inhibition of fibrinolysis.[18] However, it is important to note that there is a paucity of safety data

TABLE 155.1 Risk for Bleeding with Surgical or Invasive Procedures

Risk	Type of Procedure	Examples
Low	Nonvital organs involved, exposed surgical site, limited dissection, percutaneous access	Lymph node biopsy, dental extraction, cataract extraction, most cutaneous surgery, laparoscopic procedures, coronary angiography
Moderate	Vital organs involved, deep or extensive dissection	Laparotomy, thoracotomy, mastectomy, major orthopedic surgery, pacemaker insertion
High	Bleeding likely to compromise surgical result, bleeding complications frequent	Neurosurgery, ophthalmic surgery, cardiopulmonary bypass, prostatectomy or bladder surgery, major vascular surgery, renal biopsy, bowel polypectomy

TABLE 155.2 Perioperative Management Strategies for Patients on Chronic Oral Anticoagulant Therapy

Clinical Situation	Suggested Anticoagulation Management
Low bleeding-risk surgery (dental, cataract, skin)	• Consider reducing dose of warfarin to achieve an INR ≤2.0 • Consider holding dose of DOAC until after the procedure
Low thrombotic risk Aortic valve prosthesis without other thrombotic risk factors[a] *or* AF with low stroke risk *or* VTE >3 months previously	• Stop warfarin 5 days prior to surgery, safe to operate when INR ≤1.5 • Hold DOACs for 5 half-lives—dabigatran for 2–3 days, rivaroxaban, apixaban, edoxaban for 2 days • Restart warfarin in evening of the day of surgery after hemostasis secured; restart DOACs on postoperative day 3 or 4 • Start prophylactic LMWH on the morning of the day after surgery and continue until INR >1.8 or full dose of DOACs resumed
Moderate thrombotic risk Mitral or multiple valve prostheses *or* Aortic prosthesis with risk factors for thrombosis *or* AF at high stroke risk *or* VTE within past 3 months	• Stop warfarin 5 days before surgery • Begin twice-daily LMWH in therapeutic doses starting 3 days before surgery with last dose at least 12 h prior to surgery • Hold DOACs for 5 half-lives—dabigatran for 3–4 days, rivaroxaban, apixaban, edoxaban for 2–3 days; no bridging • Restart warfarin in evening of the day of surgery after hemostasis secured; restart DOACs on postoperative day 3 or 4 • Start prophylactic LMWH on the morning of the day after surgery and continue until INR >1.8 or full dose of DOACs resumed

[a] Risk factors include caged-ball or single tilting-disk valve, AF, history of stroke/transient ischemic attack or other embolic event, left ventricular failure, underlying hypercoagulable state including cancer.
AF, Atrial fibrillation; *DOAC*, direct oral anticoagulant; *INR*, international normalized ratio; *LMWH*, low-molecular-weight heparin; *VTE*, venous thromboembolism.

involving hemostatic agents because most trials have been designed to assess therapeutic efficacy, rather than potential complications such as thrombosis.[18,19] The use of desmopressin, topical hemostatic agents, antifibrinolytic agents, and recombinant factor VIIa (rFVIIa) will be discussed here. Blood products (platelets, fresh-frozen plasma, and cryoprecipitate) and factor VIII and IX concentrates are discussed elsewhere (see Chapters 133–136).

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, or DDAVP) is a synthetic analogue of the antidiuretic hormone arginine vasopressin. Intravenous, subcutaneous, or intranasal administration of DDAVP results in transient increases in plasma concentrations of factor VIII and von Willebrand factor as a result of their release from vascular endothelium.[20] Peak levels (typically two to four times baseline) are achieved 30 to 60 minutes after intravenous and 60 to 90 minutes after subcutaneous or intranasal administration (see Chapters 133 and 134).[21] Doses may be repeated at intervals of 12 to 24 hours, but tachyphylaxis may occur after three or four doses,[22] limiting further usefulness of DDAVP. The expression of glycoprotein Ib (GPIb) and GPIIb/IIIa on the platelet membrane is also enhanced after DDAVP administration.[23] DDAVP is the treatment of choice for patients with mild hemophilia A or type 1 von Willebrand disease who require low-risk surgical procedures (see Chapters 133 and 134). Moderate- or high-risk procedures usually require administration of clotting factor concentrates.[22] DDAVP may also be useful for patients with congenital or acquired platelet function disorders.[21,23,24]

DDAVP does not reduce blood loss or transfusion requirements after cardiopulmonary bypass surgery.[25,26] Worrisome also is the fact that a metanalysis shows a 2.4-fold increase in perioperative myocardial infarction in cardiac surgery patients treated with DDAVP.[26] Thus, the routine use of DDAVP in cardiac, orthopedic, or other elective surgical procedures is not recommended.[19,27] A more recent metanalysis of 38 randomized placebo-controlled trials that included nearly 2500 surgical patients found that DDAVP slightly reduced blood loss (by approximately 80 mL) and transfusion requirements (by approximately 0.3 units) but did not reduce the proportion of patients receiving transfusions.[28] Although the authors acknowledged that the clinical impact of the reduced transfusion requirement is questionable, they felt this could not be ignored because of the low cost of DDAVP. The incidence of thromboembolic events in the DDAVP and placebo groups was similar (5.4% and 4.6%, respectively), but they pointed out that identification of harm from DDAVP is limited by study design, and that the safety concerns remain unresolved.[28] Nonetheless, certain subgroups of patients, such as those with platelet dysfunction, may derive benefit.[23,27–29] Because of the small but important risk for myocardial infarction,[30] DDAVP should be used with caution in any surgical patient with a history of or risk factors for coronary artery disease.

Topical Hemostatic Agents

Topical hemostatic agents can be grouped into several categories: physical agents such as bone wax or alkylene oxide copolymers (Ostene), absorbable agents such as gelatin foams, oxidized cellulose, or microfibrillar collagen, biologic agents such as topical thrombin, fibrin sealants, or platelet gels, synthetic agents such as polyethylene glycol hydrogels, cyanoacrylates, glutaraldehyde or cross-linked albumin, and hemostatic dressings.[31] A thorough discussion of the currently available products, including mechanisms of action, specific advantages and disadvantages, and recommendations for their use is provided in a comprehensive review.[31] A brief overview of the different types of topical hemostatic agents follows.

Physical Agents

Bone wax and Ostene control hemorrhaging by occluding bleeding channels on cut bone surfaces and are often used in cardiac and orthopedic surgery. Theoretically, Ostene may be better than bone wax because it does not impede bone growth and is eventually absorbed. Both may increase the risk for local infection.[31]

Absorbable Agents

Gelatin foams are derived from animal products and provide a physical matrix upon which clotting occurs. These products expand to double their volume, an attractive feature for use in penetrating wounds, but potentially problematic if used near nerves or in confined spaces.[31]

Oxidized cellulose is derived from wood pulp. It provides a physical matrix for initiation of clotting and has excellent handling characteristics. By lowering surrounding pH, oxidized cellulose exerts an antimicrobial effect, but this property not only limits its use with biologic agents such as thrombin that are pH sensitive, but also can contribute to local inflammation.[31]

Microfibrillar collagen is derived from bovine components. It contributes to hemostasis by promoting platelet adherence and activation and is effective in controlling wide-spread parenchymal bleeding. Consequently, it can be useful even in the face of heparin therapy, although it is less effective in the setting of thrombocytopenia.[31]

Biologic Agents

Thrombin derived from bovine plasma was used for more than 40 years as a topical hemostatic agent in surgical patients. However, bovine thrombin can trigger the formation of antibodies that cross-react with human thrombin, leading to hemorrhagic complications.[32–34] Because of these issues, plasma-derived and recombinant forms of human thrombin were developed. A phase III randomized, double-blind trial found that the efficacy and safety of recombinant human thrombin and bovine thrombin were comparable, but there were fewer immunologic complications with recombinant human thrombin.[35]

Fibrin sealants are topical hemostatic agents composed of purified, virally inactivated human fibrinogen and human thrombin. Some products also add human factor XIII to induce fibrin cross-linking and antifibrinolytic agents to prevent clot breakdown.[36] The components of fibrin sealants are supplied in separate chambers of a dual-syringe delivery device that combines them at the time of administration. The final steps of the coagulation cascade are reproduced, resulting in the formation of a stable fibrin clot. Fibrin sealants are particularly effective for controlling oozing from raw surfaces.[31]

Platelet gel combines microfibrillar collagen and thrombin with patient-derived plasma that contains fibrinogen and platelets. Like fibrin sealants, the product is applied using a dual-chamber syringe device. The presence of platelets improves clot strength and provides growth factors, but the need for centrifugation and processing of patient blood before use is a disadvantage.[31]

Synthetic Agents

Cyanoacrylates are liquid monomers that rapidly polymerize in the presence of water and bind adjacent surfaces together. Octyl-2-cyanoacrylate is useful for closing small wounds or incisions, and provides good cosmetic results.[31]

Polyethylene glycol hydrogel can be sprayed onto tissues, where it rapidly forms a cross-linked polymer matrix and serves as a sealant that inhibits cell ingrowth and adhesion formation. It is useful for preventing pericardial adhesions and as a mechanical sealant for vascular reconstructions in situations where swelling and expansion are not a concern.[31]

Glutaraldehyde cross-linked bovine albumin is primarily used to seal sutures or staple lines in complex cardiovascular procedures. However, because it can restrict tissue growth, it should not be used circumferentially around developing structures, particularly in children.[31]

Hemostatic Dressings

Progress in the field of topical hemostatic agents over the last decade has expanded into the development of hemostatic dressings. Several products containing combinations of gauze, lyophilized fibrinogen, and thrombin, chitin, chitosan (polysaccharides found in arthropod skeletons and produced by fermenting algae), or mineral zeolite are available. In general, the use of hemostatic dressings is still under investigation, primarily by the military and emergency first responders.[31]

Antifibrinolytics

Antifibrinolytic agents include the synthetic lysine analogs 6-aminohexanoic acid (epsilon aminocaproic acid) and 4-(amino methyl) cyclohexane carboxylic acid (tranexamic acid), and the serine protease inhibitor, aprotinin. Although both types of antifibrinolytic agents have been used in managing surgical bleeding, the lysine analogs are available in oral forms that facilitate their use in other clinical situations as well.

Aminocaproic Acid and Tranexamic Acid

Both aminocaproic acid and tranexamic acid bind reversibly to the lysine binding sites on plasminogen, thereby attenuating its capacity to bind to fibrin, which is essential for its activation by plasminogen activators.[21] Although tranexamic acid is approximately 10 times more potent than aminocaproic acid and has a longer half-life, both drugs have similar hemostatic effects.[37]

Because the oral form of tranexamic acid was not commercially available in the United States for several years, aminocaproic acid became the lysine derivative of choice for oral delivery. Aminocaproic acid is commonly used to treat mucosal hemorrhage (menorrhagia, epistaxis, dental bleeding) in patients with congenital coagulopathies and is also effective for the prevention of oral bleeding in patients taking oral anticoagulants who require dental work (see Chapters 133–135). Both aminocaproic acid and tranexamic acid can be administered intravenously as well as topically.

Although aminocaproic acid is sometimes used to treat bleeding in patients with thrombocytopenia, randomized controlled trials are lacking. The use of antifibrinolytic drugs in patients with gastrointestinal bleeding is reasonable given the high concentration of fibrinolytic enzymes in the digestive tract, and a metanalysis found reductions in recurrent bleeding, need for surgery, and mortality.[38] However, improvements in the efficacy of other medical and endoscopic treatments have limited the use of these drugs in this setting, although they are still useful for some patients with underlying bleeding disorders.[21] The urinary tract is also rich in plasminogen activators, and some clinical trials comparing tranexamic acid or aminocaproic acid with placebo in patients undergoing prostatectomy have shown reduced blood loss, but not a reduced need for transfusion or decreased mortality.[21]

The largest experience with aminocaproic acid is in patients undergoing cardiac or orthopedic surgery. Two meta-analyses have shown that aminocaproic acid and tranexamic acid are effective in reducing surgical blood loss, but have yielded inconsistent results in their capacity to reduce transfusion requirements.[27,39] A wide variety of dosing schedules may partly explain these heterogeneous results.[27]

A meta-analysis showed that both agents were effective in reducing blood loss and transfusion requirements in those undergoing cardiac surgery.[40]

Several studies have demonstrated that antifibrinolytic agents reduce blood loss in orthopedic surgery. A meta-analysis of 43 randomized controlled trials in patients undergoing total hip or knee arthroplasty, spine fusion, surgery for musculoskeletal infection, or tumor surgery found that aprotinin and tranexamic acid significantly reduced the number of patients requiring transfusion, with a dose-effect relationship suggested for tranexamic acid.[41] A meta-analysis of 11 clinical trials involving patients undergoing total hip replacement found a significant reduction in intraoperative blood loss and transfusion requirements with tranexamic acid, without any increase in VTE or other complications.[42] Therefore, many centers routinely administer tranexamic acid to patients undergoing elective joint arthroplasty to reduce blood loss and decrease the need for transfusion.

Antifibrinolytics, particularly tranexamic acid, have also been studied for the treatment of trauma patients, in whom 30% of deaths are attributed to hemorrhage.[43] A landmark trial, Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage 2 (CRASH-2), evaluated the safety and efficacy of tranexamic acid in the setting of trauma.[44] This randomized, placebo-controlled, multinational trial that included more than 20,000 trauma patients demonstrated a significant reduction in all-cause mortality and death because of bleeding in the treatment group. More severely injured patients and those treated within 3 hours of injury derived the greatest benefit, and there was no difference in the rate of vascular occlusive events between the two groups.[44] Tranexamic acid is now incorporated into trauma clinical practice guidelines and treatment protocols.[45]

In the CRASH-3 trial, tranexamic acid was compared with placebo in 12,737 patients with traumatic brain injury, 72% of whom were treated within 3 hours of their injury.[46] With tranexamic acid, the risk of head injury-related death was reduced in patients with mild-to-moderate head injury but not in those with severe head injury.[46] Therefore, early administration of tranexamic acid may be of benefit in patients with mild to moderate traumatic brain injury.

Aminocaproic acid and tranexamic acid are not without risks. Although there are reports of thrombosis associated with these agents, no significant increase in thrombotic complications was observed when the drugs were used in patients undergoing cardiac surgery, liver transplantation, or orthopedic surgery.[22,24,41,47,48] However, when tranexamic acid is administered to patients undergoing cardiac surgery in doses exceeding 80 mg/kg, there is a risk of seizures.[49,50]

OFF-LABEL USE OF rFVIIA

A 56-year-old man has undergone aortic arch replacement for an aortic dissection. During the procedure he underwent circulatory arrest for 35 min, with a lowest recorded temperature of 18°C. His total bypass time was 225 min. After rewarming, there was considerable bleeding and he received 10 units of packed red blood cells, 8 units of fresh frozen plasma, 4 pooled units of platelets, and 20 units of cryoprecipitate. He was transferred from the operating room to the intensive care unit in stable condition.

A consultation is made to the hematologist 1 h later because of excessive drainage (>500 mL) from his chest tubes.

Important information to consider:

- likelihood of surgical bleeding versus coagulopathy
- current temperature
- evidence of clotting within the chest tubes
- current coagulation studies (if available)
- hemodynamic status

Upon discussion with the surgeon and intensive care unit team, it is noted that the temperature is 35.5°C, there is little clot in the chest tubes, and he requires hemodynamic support with epinephrine and norepinephrine. His recent coagulation studies reveal an INR of 1.8, an aPTT of 48 s, a thrombin time of 59 s, and a fibrinogen level of 2.5 g/L.

Possible treatments:

1. warming blanket
2. protamine sulfate 50 mg by slow intravenous infusion: for heparin rebound
3. calcium gluconate 1–2 g intravenous bolus: for excessive citrate (from blood products)
4. blood products (using a warming line)
5. consider rFVIIa: 40–80 μg/kg

Interpretation: The likelihood is that despite the extensive transfusion, the combination of a prolonged time on bypass and cooling to 18°C has resulted in a coagulopathy. This is further evidenced by the prolongation of the coagulation tests and the lack of visible clots within the chest tubes. Although items 1–3 are important as adjunctive therapies, they are unlikely to be sufficient on their own. The utility of further blood products in this situation cannot be understated, because in order for rFVIIa to work effectively, it relies on the presence of underlying substrate, which is effected by judicious use of blood products. Although the use of rFVIIa in this scenario is off-label, its use is justified when the surgeon feels that the likelihood that bleeding is too diffuse to be stopped by surgical intervention and is likely caused by coagulopathy.

aPTT, Activated partial thromboplastin time; *rFVIIa*, recombinant factor VIIa.

Recombinant Factor VIIa

rFVIIa is licensed in the United States only for the prevention and treatment of bleeding in hemophilia A or B patients with inhibitors, patients with acquired hemophilia, and in those with congenital factor VII deficiency (see Chapters 134 and 135). This drug is believed to induce hemostasis at local sites of tissue injury through enhancement of thrombin generation on the surface of thrombin-activated platelets.[51] rFVIIa also activates thrombin activatable fibrinolysis inhibitor, which in turn stabilizes the clot by inhibiting fibrinolysis.[52]

rFVIIa is often used for a variety of off-label indications, such as to control refractory bleeding after surgery or major trauma, and to prevent bleeding in surgeries where blood loss is expected to be excessive (see box on Off-Label Use of rFVIIa). A prospective, multicenter, randomized, controlled trial that included 143 patients with blunt trauma and 134 patients with penetrating trauma found that in the group with blunt trauma, three successive doses of rFVIIa significantly decreased red blood cell transfusion (mean reduction of 2.6 units) and decreased by approximately half the number of patients requiring massive transfusion (more than 20 units of red blood cells).[53] Although similar trends were observed in the patients with penetrating trauma, the differences were not statistically significant. Despite the reduction in the need for blood products, there was no survival benefit. After these initial encouraging reports of the use of rFVIIa in trauma patients, questions regarding optimal dosing and timing of administration remained. To address these issues, the Western Trauma Association Multi-Center Trials Group conducted a case registry of 380 adult trauma patients who received adjunctive rFVIIa for hemorrhage control.[54] This registry was unable to define a precise role for rFVIIa in traumatic bleeding. However, pH less than 7.2, platelet count less than 100,000/μL, and blood pressure less than or equal to 90 mmHg were each found to be predictors of poor response to rFVIIa, suggesting that shock, acidosis, and thrombocytopenia should be corrected before rFVIIa is given to trauma patients who are bleeding.[54] The CONTROL trial, which randomized 560 actively bleeding trauma patients to rFVIIa or placebo, found no differences in overall mortality, organ system failure, or adverse events in either group.[55] Thus, despite the encouraging initial reports, there is currently insufficient evidence to support the routine use of rFVIIa in the setting of trauma.

The use of rFVIIa in cardiac surgery is controversial. Because perioperative bleeding is a major cause of morbidity and mortality, there is off-label use of rFVIIa in this patient population.[56] Several case reports and uncontrolled case series in both adult and pediatric populations have suggested that rFVIIa is effective in decreasing blood loss and transfusion requirements in patients with intractable bleeding after cardiopulmonary bypass. However, in the absence of data from well-designed clinical trials demonstrating efficacy and with the current widespread use of tranexamic acid in such patients, rFVIIa is rarely used in this setting.

The primary safety concern with the off-label use of rFVIIa is thrombosis. In hemophilia, the risk for thrombosis is estimated to be less than 1%.[57,58] In contrast, the risk is much higher with off-label use. Both arterial and venous thromboembolic events have been reported, and thromboembolic events were the probable cause of death in most of the reported fatalities. Half of the thromboembolic events occurred within 24 hours of the last dose of rFVIIa, and many occurred within 2 hours.[59] Therefore, off-label use of rFVIIa should be restricted to cases where there are no alternatives. The results of a metanalysis that assessed the use of rFVIIa in randomized trials suggested that most the arterial complications occur in older patients (>65 years) and in those patients receiving rFVIIa doses in excess of 80 μg/kg.[60]

MANAGEMENT OF PATIENTS WITH HEMOSTATIC ABNORMALITIES

Patients with known hemostatic abnormalities are often referred before surgery for assessment of bleeding risk and recommendations regarding perioperative management. The approach to these patients should be according to the following considerations: (1) evaluation of the risk for bleeding associated with the specific surgery or procedure (see Table 155.1); (2) careful consideration of the need for surgery and its urgency; greater risks are warranted for correction of life-threatening conditions than for elective procedures; (3) recognition of the nature and severity of the patient's hemostatic abnormality and the ability to correct it; and (4) consideration of the duration of replacement that will be required, with potential bleeding that may be associated with events in the postoperative period such as removal of sutures and deep drains, and the need for postoperative rehabilitation. The following sections discuss perioperative management of some common coagulation abnormalities; the management of congenital factor deficiencies and von Willebrand disease in Chapters 133–136.

Thrombocytopenia

Thrombocytopenia is one of the most common acquired hemostatic abnormalities, and the availability of platelet transfusion makes consideration of both emergency and elective surgery reasonable even in patients with severe thrombocytopenia. The best index of bleeding risk in thrombocytopenic patients is the platelet count. In nonsurgical patients, a threshold platelet count of 10,000/μL is widely used for prophylactic transfusion, yet there is inadequate scientific evidence to determine the platelet count below, which increased the risk for surgical bleeding.[61,62] The American Society of Anesthesiologists Task Force on Perioperative Blood Management concluded that prophylactic platelet transfusion in surgical patients is usually indicated when the count is below 50,000/μL and is rarely indicated when the count is above 100,000/μL.[62] Clinical trials addressing this issue are still lacking.[63] For low-risk surgery, a single transfusion to increase the platelet count above 50,000/μL followed by close observation may suffice, whereas transfusion to maintain the platelet count at greater than 50,000/μL for moderate-risk surgery and greater than 100,000/μL for high-risk surgery is usually appropriate. The optimal duration of postoperative platelet support has not been carefully studied, but even for moderate or high-risk surgery, platelet transfusions may be needed for less than 1 week because they are principally required for primary hemostasis. The platelet count should be monitored closely during the postoperative period, with the expectation that platelet survival will be shortened by infection, fever, or bleeding. In addition, platelet transfusion may be indicated for surgical patients even on the face of a normal count if there is known or suspected platelet dysfunction, intake of long-acting antiplatelet drugs, or microvascular bleeding.

When thrombocytopenia is caused by increased platelet destruction (e.g., immune thrombocytopenic purpura), prophylactic platelet transfusion is largely ineffective and is indicated only for active, serious bleeding (see Chapters 128 and 129). In preparation for surgery, therapy with steroids and/or intravenous γ-globulin often will increase the platelet count to a satisfactory level so that transfusion is not needed. Rho(D) immunoglobulin (WinRho) may also be useful in this setting (see Chapter 128).

Platelet Dysfunction

Patients with platelet dysfunction represent a large group for whom preoperative consultation is sought, typically because of a history of abnormal bleeding or the discovery of a prolonged bleeding time, or abnormalities in other tests of platelet function despite a normal platelet count (see Chapters 126 and 127). Drugs are the most common cause of acquired platelet dysfunction (see Chapter 128). Many commonly used medications, including aspirin, nonsteroidal anti-inflammatory drugs, antibiotics, antidepressants (selective serotonin reuptake inhibitors), cardiovascular drugs, and newer antiplatelet agents, including ADP receptor, GPIIb/IIIa and protease-activated receptor-1 antagonists (see Chapter 143), can cause platelet dysfunction. Ethanol as well as certain foods and herbal supplements can also inhibit platelets (see Chapter 128); a careful history is therefore essential. Any drugs that interfere with platelet function should be reviewed before surgery and their need for ongoing use considered.

Several medical conditions can cause acquired platelet dysfunction (see Chapter 128). The etiology may be obvious in cases of renal or liver disease, myeloproliferative disorders, leukemia, myelodysplastic syndromes, or dysproteinemia, but consideration of undiagnosed intrinsic platelet defects (storage pool disease or platelet release defects) or von Willebrand disease may be necessary. Treatment of the underlying disease is the most effective approach, if possible. If not, platelet transfusion may be indicated, but the dose required to achieve hemostasis is difficult to predict and depends in part on the severity of the underlying platelet abnormality. As discussed earlier, treatment with DDAVP may be appropriate in selected patients. The exact mechanism of action of DDAVP in acquired platelet dysfunction is not well understood, but one study suggests that DDAVP interacts directly with platelets and exerts a priming effect on platelet aggregation stimulated by ADP or collagen.[64] Expression of GPIb and GPIIb/IIIa on the platelet surface is enhanced after DDAVP administration.[24]

Kidney Disease

Impaired hemostasis has long been recognized in patients with chronic kidney failure and is discussed in greater detail in Chapter 128. The pathogenesis is multifactorial but is due in large part to alterations in platelet function.[65] Anemia also contributes to platelet dysfunction in chronic kidney failure. Red blood cells release ADP, which in turn inactivates vascular prostacyclin, an inhibitor of platelet function.[66] Correction of anemia, now routinely accomplished using recombinant erythropoietin, also improves the rheologic factors that facilitate platelet interaction with the vessel wall. An increase in hematocrit, whether using erythropoietin or transfusion, is accompanied by significant shortening of the bleeding time and improvement of platelet adhesion.[67] In addition to platelet dysfunction and altered balance between mediators of normal endothelial function, the pathophysiology of uremic bleeding is complicated by the comorbidities in this patient population, such as vascular disease and hypertension, and the medical treatment of those conditions.[68]

Liver Disease

Hemostatic alterations in patients with acute or chronic liver disease (see Chapter 128) are complex and involve both procoagulant and anticoagulant pathways.[69,70] Although patients with liver disease are typically felt to have deficient hemostasis, this concept has been challenged in the recent literature.[71] These patients are not "autoanticoagulated," as is often assumed. In fact, they are not protected from and may even be at increased risk for thrombosis, particularly in the portal venous system.[72–74] The presence of genetic thrombophilic mutations may further increase this risk.[75] The procoagulant tendency associated with chronic liver disease[76,77] suggests that prophylaxis against VTE may be warranted in high-risk situations.[71] However, the perceived bleeding risk often limits the use of anticoagulant prophylaxis,[78] and appropriately designed pharmacologic clinical studies are clearly needed.[72] Mechanical thromboprophylaxis is a reasonable alternative for hospitalized patients with severe liver disease.

Patients with severe decompensated liver disease and markedly abnormal coagulation test results are at increased risk for bleeding, and surgery should be avoided except as a lifesaving measure. In evaluating hemostasis in patients with less severe disease, the PT/INR and aPTT may be good indicators of decreased synthesis of clotting factors and vitamin K deficiency, but they are poor predictors of bleeding risk. Several studies have shown the failure of the PT/INR and aPTT to predict bleeding after liver biopsy.[79,80] Similarly, preoperative hemostatic testing has generally not been shown to be useful for predicting bleeding during liver transplantation.[81] A study in patients with liver disease found that INR values in the range of 1.3 to 2.0 generally correspond to levels of factors II, V, and VII that are adequate for hemostasis.[82] A preoperative platelet count is needed to identify thrombocytopenia, and some assessment of platelet function may be useful to determine whether platelet function is abnormal in the setting of a normal or near-normal platelet count. The thrombin time or fibrinogen level should also be determined to evaluate for dysfibrinogenemia. Tests for fibrinogen/fibrin degradation products, D-dimer levels, euglobulin clot lysis time, or thromboelastography may be useful to evaluate for disseminated intravascular coagulation (DIC) or accelerated fibrinolysis (see Chapter 137).

In patients with mild liver disease and a mild-moderate prolongation of the INR (<2.0), serious surgical bleeding is unlikely in the absence of other hemostatic abnormalities, and prophylactic intervention is rarely required for low- or moderate-risk surgery. For high-risk surgery or for patients with markedly abnormal coagulation tests, transfusion of fresh-frozen plasma is the most frequently used approach for correcting the coagulation abnormality, although prospective studies demonstrating the value of fresh-frozen plasma administration in this setting are lacking. There are, however, guidelines that caution against the indiscriminate use of plasma before invasive procedures.[83] It should be noted that the PT of fresh-frozen plasma is approximately 15 seconds, which corresponds to an INR of 1.5, so complete correction of the PT/INR is unlikely to be achieved.[84] Administration of platelets should be considered for more severe degrees of thrombocytopenia, although recovery will be decreased in the presence of splenomegaly. Administration of DDAVP may be useful in some cases for correcting abnormal platelet function.[85] Intravenous administration of 5 to 10 mg of vitamin K will usually shorten the PT/INR if vitamin K deficiency is a contributory factor. Antifibrinolytic agents also may be useful for the reduction of perioperative hemorrhage in patients with liver disease.

INTRAOPERATIVE AND POSTOPERATIVE BLEEDING

Patients with excessive bleeding during or after surgery require rapid evaluation and treatment. The first step is to distinguish between "surgical" and "coagulopathic" causes of bleeding. Failure to surgically control bleeding vessels at the operative site is the most frequent cause of postoperative bleeding and is suggested by evidence of hemorrhage restricted to the operative site and manifesting as an expanding hematoma, excessive blood in surgical drains, or saturated wound dressings. Conversely, coagulopathic bleeding is suggested by oozing at the operative site in addition to evidence of bleeding outside the operative field that may manifest as petechiae, purpura, or bleeding at sites of venipuncture, urinary or vascular catheters, or nasogastric and endotracheal tubes.[86] In addition to careful physical examination, laboratory tests, including PT/INR, aPTT, and platelet count, are an essential part of the evaluation. Other useful tests may include a fibrinogen level, and a test for fibrin degradation products or D-dimer and thromboelastography to search for evidence of DIC or increased fibrinolysis (see Chapter 137). The peripheral blood smear should also be reviewed to examine platelet morphology and number, and to identify possible red blood cell fragmentation that may occur in DIC. The possibility of a pre-existing hemostatic abnormality that may have been missed before surgery should also be considered.

When evaluating coagulation test results in surgical patients, changes that normally occur in response to surgery must be considered. These vary depending on the extent of tissue dissection and the duration of the procedure. Consumption and hemodilution from crystalloid and blood product infusion can lead to acute reductions of coagulation factors and platelets during surgery and in the initial postoperative period. This is typically followed by changes resulting from the acute-phase response, including increases in fibrinogen and factor VIII levels and the platelet count during the first postoperative week.[87]

Alterations in coagulation factor levels that occur during surgery and in the initial postoperative period can limit the reliability of the PT/INR and aPTT when evaluating the bleeding surgical patient. Clinical practice guidelines have consistently recommended transfusion of fresh-frozen plasma if the PT/INR and aPTT results are prolonged more than 1.5-fold compared with the mean reference range.[88,89] However, there are differing opinions on the utility of coagulation studies to guide transfusion practices,[89,90] and prospective studies are needed.

Coagulopathy Associated With Massive Blood Loss/Transfusion

Massive bleeding (loss of one or more blood volumes in a 24-hour period) may occur in the setting of severe trauma or major surgery and requires aggressive fluid resuscitation and transfusion of blood products. The mechanisms involved in the coagulopathy that accompanies massive transfusion have not yet been fully elucidated, but are multifactorial in nature.[91] Similar to chronic liver disease, procoagulant, anticoagulant, profibrinolytic, and antifibrinolytic factors are all affected, resulting in a complex coagulopathy. Impaired thrombin generation is compensated in part by reductions in the activity of antithrombin and other protease inhibitors. Fibrinogen levels can fall rapidly and are proportional to the degree of hemodilution. Antifibrinolytic protein levels are decreased, rendering clots more susceptible to lysis.[92] In addition to a dilutional coagulopathy, other complications, including consumptive coagulopathy, hypothermia, electrolyte abnormalities (because of citrate intoxication), and acid-base disturbances, may also develop.[92]

In patients without a pre-existing coagulopathy, replacement of approximately 1.5 blood volumes is the threshold for the development of dilutional coagulopathy.[93] At that point, PT/INR, aPTT, fibrinogen level, and platelet count should be determined. If the PT/INR or aPTT is prolonged greater than 1.5 times the control, the fibrinogen level is below 100 mg/dL, or the platelet count is reduced to 50,000 to 70,000/μL, clinical coagulopathy is suspected and appropriate blood product administration is indicated, particularly if additional blood loss is expected. The same coagulation parameters should be measured again with the replacement of each additional half-blood volume (i.e., 5 to 6 units of red blood cells).[94]

Over the last several years, there has been an increased emphasis on more aggressive blood component therapy, driven by data from both military and civilian trauma populations.[95–98] These studies have demonstrated that higher ratios (approaching 1:1:1) of plasma and platelets to red blood cells are associated with improved outcomes in massively transfused patients.[99] Patients receiving less than massive transfusion may also benefit from higher plasma-to-red blood cell ratios.[100] Furthermore, maintaining an adequate fibrinogen level is essential for the successful management of dilutional coagulopathy.[92] Appropriate and timely management of these patients must be facilitated to avoid prolonged hypotension, acidosis, and tissue-level ischemia, all of which can predispose to the development of DIC (see Chapter 136).

Cardiopulmonary Bypass

Cardiopulmonary bypass is associated with unique hemostatic changes. Perfusion through the extracorporeal membrane oxygenator has profound effects on platelets and clotting factors: platelet count, hematocrit, and levels of coagulation and fibrinolytic factors are reduced to approximately 50% of baseline after starting bypass and remain reduced throughout the procedure, with the exception of factor V, which may be further reduced to less than 20%.[101–103] These changes may be caused in part by exposure to artificial surfaces and also by a tissue factor–dependent pathway related to surgical trauma.[104] Cardiopulmonary bypass results in significant platelet dysfunction[105] reflected by the release of α-granule contents, the generation of platelet microparticles, abnormal ex vivo platelet aggregation test results, and transient prolongation of the bleeding time (see Chapter 127).[102–106] In addition to quantitative and qualitative platelet function defects, cardiopulmonary bypass also results in platelet activation, which may trigger thrombotic and inflammatory complications.[106] Patients with acute coronary syndrome (who may be candidates for urgent cardiac surgery) are sometimes given GPIIb/IIIa inhibitors, which may further impair platelet function (see Chapter 145). If surgery cannot be delayed, consideration of prophylactic platelet transfusions may be required.[107] Inadequate neutralization of heparin with protamine sulfate after cardiopulmonary bypass may result in a prolonged aPTT and thrombin time with a normal reptilase time and is an indication for administration of additional protamine sulfate. The use of DDAVP, antifibrinolytic drugs, and rFVIIa to reduce the hemorrhagic complications of cardiac surgery was discussed earlier. Fibrinogen concentrate has also been shown to reduce blood loss and transfusion requirements during cardiac surgery.[108]

Orthotopic Liver Transplantation

In addition to the complex coagulopathy of end-stage liver disease, orthotopic liver transplantation is accompanied by major alterations in hemostasis. The surgical procedure itself can be divided into three stages, each with its own profile of coagulation abnormalities.[109] Bleeding during the pre-anhepatic stage, while the host liver is surgically isolated, is due primarily to the patient's pre-existing coagulopathy and is determined by the severity of the underlying liver disease. Excessive fibrinolysis may be encountered during this stage in 10% to 20% of those with cirrhosis. The anhepatic stage begins with surgical removal of the liver. Bleeding during this stage is primarily hemostatic because of DIC and excessive fibrinolysis.[110] As the donor liver is re-perfused, the post-anhepatic stage begins, and serious bleeding is often encountered because of a combination of hyperfibrinolysis, metabolic acidosis, hypothermia, electrolyte abnormalities, and sometimes impaired cardiac function.[110,111]

The multifactorial nature of the coagulopathy associated with orthotopic liver transplantation requires a combination of therapeutic interventions. In addition to transfusion of blood products, other hemostatic agents such as DDAVP and antifibrinolytics may be useful and were discussed earlier. There has also been much interest in the use of rFVIIa, and some randomized, placebo-controlled trials have been completed, but questions about optimal dosing, cost-effectiveness, and safety remain to be fully answered. Furthermore, it is still questionable whether rFVIIa should be used prophylactically in liver transplantation patients outside of a prospective clinical trial.[112]

PERIOPERATIVE ANTICOAGULATION MANAGEMENT

Hematologists are frequently consulted for advice on the perioperative management of patients who are taking oral anticoagulants. Important considerations to be considered include: (1) the bleeding risk associated with the surgery; (2) the underlying indication for anticoagulant therapy; (3), the timing of the most recent thrombotic event; (4) other comorbid conditions that may increase the risk for thrombosis and/or the potential consequences of thrombosis while oral anticoagulation is temporarily interrupted; and (5) the half-life of the anticoagulant agent. Regarding the first point, experience has accumulated in recent years suggesting that many relatively minor procedures can be carried out without any interruption of warfarin or direct oral anticoagulant (DOAC) therapy.[113] These include minor dental procedures (single or multiple extractions and simple endodontic procedures), cataract removal, minor dermatologic procedures, and low-risk endoscopy procedures. Audits suggest that discontinuation of anticoagulation occurs more frequently than is necessary in patients undergoing these minor procedures.[114] Apart from the risk for thromboembolism, the inappropriate use of bridging therapy also places patients at risk for bleeding complications. Suggested management strategies are summarized in Table 155.2.

Traditionally, patients on chronic oral anticoagulation therapy with warfarin were admitted to the hospital several days before surgery for "bridging" anticoagulation, at which time warfarin was discontinued and dose-adjusted unfractionated heparin (UFH) was administered by continuous infusion (see Chapter 143). The short half-life of UFH allows it to be safely discontinued approximately 4 to 6 hours ahead of the procedure. This was followed using subcutaneous low-molecular-weight heparin (LMWH) in place of UFH.[115–117] LMWH has the advantage that in most patients with normal renal function, no monitoring is required, so that therapy can be administered in the outpatient setting. In addition, the risk for heparin-induced thrombocytopenia is less with LMWH than with UFH.[118] However, the longer half-life (generally in the range of 4 to 6 hours) necessitates withdrawal of these agents at least 12 hours (for prophylactic doses) or 24 hours (for full therapeutic doses) preoperatively, although even then significant circulating anticoagulant activity may remain in the plasma.[119] A randomized trial suggests that bridging with LMWH does not reduce the risk of thromboembolic events and increases the risk of bleeding in patients with atrial fibrillation.[120] Although these results have changed practice, it is important to note that atrial fibrillation patients with prior stroke were underrepresented in the study, and patients with mechanical heart valves were excluded.

Temporary interruption of warfarin is often required for more major surgery. Even with a normal diet, 4 to 5 days should be allowed for full or near-full reversal of warfarin when it is being targeted to an INR of 2.0 to 3.0. More rapid reversal over 24 to 36 hours can be achieved, if necessary, by administration of a small oral dose of vitamin K1 (1.0 to 2.5 mg).[121,122] Large doses of vitamin K1 (>10 mg) are generally unnecessary for this purpose and will lead to prolonged refractoriness to warfarin after it is reinitiated. Although frequently used, subcutaneous administration of vitamin K1 is associated with highly variable absorption and should be avoided. Intravenous vitamin K1 has the advantage of more rapid INR reversal compared to the oral route,[123] but it should be administered slowly to avoid anaphylactoid reactions. Urgent reversal of warfarin before surgery should not be attempted using fresh-frozen plasma, because large volumes (15 to 20 mL/kg) are usually required to reverse the INR, and complete normalization cannot usually be achieved. Furthermore, the effect is relatively short-lived because of the short half-life (approximately 6 hours) of transfused factor VII. Therefore, concomitant vitamin K1 administration is required to ensure the maintenance of

TABLE 155.3 **Comparison of the Features of the Direct Oral Anticoagulants**

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Target	Thrombin (IIa)	Factor Xa	Factor Xa	Factor Xa
Active drug	No	Yes	Yes	Yes
Onset time (h)	0.5–2	2–4	3–4	1–3
Half-life (h)	12–17	5–13	~12	10–14

Reversal agent	Idarucizumab	Andexanet alfa; four-factor PCC if andexanet unavailable		

IV, Intravenous; *PCC*, prothrombin complex concentrate.

adequate hemostasis. Four-factor prothrombin complex concentrate (PCC; 25 to 50 units/kg) is preferred over plasma for urgent warfarin reversal prior to surgery or to control hemorrhage in warfarin-treated patients.[122,124]

DOACs have replaced warfarin for the prevention of stroke and systemic embolism in most patients with atrial fibrillation and for prevention and treatment of VTE (see Chapters 140 and 147). Working knowledge of the elimination half-lives of these agents is important in deciding when and if to discontinue them before elective procedures (Table 155.3). In general, for all but minor procedures, the goal is to have negligible amounts of the drug (<10%) in the circulation at the time of surgery. This means stopping dabigatran 2 to 3 days before surgery depending on kidney function, and stopping rivaroxaban, apixaban, or edoxaban 1 to 2 days prior to surgery.[125–127] In the setting of urgent surgery, dabigatran can be reversed with a 5 g bolus of idarucizumab.[128–130] Although andexanet alfa can reverse the anticoagulant effects of rivaroxaban, apixaban and edoxaban, it has not been evaluated for urgent reversal prior to surgery. In such cases, four-factor PCC can be considered.[131,132]

Perioperative Thromboprophylaxis

VTE is the most common cause of preventable death in hospitalized patients. Thromboprophylaxis in medical patients is discussed in Chapters 140 and 141. In surgical patients, the risk of postoperative VTE depends on the type of surgery and patient factors. Patients undergoing non-orthopedic surgery have a variable risk of postoperative VTE, whereas those undergoing major orthopedic procedures or surgery for abdominal or pelvic cancer are at high risk. Therefore, the two groups are discussed separately.

Non-orthopedic Surgery

In patients undergoing non-orthopedic surgery, the risks of VTE are grouped into four categories: very low (<0.5%), low (~1.5%), moderate (~3%), and high (~6%).[133] In both the very low- and low-risk groups, guidelines recommend that patients be managed with early ambulation. In the moderate- and high-risk groups, guidelines recommend pharmacologic thromboprophylaxis with LMWH.[133] LMWH is preferred over low-dose UFH because its use is associated with a reduced risk of heparin-induced thrombocytopenia (see Chapter 131).[134] Although LMWH is usually given only while the patient is hospitalized, extended prophylaxis for at least 4 weeks is recommended for patients undergoing abdominal or pelvic surgery for cancer. If the risk of bleeding is deemed to be too high to enable pharmacologic thromboprophylaxis, such as in patients undergoing neurosurgery or spinal surgery, intermittent pneumatic compression devices should be used until the bleeding risk subsides.[133]

Orthopedic Surgery

Patients undergoing orthopedic surgery are at high risk for postoperative VTE because they are relatively immobile after surgery and because manipulation of the lower limb vascular structures may disrupt the vascular endothelium.[135] Therefore, patients undergoing hip or knee arthroplasty or surgery for hip fracture are all categorized as high risk. Accordingly, postoperative pharmacologic prophylaxis is recommended, and the choices in patients undergoing hip or knee arthroplasty include rivaroxaban, apixaban, LMWH, or dose-adjusted warfarin; aspirin is also included as an option in preference to no prophylaxis.[133] In patients undergoing knee arthroplasty, guidelines recommend that prophylaxis be continued for at least 10 to 14 days after surgery, and in those undergoing hip arthroplasty or surgery for hip fracture, prophylaxis should be continued for at least 35 days.[136] A recent trial that randomized patients undergoing hip or knee arthroplasty to extended thromboprophylaxis with rivaroxaban or aspirin after an initial 5-day course of rivaroxaban reported similar rates of postoperative VTE and bleeding.[137] The DOACs have not been extensively evaluated in patients undergoing surgery for hip fracture, and LMWH is often used for thromboprophylaxis in such patients although rivaroxaban is more convenient for out-of-hospital administration.[136] Most patients without a prior history of VTE do not require thromboprophylaxis after arthroscopic surgery.[136]

SUMMARY

The management of surgical or trauma patients in the perioperative period can be challenging because of the divergent procedures, patient-related and procedure-related risks, and the limitations of time and acuity of the situation. Prior bleeding or thrombotic events and the use of concomitant medications need to be considered when developing a management plan that incorporates judicious use of coagulation tests, hemostatic agents, and/or blood products. Collaboration with the surgical or trauma teams improves patient outcomes. Ongoing research into the management of surgical and trauma patients will likely aid clinical decision-making in the future.

CHAPTER 156

THE SPLEEN AND ITS DISORDERS

Thomas A. Ollila, Adam S. Zayac, and Fred J. Schiffman

Galen described the spleen as the "organ of mystery," with functions related to mood and good or ill humors. It was not until the 18th century that the spleen's relationship to the immune and hematologic systems was appreciated. The complexities and multiplicity of splenic function continue to be the focus of research and observation. Although many of its functions overlap with, or can be assumed by other organs, it is an important regulator of immune response and hematologic homeostasis. The spleen efficiently phagocytoses erythrocytes, recycles iron, recognizes and destroys pathogens, and induces adaptive immune responses. An appreciation for the subtleties of its anatomy and function is important for the physician evaluating patients with many hematologic, immunologic, hepatic, and infectious diseases.

NORMAL SPLENIC ANATOMY AND FUNCTION

Embryology

The spleen arises from the mesoderm and, by the ninth week of gestation, layers of the left dorsal mesogastrium condense with the appearance of blood vessels. Sheaths are formed around arterioles by reticular cells and fibers.[1,2] Macrophages are present and develop phagocytic function by the end of the first trimester. Lymphocytes appear during the fourth month, and a formal delineation between red and white pulp can be identified by the sixth month. Germinal centers do not develop during fetal development, but primitive inactive follicles are evident at birth. In mice, the homeobox gene *Tlx1* (formerly known as *Hox11*), which controls the genesis of the splanchnic mesodermal plate, is essential for development of the spleen.[3] Both the basic helix-loop-helix transcription factor capsulin and the Wilms tumor suppressor 1 (*WT1*) gene are necessary for formation of the spleen.[2] The genetic basis for development of the human spleen is less well understood. The role of the ribosome in splenic development has recently risen to the forefront with discovery of isolated congenital asplenia (ICA) with variable penetrance amongst patients with mutations in ribosomal protein SA, a component of the small subunit of the ribosome.[4,5] However, to date its exact role has not yet been elucidated. The spleen is capable of supporting hematopoiesis during fetal life and, in a variety of pathologic states, postnatally.[6] The circulation of primitive hematopoietic stem cells in peripheral blood during prenatal life through birth makes it difficult to distinguish hematopoiesis arising from stem cells in the spleen as opposed to the incidental presence of hematopoietic cells within the circulation.

Anatomy

The spleen is the body's largest filter of the blood.[1,2,7] Located directly below the diaphragm and adjacent to the stomach, it is covered by a fibrous capsule with blood vessels, lymphatics, and nerves coated by peritoneal mesothelium. The splenic artery arises from the celiac axis, enters the capsule at the hilum, and branches into trabecular arteries. The trabecular arteries then branch into central arteries and enter the white pulp. The periarterial lymphatic sheath consists of a cuff of T lymphocytes, plasma cells, and macrophages around the central arteries. As the arteries branch, the sheath narrows. B-lymphocyte clusters appear in follicles along the periarterial lymphatic sheath at arterial branch points (Fig. 156.1).

The components of the white pulp are connected by a reticular network and supporting stromal cells.[1] On the cut surface of the normal spleen, white pulp is visible as white nodules approximately 1 to 2 mm in diameter, although their size varies with age and antigenic stimulation. The nodules are fully developed at birth, increase in size during childhood (especially following immunizations and infections), peak during puberty, and involute in adulthood. Uninfected adults with an intact immune system usually do not show evidence of germinal centers. The secondary germinal center comprises a mantle zone of B lymphocytes surrounding the follicle. Antigen trapping and processing take place in the marginal zone of the white pulp.

The red pulp of the spleen consists of vascular sinuses, the cords of Billroth, and the terminal branches of the penicilliary arteries (Fig. 156.2).[1,2] Vascular sinuses are lined with $CD8^+$ littoral endothelial cells that resemble endothelial cells with long processes and a basement membrane with ring fibers that attach to macrophage-derived dendritic processes. No tight junctions or interdigitations connect the cytoplasmic processes. Intact leukocytes, erythrocytes, and platelets are able to squeeze through the potential spaces between these cells and between the ring fibers (Fig. 156.3). Processes of the reticular cells of the cords of Billroth are outside the sinus walls. Endothelial cells line pulp veins but not the cords.

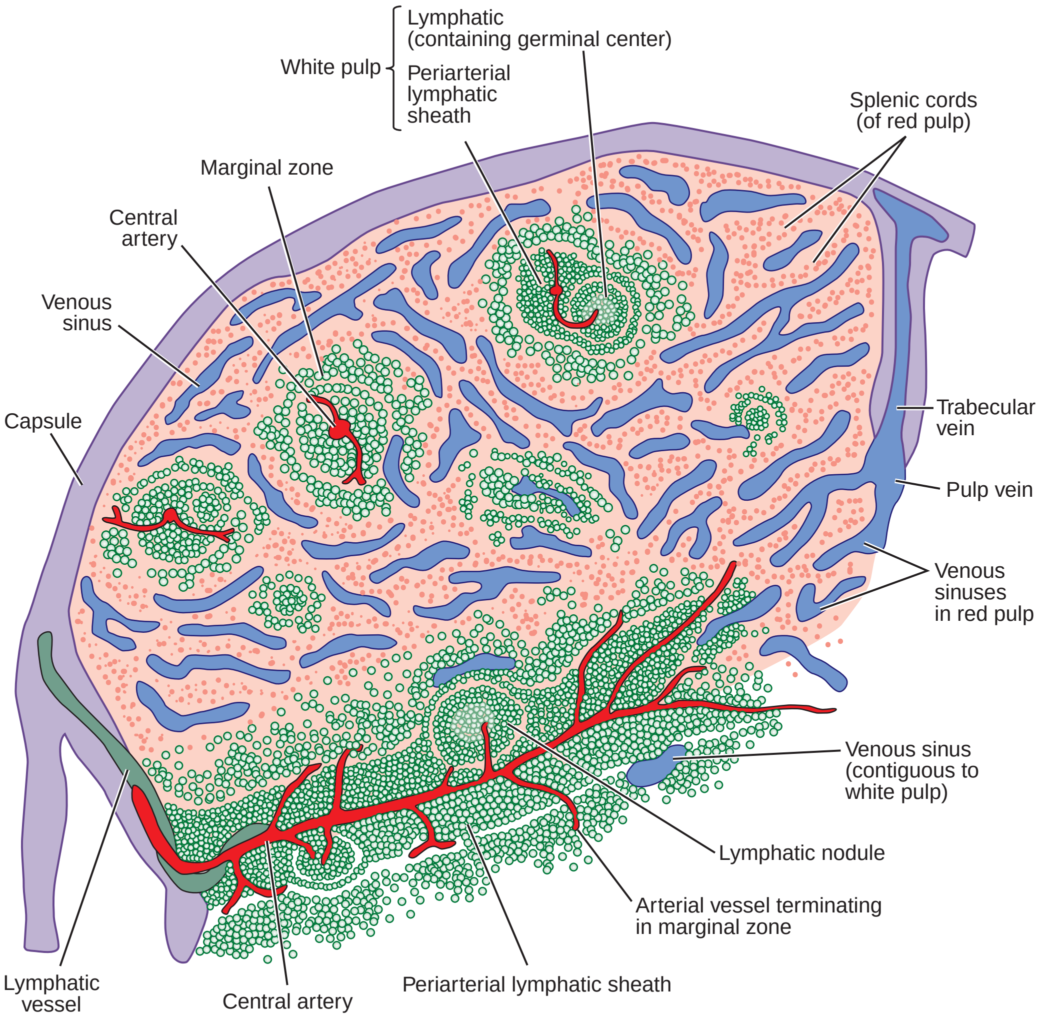
The reticular structure of the spleen facilitates its immune response. Venous sinus endothelial cells contain a plasma membrane-associated network of stress fibers composed of actin and myosin-like filaments. These filaments may cross the plasma membrane and insert into the mesh-like basement membrane. As the fibers tense, they create fenestrations through which erythrocytes must pass if they hope to continue their journey. With age, erythrocytes lose the ability to change their shape and navigate the pathways created by these fibers and are unable to continue into the circulation. The limitation is similar for erythrocytes containing parasitic infections. This mechanism, combined with mannose receptors and Toll-like receptors, helps the infrastructure of the spleen play a role in the host's overall immune response.

Circulation of blood through red pulp lined with endothelial-like littoral cells represents a rapid and closed circulation. Circulation into the cords is slower and open, thereby permitting the macrophages lining the cord to remove damaged or aged cells.

Accessory spleens are present in up to a third of the population and result from failure of precursor cells to fuse during embryologic development. Usually, they receive blood flow from the splenic artery and are located near the spleen, but they can be distant and mistaken for a tumor when noted on imaging studies or physical examination. Accessory spleens may develop similar conditions as the spleen proper and should be considered within the differential diagnosis for patients who have continued abnormalities after splenectomy.

Functions

The functions of the spleen and their anatomic locations are summarized in Table 156.1. Correlation with anatomy and histology are shown in Fig. 156.4.



White pulp
Lymphatic (containing germinal center)
Periarterial lymphatic sheath
Splenic cords (of red pulp)
Marginal zone
Central artery
Venous sinus
Capsule
Trabecular vein
Pulp vein
Venous sinuses in red pulp
Venous sinus (contiguous to white pulp)
Lymphatic nodule
Arterial vessel terminating in marginal zone
Lymphatic vessel
Central artery
Periarterial lymphatic sheath

Figure 156.1 ORGANIZATION OF THE HUMAN SPLEEN PRESENTED SCHEMATICALLY. See text for description of blood flow and cell distribution. *(Used, with permission, from Emerson SG. Hematopoiesis: The development of blood cells. In: Schiffman FJ, ed. Hematologic Pathophysiology. Philadelphia, PA: Lippincott-Raven; 1998:10.)*

The Red Pulp

Splenic macrophages dominate the function of the red pulp and are responsible for filtering blood, removing bacteria, and recycling iron.[1,2] The macrophages in the spleen have distinct features, including distinct Fc-γ receptors, than those derived from blood monocytes.[8]

Removal of Damaged and Aged Formed Elements

The venous system of the red pulp enables it to filter whole blood, removing senescent erythrocytes and other blood cells.[2,9] Arterial blood is delivered to the cords of the red pulp through an open system of reticular fibers, fibroblasts, and macrophages without an endothelial lining. Blood then passes from the cords into the efferent venous sinuses, which are lined with endothelial-like littoral cells with a discontinuous structure. Stress fibers extend beneath the basal plasma membrane and run parallel to the axis of the littoral cells. These cords direct the blood into sinuses through slits modulated in size by the stress fibers. In many animals, the stress fibers and splenic capsule are contractile, giving the spleen the ability to serve as a reservoir of red cells while reducing blood viscosity at rest. In humans, however, there is no evidence that the spleen serves such a function or is capable of significant changes in volume with rest and exercise. To return to the circulation, cells must pass through the slits between venous sinus littoral cells (see Fig. 156.3), the size of which may be controlled in part by actin and myosin filaments within the stress fibers in the basal portion of endothelial cells. This surface is believed to be an important site for the culling and pitting of aged or damaged cells.

Compared with when they are young and have a healthy metabolic reserve, older erythrocytes and platelets are unable to tolerate the hostile splenic environment. The spleen has a pH between 6.8 and 7.2, is hypoxic (partial pressure of oxygen [PO_2]: 54 mm Hg), and hypoglycemic (glucose concentration approximately 60% of that in venous blood). With age, damaged enucleated cells undergo changes in complex membrane carbohydrates, which facilitate recognition by splenic macrophages and removal from the circulation. *Culling* describes the destruction of erythrocytes: the normal removal of aging cells or the removal of damaged cells in pathologic states. Most platelets and leukocytes are not removed by the spleen as they age but adhere to vessel walls and migrate into tissues where they die. *Pitting* refers to the removal of inclusions from within erythrocytes, which are then released back into the circulation. The erythrocyte membrane is in close apposition to the macrophage membrane so that aged or damaged glycoproteins, antibody, or complement on the surface of the cell are easily recognized and activate phagocytosis. Particulate matter—Howell-Jolly bodies (basophilic nuclear remnants), Heinz bodies (clumps of damaged hemoglobin), Pappenheimer bodies (abnormal iron granules), and malarial and other parasites—are removed and the cell is returned to the bloodstream. If membrane-containing adsorbed antibody is present, it is removed and the remainder of the cell is released with changes in shape and volume. Internal vesicles near the erythrocyte membrane appear as if they were on the surface of the cell and are termed *pits* or

Hematopoiesis: The development of blood cells. In: Schiffman FJ, ed. Hematologic Pathophysiology. Philadelphia, PA: Lippincott-Raven; 1998:12.)*

pocks. The spleen also normally removes these, with the polished erythrocyte returned to the circulation. The lack of this polishing function can be used to assess splenic dysfunction as the number of pits or pocks per erythrocyte is increased when the spleen fails to remove them.

Recycling of Iron

Macrophages in the liver and spleen are important for recycling iron as erythrocytes are phagocytized and hydrolyzed in the phagolysosome (Chapters 36 and 37).[2] Degradation of hemoglobin releases heme, which is catabolized into biliverdin, carbon monoxide, and ferrous iron (Fe^{2+}). Iron is then either released as a low-molecular-weight species for rapid reuse or stored as ferritin. As ferritin accumulates, it aggregates into hemosiderin. Iron-laden macrophages are a feature of iron overload states in both the liver and spleen. Erythrocytes that are destroyed intravascularly release hemoglobin that binds to haptoglobin. CD163 on the surface of splenic macrophages mediates endocytosis of circulating hemoglobin and haptoglobin-bound hemoglobin.

Iron is released from stores in splenic macrophages in response to the erythropoietic drive expressed by the bone marrow. The precise mechanisms are not well understood. Uptake of iron is mediated in most cells by a divalent cation transporter, the natural resistance-associated macrophage protein 2 (NRAMP2), in recycling endosomes that express the transferrin receptor. NRAMP2 transports ferritin into the cytoplasm across the endosomal membrane. In addition to the more widely expressed NRAMP2, macrophages and monocytes express NRAMP1, which was initially described as an iron-transporting protein affecting resistance to intracellular pathogens. A third molecule involved in iron metabolism in the spleen is lipocalin-2, which is secreted by macrophages and other myeloid cells when activated by exposure to bacterial metabolites. Lipocalin-2 binds to bacterial siderophores and sequesters iron from microorganisms. These and other related molecules tightly link the iron-recycling and host-resistance functions of the red pulp of the spleen.

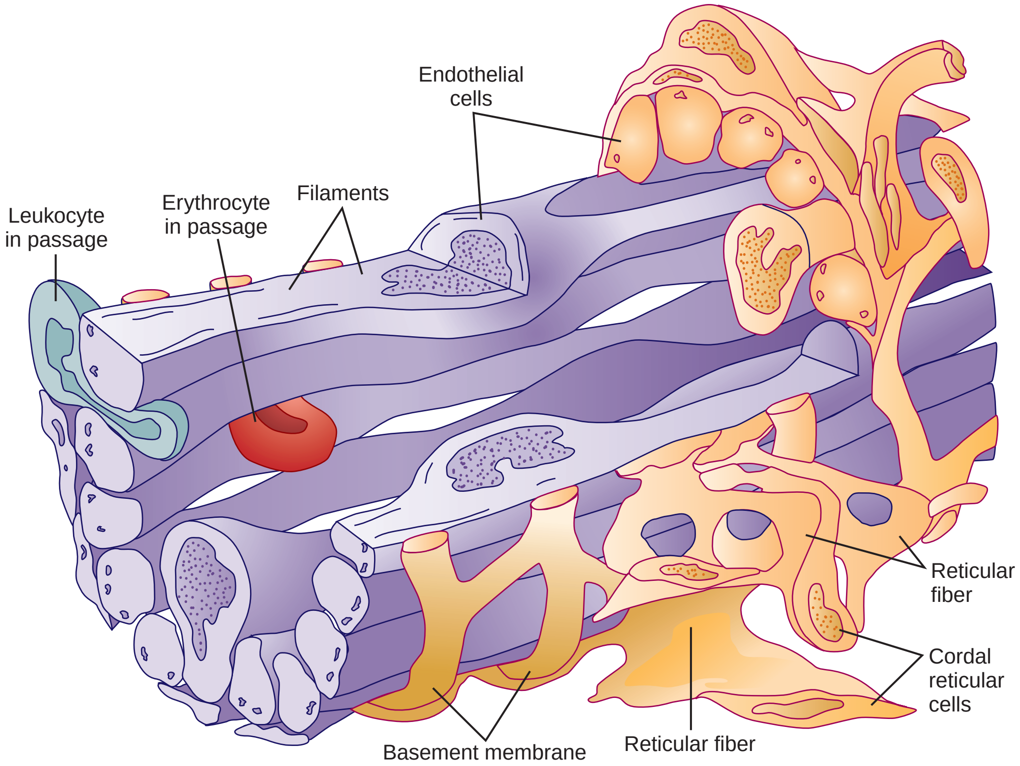


Figure 156.3 ORGANIZATION OF THE SPLENIC SINUSES. Erythrocytes and leukocytes are scrutinized as they squeeze through the reticular fibers of endothelial cells to enter the splenic sinuses. The fenestrae contract and relax according to sympathetic stimuli to regulate cell passage. *(Used, with permission, from Emerson SG. Hematopoiesis: The development of blood cells. TABLE 156.1 **Functions of the Spleen**

Category	Function	Effector Cells/Areas
Clearance/ Filtration	Antibody-mediated clearance Culling and pitting	Macrophages Reticular meshwork
Immune Response		
Marginal zone	Interaction of antigens with effector cells	Monocytes, lymphocytes
	Antigen processing	Macrophages
	Immune recognition	T cells (periarteriolar sheath)
White pulp	Immunoregulation, antibody production	B cells (lymphoid follicles)
	Antigen processing, preservation	Macrophages
Red pulp	Phagocytosis	Macrophages, monocytes, neutrophils
Hematologic	Hematopoiesis	Cords and sinuses
	Storage of erythrocytes, platelets, leukocytes	Reticular meshwork, red pulp
	Finishing/polishing of erythrocytes	Reticular meshwork, macrophages
Hemostasis	Production of factor VIII, von Willebrand factor	Endothelial cells

Antibody Production

After stimulation and differentiating in the follicles of the white pulp, antigen-specific plasmablasts and plasma cells lodge in the red pulp, where they are closer to macrophages.[2] A similar translocation occurs in lymph nodes, where plasmablasts migrate to the medullary cords. This translocation occurs after upregulation of expression of CXC-chemokine receptor 4 (CXCR4), which binds CXC-chemokine ligand 12 (CXCL12) expressed in red pulp.

The White Pulp

The lymphoid region of the spleen incorporates multiple components of the immune system that are organized to enhance recognition and/or response to pathogens.[10] The white pulp contains lymphoid sheaths around branching arterial vessels, similar to the structure of lymph nodes. Specific chemokines attract B and T cells to their appropriate domains. The periarteriolar lymphatic sheath contains T cells that interact with dendritic cells and circulating B cells. T cells and dendritic cells are attracted to the periarteriolar lymphatic sheath through CC-chemokine ligands 19 and 21. Clonal expansion of activated B cells occurs in follicles. B-cell migration to follicles requires CXCL13. Expression of all these homeostatic chemokines is reduced when signaling through the lymphotoxin receptor or tumor necrosis factor (TNF)-α receptor 1 is absent, which results in disorganization of the domains of the white pulp.

Marginal Zone

Similar to the migration of leukocytes across endothelial barriers in inflammation, leukocytes leave the bloodstream and enter the white pulp in the marginal zone of the spleen due to the function of

G protein-coupled receptors.[2,10] The marginal zone is an area for cells in transit and home to resident cells with complex interactions. Marginal zone metallophilic macrophages form an inner ring close to the white pulp, marginal zone macrophages form an outer ring, and dendritic cells and B cells are located between the two sets of macrophages. Both trafficking and retention of dendritic cells and B cells involve complex interactions with integrins and other adhesion molecules.

Innate Immunity

The spleen is important in the recognition of antigens, in the production of antibodies, and in the clearance of opsonized and nonopsonized particles from the bloodstream (see Table 156.1).[2] The spleen structure facilitates monitoring of the contents of the blood, with blood flowing through the marginal zone directly along the white pulp. The white pulp is involved in adaptive immunity, whereas the marginal zone is involved in both innate and adaptive immunity (Table 156.2).

Trapping and processing antigens is a major function of the marginal zone. Macrophages are abundant here, and the spleen captures more than 5% of the cardiac output (> 250 mL/min), which allows a large volume of blood to be immunologically scrutinized. Antigens penetrate the germinal center where T lymphocytes predominate. Processing carbohydrate antigens is a special function of splenic marginal zone lymphocytes. Marginal zone macrophages express lectin receptors and scavenger molecules.

Splenic macrophages are more sensitive to small amounts of opsonic antibody or complement present on the surface of particles than are macrophages in the liver, lung, or bone marrow. In the absence of a spleen, individuals may fail to remove bacteria with limited opsonic coating, and the production of antigen-specific immunoglobulin (Ig) M is impaired. An asplenic individual has defective recognition of carbohydrate antigens, defective production of IgM early during infection, and defective removal of lightly opsonized particles—all crucial components of response to an invasive infection with encapsulated organisms.

Marginal zone B lymphocytes are sensitive to detection of blood-borne pathogens and rapidly differentiate into either antigen-presenting cells (APCs) or IgM-producing plasma cells. After activation in the marginal zone, some B cells migrate into the white pulp, where they function to activate naive CD4$^+$ T cells.

Similarly, blood-borne dendritic cells activated in the marginal zone migrate into the white pulp. This process appears to be important in control of certain parasitic infections. For example, in *Leishmania donovani* infection, the spread of infection is inversely proportional to the upregulation or downregulation of CCR7 expression on activated dendritic cells and migration of APCs into the white pulp. In human immunodeficiency virus (HIV)-positive patients with low CD4 T-cell counts (less than 300 cells/μL), there is evidence that IgM memory B-cell depletion might be a risk factor for pneumococcal disease. Effective antiretroviral therapy appears to reverse this depletion, in turn decreasing the risk for pneumococcal infection.

Adaptive Immunity

Although the white pulp is both anatomically and functionally similar to lymph nodes, all cells enter the white pulp via the marginal zone rather than through high endothelial venules and afferent lymphatic vessels, exposing them to an environment highly sensitive to detection of blood-borne pathogens.[2,10] Circulating dendritic cells capture bacteria from the blood and transport them to the spleen, where they mediate the initial differentiation of B cells to plasmablasts or APCs. Activated APCs entering the white pulp activate T cells, resulting in changes in receptor expression that enable them to migrate to the edge of B-cell follicles. Contact with activated T cells induces an isotype switch in follicular B cells, which then migrate to the red pulp and marginal zones or remain in splenic germinal centers. The white pulp of the spleen is the largest mass of lymphoid tissue in the body. The B lymphocytes, which ultimately produce antibodies, predominate in the nearby germinal centers and mantle zones. These areas all increase in size and activity with immunization or infection. The complex interaction between the cells in close apposition, autocrine, and paracrine signaling, and migration of cells into, within, and ultimately out of the spleen, contributes to the extraordinary repertoire of innate and adaptive immunity within the organ. Changes in splenic architecture are quite dramatic with septicemia, the most marked being depletion of splenic B-cell areas that occurs during overwhelming enterococcemia. Bacterial virulence factors appear to contribute to depletion of B- and T-cell areas.

Hematopoiesis

Active hematopoiesis can be seen in the fetal spleen throughout the second trimester, decreasing during the third trimester.[7] Erythropoiesis and megakaryocytopoiesis predominate, with myelopoiesis present to a lesser extent. As hematopoiesis transitions from the hepatic phase

into the bone marrow, it becomes less evident within the fetal spleen. The spleen is not normally a site of hematopoiesis in postnatal life in humans, but it is a rich source of hematopoietic stem cells. In pathologic states associated with bone marrow failure, its role expands from that of a primarily lymphoid organ to that of a hematopoietic organ.[2,11,12] Extramedullary hematopoiesis is a significant cause of splenomegaly primarily in bone marrow disorders (e.g., myelofibrosis or osteopetrosis (Chapter 72) and chronic hemolytic anemias (Chapters 41, 44, and 47) (e.g., thalassemia). The stromal cells of the spleen appear to be capable of supporting hematopoiesis and may produce the C-KIT ligand, as do marrow stromal cells. When splenic hematopoiesis occurs, the erythrocytes and platelets that circulate tend to be less mature than when hematopoiesis occurs in the bone marrow, which suggests that egress from the spleen is easier than from the marrow. This may not always be a benign function; emerging evidence suggests that the myeloid progenitors in the spleen may offer a therapeutic target in hematologic malignancy.[14]

Stem Cells

Experiments from the 1950s first demonstrated the presence of splenic stem cells.[15] Either lead shielding around the spleen or the injection of spleen cells allowed for the reestablishment of hematopoiesis in lethally irradiated mice. Resident stem cells are capable of restoring hematopoietic and immunologic function after lethal irradiation.[13] The spleen has been shown to be a source of multipotent stem cells in humans and other animals. These stem cells have been shown to contribute to the regeneration of multiple types of tissue, including pancreatic islet cells, bone, cranial nerves, and salivary glands. Undifferentiated splenic monocytes assembled in clusters in the cords of the subcapsular red pulp have been shown to accumulate in injured myocardial tissue.[16,17] In murine models, splenic stem cells are in a G1 “pre-activated” phase, as opposed to the G0 phase of bone marrow, perhaps explaining how they are quickly deployed in response to acute inflammatory stress.[18] These stem cells are considered to have limited potential to undergo malignant transformation.

Storage of Cells

The normal adult human spleen contains 20 to 40 mL of blood and does not serve as a reservoir for blood or erythrocytes. However, in many conditions associated with splenomegaly, especially portal hypertension, the pulp cords widen to create an organ with more storage volume. Vascular pooling of blood and formed elements occurs, regardless of the underlying cause of the splenomegaly. Platelets and granulocytes, however, are normally stored in the red pulp of the spleen. As much as one-third of the total platelet mass may be stored in the spleen and released when cytokines affecting platelet adhesiveness are released. The lack of musculature in the human splenic capsule prevents the distention and contraction that occur in many animals, such as dogs, although the spleen appears to contract in divers during periods of breath-hold apnea. Indeed, the indigenous Bajau people of Southeast Asia with increased variants in the PDE10A gene have increased spleen size, possibly explaining their extraordinary diving ability as a result and an increased pool of oxygenated blood which can be expelled into circulation with splenic contraction, an action formerly not thought to occur in humans.[19] Platelet counts and granulocyte counts rise significantly after splenectomy, then fall.

The circulating masses of these cell pools are chronically increased post-splenectomy, which may contribute to an increased incidence of atherosclerosis years after splenectomy.

EXAMINATION OF THE SPLEEN

Maneuvers for examination of the spleen involve inspection, percussion, and palpation, but their sensitivity and specificity vary based on patient factors (such as body habitus) and operator skill.[20] The pretest probability of splenomegaly, based on associated historical and clinical data, influences the positive-predictive value of finding splenomegaly on physical examination. If the pretest probability of splenomegaly is less than 10%, then physical examination maneuvers are inadequate for determining the presence or absence of splenomegaly. For those patients with a greater than 10% pretest probability of splenomegaly (for instance, patients with suspected infectious mononucleosis), the examination begins with inspection and then percussion of Traube's space—defined by the left sixth rib superiorly, the left anterior axillary line, and the costal margin. For adequate examination of the spleen, the patient must be fully supine, relaxed, with arms adjacent to the trunk. The sensitivity and specificity of Traube's method is 62% and 72%, respectively, amongst all patients, and improves to 78% and 82%, respectively, amongst fasting, non-obese patients.[20] There are multiple methods for percussion to assess for splenomegaly, each with their own eponymous signs. In addition to percussion of Traube's space, Nixon's method is performed by percussing cranially, starting at the midpoint of the left costal margin with the patient in right lateral decubitus position. A positive Nixon's sign is denoted by dullness to percussion extending over eight centimeters above the costal margin perpendicularly, with a sensitivity of 59% and specificity of 94%.[20] Lastly Castell's method, felt to be the most sensitive physical examination technique, is elicited by percussion of the lowest intercostal space (either eighth or ninth rib) in the left axillary line at full inspiration and full expiration with the patient laying supine. A positive Castell's sign is characterized by resonance with percussion on full expiration and dullness upon full inspiration, with a sensitivity of 82% and specificity of 83%.[20] Dullness to percussion in Traube's space, or by any of the above percussive tests should be followed by palpation. Beginning in the right iliac fossa, the examiner's hand gently advances toward the left upper quadrant. This minimizes the likelihood that a grossly enlarged spleen will be missed, and the lower pole and medial border should be easily appreciated. If the spleen cannot be felt with this approach, the left hand of the examiner is placed on the left flank, lifting the lower part of the rib cage to displace the spleen medially toward the examiner's right hand. The splenic notch should be felt in the inferior medial border. Rotating the patient into the right lateral decubitus position while still recumbent may make it easier to palpate the spleen. The spleen should move with deep inspiration. The degree of enlargement is usually measured in centimeters below the costal margin. Depending on the position of the spleen within the abdomen, it may be difficult to appreciate even significant enlargement. Normal splenic size in an adult is up to 250 g and up to 13 cm in its long axis. Up to half of spleens weighing 600 to 750 g are not palpable. Greater degrees of splenomegaly are easier to appreciate on physical examination. In terms of sensitivity and specificity, there does not appear to be a difference between examination in the supine position and examination in the right lateral decubitus position, although both of these parameters are dependent on the experience of the examiner.

Up to 15% of normal children and 3% of young adults have palpable spleens without evidence of illness. The spleen involutes with age, and a spleen that is palpable in an older person is unlikely to be a normal variant and more likely to be associated with clinical disease.

Due to various abnormalities, the spleen may not be located in its usual anatomic position. It may migrate from its normal abdominal position to the left mid-abdomen or even the left lower quadrant.[21] While a rare finding, this highlights the importance of attentive examination of the lower abdomen when palpating for the spleen especially as a "wandering spleen" may be associated with other abnormalities.[22]

IMAGING OF THE SPLEEN

Radionuclide scintigraphy assesses anatomic and functional aspects of the spleen. The most common procedure is a liver-spleen scan in which technetium-99m (^{99m}Tc) sulfur colloid is injected intravenously and taken up by hepatic and splenic macrophages. It is the phagocytic activity of macrophages, rather than the presence of the spleen itself or any aspects of lymphoid function, that is assessed. A dynamic ^{99m}Tc scan can also assess the distribution of blood within the portal system and suggest the presence of portal hypertension. Infusion of ^{99m}Tc-labeled or Indium-111–labeled platelets with scintigraphy to determine their relative distribution in the liver and spleen has been used with considerable, but not absolute, success to predict the clinical efficacy of splenectomy in patients with immune thrombocytopenia purpura (ITP).

Ultrasonography readily shows the size, shape, and several aspects of splenic anatomy, including the presence of cysts and abscesses. The procedure is noninvasive, painless, of low cost, avoids radiation exposure for patients, and is a good screening study when the spleen is thought to be enlarged. In 95% of the normal population, the long axis of the spleen measures less than 12 cm on ultrasound examination. Accessory spleens tend not to be well-visualized on routine ultrasonography. In the hands of a skilled operator, endoscopic ultrasound-guided biopsy permits accurate diagnosis of lesions as small as a centimeter or less, which compares well with results obtained using computed tomography (CT). High-frequency sonography has significantly better resolution and can visualize both nodularity within the spleen, which occurs in childhood as immunity is acquired, and accessory spleens and splenosis after splenic rupture or trauma.

CT imaging has the advantage of showing the anatomy and some aspects of splenic function. Contrast material in the gastrointestinal tract helps delineate splenic tissue when it impinges on this system. Intravenous contrast material is required to delineate splenic lesions whose density is the same as normal splenic tissue. Abscesses have a rim of contrast agent enhancement.

CT can be used to estimate the volume of the spleen. Accessory spleens have the same attenuation as a normal spleen, which is somewhat less than that of liver. Accessory spleens are usually located in the gastrosplenic ligament near the hilum. Subcapsular and intrasplenic hematomas and splenic lacerations are clearly seen on CT. Leukemias and many inflammatory diseases produce diffuse splenomegaly, while granulomas and infarcted areas eventually calcify. Cysts, abscesses, and some malignancies may have a homogeneous pattern on CT scan. Although not replacing other methods of staging, splenic enlargement on CT may direct follow-up studies and indicate prognosis.

In addition to imaging the spleen, CT can be used to direct therapeutic interventions. Abscesses, hematomas, and cysts can be drained (see box on Management of Splenic Cysts). As long as portal pressures are normal and vascular lesions have been adequately excluded, thin-needle aspiration under CT guidance is generally a safe intervention. The safety and value of core needle biopsy has been better explored in recent years as in the past it was frequently avoided from perceived risk of bleeding. In a prospective series of 30 patients, there was only one bleeding complication successfully managed with conservative measures.[23] Two retrospective series of 52 and 97 patients along with a pooled analysis of 748 patients found low rates (1% to 4%) of major complications after ultrasound-guided splenic needle biopsy and high-diagnostic yield, with 18G-25G biopsy needles.[24,25]

MANAGEMENT OF SPLENIC CYSTS

A 37-year-old woman with no past medical history comes in for evaluation of early satiety and left shoulder pain. She reports that she feels full after only a few bites of any meal and sometimes becomes nauseated and vomits. Physical examination is remarkable for an enlarged, nontender spleen. Imaging shows a large splenic cyst.

- Many conditions can lead to cyst formation in the spleen, including parasitic infections, trauma, hemangiomas, and polycystic kidney disease.
- Asymptomatic nonparasitic cysts may be observed with careful attention, and one should plan for intervention should they become symptomatic, rupture, or become infected.
- Symptomatic cysts may require percutaneous drainage with radiologic guidance or sometimes surgical procedures, including partial or total splenectomy.
- Parasitic cysts should be treated in consultation with infectious disease specialists as the particular parasitic infection, radiologic appearance, and patient comorbidities will guide choice of therapies.

CT scanning of the abdomen, performed as part of the initial emergency department evaluation of patients with abdominal trauma, may avert hospital admission and prevent exploratory laparotomy.[26]

Magnetic resonance imaging (MRI) is useful for identifying vascular lesions, which would otherwise require angiography, and splenic infections. It is more difficult to image the contents of the upper abdomen with MRI than with CT because of respiratory motion. With more rapid imaging technology, MRI has gained considerable utility for imaging infectious and vascular lesions of the spleen. Hepatosplenic candidiasis and other infections to which immunocompromised patients are susceptible can be identified noninvasively with modern MRI technology.

Through the use of T2 and T2* relaxation sequences, MRI imaging of the spleen allows quantitative measurement of iron burden in organs that accumulate iron, although the liver and heart are more commonly imaged for this purpose.[27,28]

Positron emission tomography (PET) scanning using ^{18}F-2-deoxyglucose is used in the diagnosis, staging, and monitoring of both non-Hodgkin and Hodgkin lymphoma (Chapters 80 and 81). It is more sensitive than CT scanning for identifying involved lymph nodes and superior to both lymphangiography and CT scanning at imaging the spleen. The availability of more sensitive, specific, and less toxic approaches to imaging permits more precise staging of Hodgkin lymphoma without the complications of splenectomy (Fig. 156.5).[29,30]

The role of PET scanning is expanding in other disorders as whole-body PET scanners and appropriate small-molecule markers for individual diseases are more widely available. Imaging studies in small-animal models are very promising; splenic involvement can be identified with high sensitivity in mice.

TESTS OF SPLENIC FUNCTION

The peripheral blood smear may be the most sensitive tool for identification of functional or anatomic hyposplenia. The presence of Howell-Jolly bodies, which are nuclear remnants normally removed by the spleen, is an excellent indicator of hyposplenism (Fig. 156.6). These are rarely seen until the spleen is largely nonfunctional or overwhelmed by other phagocytic functions, such as extravascular hemolysis. Newborn infants commonly have visible Howell-Jolly bodies, and splenic function appears to be at least somewhat impaired in the first week of life. Pappenheimer bodies (siderotic granules normally removed by the spleen) are often seen in hyposplenic states, particularly when a component of hemolysis exists. Erythrocyte morphologic features reflect the lack of membrane polishing by the spleen, with the presence of acanthocytes and target cells. Granulocyte and platelet numbers are increased during asplenic states, including splenic infarction and surgical splenectomy.

To confirm suspected hyposplenism, the simplest test is a count of pitted or pocked erythrocytes. Fixation in 0.5% to 1.0% glutaraldehyde and examination under interference optics should reveal endocytic vesicles containing hemoglobin, ferritin, and remnants of mitochondria. These form in mature erythrocytes and are normally removed by the functioning spleen. The number of pitted cells (not the number of pits per cell) is inversely proportional to splenic function, with normal persons having less than 2% pitted cells.[31] The absence of Howell-Jolly bodies on a peripheral blood smear cannot be used as evidence of adequate splenic immune function.[32]

ASPLENIA AND HYPOSPLENIA

Congenital asplenia may be an isolated lesion or associated with severe cyanotic congenital heart disease and bilateral right-sidedness. Life-threatening cardiac lesions, including transposition of the great vessels, pulmonary artery atresia or stenosis, septal defects, anomalous venous drainage, and a single atrioventricular valve, are components of bilateral right-sidedness. The liver is central, and both lungs have three lobes. The peripheral blood smear shows Howell-Jolly bodies and other signs of hyposplenism. There is considerable variation in the anatomic and functional findings, and it is difficult to predict with accuracy the degree of splenic dysfunction on the basis of the anatomy alone. Children who survive the cardiac difficulties in the neonatal period have a significant incidence of sepsis secondary to a variety of organisms.

Polysplenia is associated with bilateral left-sidedness. Dextrocardia, bilateral superior venae cavae, septal defects, and anomalous pulmonary venous return are associated cardiac lesions. Both lungs have two lobes, the liver is midline, and bowel malrotation is common. The splenic tissue is divided into two to nine masses. The peripheral blood smear usually does not suggest hyposplenism, and no clear association with an increased risk for infection has been documented.

Asplenia occurring without heart disease is less likely to be detected before an infection develops than when associated cardiac lesions bring the patient to medical attention. Some of these patients also have *situs inversus*. Isolated cases have been reported of asplenia discovered after death of an otherwise healthy adult or child from overwhelming sepsis with encapsulated organisms. Familial instances of congenital asplenia are likely to be instances of genetic abnormalities (e.g., *HOX1/TLX1*), but these have not yet been documented. Examination of a blood smear for Howell-Jolly bodies is a simple procedure and may be lifesaving in the rare patients affected with these disorders.

If Howell-Jolly bodies are observed on the blood smear of an otherwise healthy person, imaging should be performed to assess for the presence of a spleen. Immunization with polysaccharide vaccines and early intervention with antibiotics for apparent infection may prove lifesaving for these individuals. Because approximately 20% of invasive pneumococcal infections in these patients are non-vaccine strains, a high degree of vigilance remains essential, even with more widespread immunization of healthy children.

Splenic Infarction

Although the classic teaching of splenic infarct is that of left upper quadrant or flank tenderness, many are noted incidentally on imaging with a third without any pain.[33] The causes are diverse with the most frequent etiologies atrial fibrillation or other cardioembolic and malignancy followed by hypercoagulability, hemoglobinopathy, infection including sepsis, trauma and complications of cirrhosis. Atherosclerosis of the splenic or celiac artery may be a risk factor. The choice of whether or not to anticoagulate is less clear and one needs to consider the cause. For example, atrial fibrillation or a thrombosis associated with malignancy would typically trigger anticoagulation, but a splenic infarct associated with sickle cell disease does not.

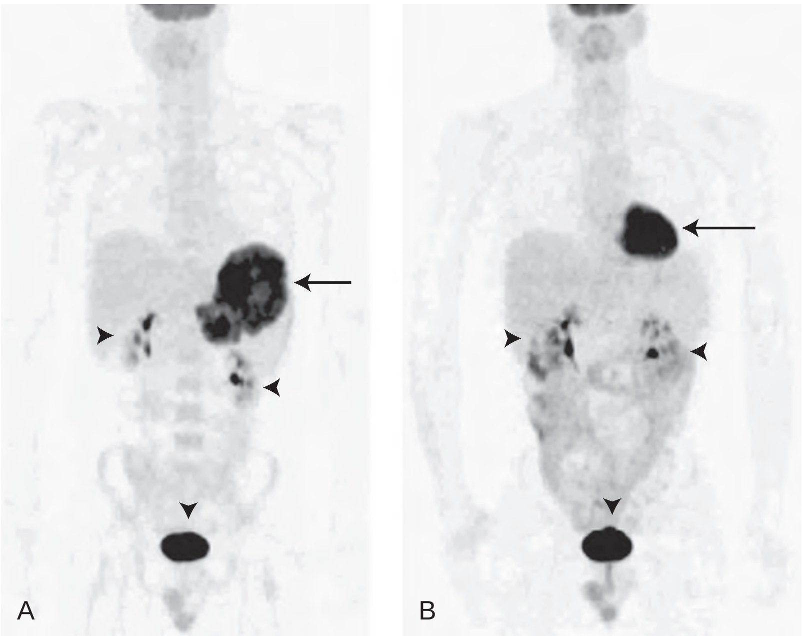

Figure 156.5 POSITRON EMISSION TOMOGRAPHY SCANNING TO IMAGE AREAS OF INVOLVEMENT IN HODGKIN DISEASE. (A) Pretreatment imaging showing the spleen *(large mass in left upper quadrant with arrow)* and activity in the kidney and bladder *(arrowheads)*. (B) The same patient after three cycles of chemotherapy. The *arrow* now points to normal activity in the myocardium not seen previously and *arrowheads* point to persistent urinary tract activity. The spleen is particularly well imaged on positron emission tomography scan. *(Used, with permission, from Friedberg JW, Chengazi V. PET scans in the staging of lymphoma: Current status. Oncologist. 2003;8:438.)*

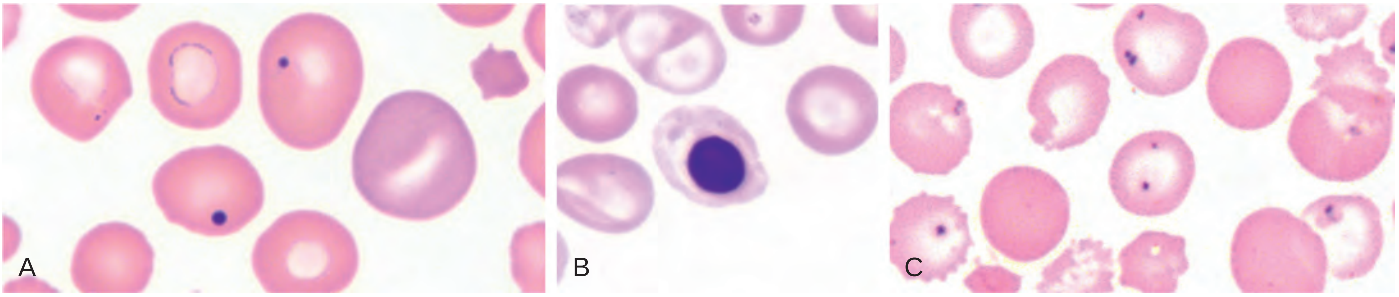

Figure 156.6 RED BLOOD CELL FINDINGS IN HYPOSPLENISM. (A) Red blood cells with Howell-Jolly bodies. (B) Nucleated red blood cell. (C) Cells with Pappenheimer bodies. Red blood cells with Howell-Jolly bodies are seen in patients with hyposplenism. The cytoplasmic inclusions (A) are nuclear remnants that are usually round and stain similar to the nucleus of a nucleated red blood cell (B). They occur normally during red cell maturation but are typically removed by a normal spleen. Their presence in the blood indicates less-than-normal splenic function. Pappenheimer bodies (C), which can also be seen in hyposplenism, are siderotic granules that are irregular in shape and frequently multiple.

ACQUIRED HYPOSPLENISM

Infarction in Sickle Cell Disease

The course of sickle cell disease is marked by progressive dysfunction of multiple organs over many years, and one of the earliest organs to be affected is the spleen. Serial measurements of the numbers of pitted erythrocytes in patients with sickle cell disease demonstrate that splenic dysfunction develops progressively over the first few years of life in the major sickle syndromes (Figs. 156.7 and 156.8). The hypoxic, acidotic, hypoglycemic environment of the spleen creates optimal conditions for tactoid formation and for sickling of the poorly deformable erythrocytes, which then block splenic blood vessels and infarcts the tissues. Splenic environmental conditions that enhance acidosis or hypoxia, or additional erythrocyte membrane or enzyme abnormalities that promote irreversible sickling, increase splenic infarction. The hyposplenism is reversible with transfusion for at least the first few years of life but becomes irreversible with progressive damage to blood vessels by 6 years of age in patients with sickle cell disease.

Splenic sequestration is a manifestation of the infarction process due to sickling in the spleen that extends to involve larger veins. Distensible splenic tissues result in pooling of a large amount of blood, whereas the venous drainage is occluded by sickled hypoxic erythrocytes. Patients with sickle cell disease who have not yet had multiple episodes of infarction and whose spleens have not undergone fibrosis are susceptible to this syndrome. Unlike the chronic process of smaller vessel infarction, the acute splenic sequestration crisis can be life threatening because a large amount of blood can collect in the highly distended spleen. The tendency for recurrence and the potential for a fatal outcome have resulted in the common recommendation for splenectomy in a patient who has had one severe splenic sequestration crisis, or more than one less severe crisis. Occlusion of venous drainage also occurs in the liver, but the less distensible capsule of the liver and the options for venous drainage through the portal system make this less likely to be life-threatening.

Immunologic and Autoimmune Diseases

Poor phagocytic function of the spleen is associated with impaired function of the Fc receptors on splenic macrophages in a variety of immunologic, rheumatic, and inflammatory disorders. Among those disorders in which hyposplenism has been clearly defined and associated with a risk for infection are systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, systemic vasculitis, ulcerative colitis, celiac disease, amyloidosis, chronic graft-versus-host disease, mastocytosis, and congenital and acquired immunodeficiency. The diseases themselves and the immunosuppressive therapies that are used in their management may contribute to the risk for infection in these conditions. Immunization with polysaccharide antigens and recognition of the risk of bacterial infection are important steps in reducing the risks of splenic hypofunction.

Splenomegaly and the production of autoantibodies such as antiplatelet or antiphospholipid antibodies, are features of the acquired immunodeficiency syndrome (AIDS). In the late stages of AIDS, atrophy of lymphoid follicles and depletion of T-cell-dependent areas are common. It is not clear that impairment of phagocytic function is a component of splenic atrophy in AIDS.

Therapy-Induced Splenic Hypofunction

Radiation therapy affects splenic function depending on the dose administered. In general, phagocytic cells are not affected by irradiation, but lymphoid cells are extremely sensitive. B-cell function is nearly ablated with as little as 500 cGy. T-cell lymphoblastogenesis is eliminated by administration of 3000 cGy. With doses of 2000 cGy, splenic hypofunction is usually transient because the macrophages and splenic stroma are not affected, and circulating B and T lymphocytes can repopulate the splenic follicles. Permanent splenic hypofunction may develop with doses of 4000 cGy or higher. The risk for infection is significant after such therapy.

Corticosteroid therapy impairs the affinity of the Fc receptors of splenic macrophages for opsonized IgG and decreases the adhesiveness of granulocytes and monocytes. This results in an acute pharmacologic splenectomy, even at commonly administered therapeutic dosages. The function of the Fc receptors on hepatic, pulmonary, and bone marrow macrophages is far less affected than that of splenic macrophages. The acute rise in platelet count or hemoglobin values seen with corticosteroid therapy in ITP or warm autoimmune hemolytic anemia is due to decreased clearance of sensitized cells. With prolonged therapy, the production of antibodies by splenic lymphocytes is also affected, and splenic function continues to be impaired.

Intravenous IgGs appear to decrease the phagocytic function of the spleen by binding to Fc receptors and impeding their recognition of opsonized particles. This is a transient effect because the Fc receptors are internalized and recycled, and opsonic function returns to normal within 2 to 3 weeks. Occupancy and impairment of function of Fc receptors is also seen with administration of anti-IgD to Rh-positive patients, which induces a transient hemolytic anemia. Reticuloendothelial blockade, or occupancy of these receptors, refers to the impaired ability of the spleen to recognize and remove other IgG-coated particles, including bacteria, in the presence of these agents.

SPLENOMEGALY AND HYPERSPLENISM

An enlarged spleen is not a disease state in itself but usually indicates some underlying pathologic state.[34] The processes run the gamut from minor to life threatening, from congenital disorders to those at the end of life. It is useful to approach the differential diagnosis of splenomegaly by considering the processes that may cause splenic enlargement and then to focus on the specific diagnoses within those categories. The spleen may be enlarged as a result of infiltration, hypertrophy of normal elements (macrophages and lymphoid components), extramedullary hematopoiesis, inflammatory or immunologic processes, and systemic or portal congestion (see box on Timing of Return to Contact Sports in Athletes Who Have Had Infectious Mononucleosis). The degree of splenomegaly correlates well with involvement of the spleen in many malignant disorders, such as Hodgkin disease. Rarely, anatomic abnormalities will cause splenomegaly. Acutely, the spleen can be enlarged with splenic sequestration crisis (Chapter 43).[35] Splenomegaly is important to investigate because it is frequently the finding of a serious disorder whose earlier recognition and treatment may prevent significant long-term morbidity and mortality. The diseases associated with splenomegaly are detailed in Table 156.3. Patients with splenomegaly do not necessarily have hypersplenism, and patients with hypersplenism may indeed have normal-sized spleens, such as those seen in ITP.

TIMING OF RETURN TO CONTACT SPORTS IN ATHLETES WHO HAVE HAD INFECTIOUS MONONUCLEOSIS

A 17-year-old male high school student is diagnosed by his primary care physician with infectious mononucleosis. The patient is concerned about the upcoming soccer season and wants to start training with the team in 4 weeks.

- More than half of patients with infectious mononucleosis develop splenomegaly within the first 14 days of illness.
- Most reports of splenic rupture in the setting of infectious mononucleosis occur in the first 21 days of illness.
- There is a paucity of data to support imaging the spleen to document resolution of splenomegaly before returning to contact sports. Although one study, by O'Connor, et al., evaluated 19 patients after infectious mononucleosis with ultrasonography, which showed normal spleen size (<12 cm) in 16 patients 1 month after diagnosis, with the remaining 3 patients having normalization of spleen size at 2 months.[36] However, there remain no consensus guidelines for return to play or integration of imaging into this decision-making process.
- Noncontact sports may be safely resumed after at least 21 days from the onset of initial symptoms, and contact sports should be safe in most cases after at least 28 days. Infectious mononucleosis-associated splenic rupture has been reported as far as 8 weeks after symptom onset.[37]
- The timing of return to sports and the risks should be discussed with the patient, especially if the patient may not have returned to baseline after prolonged fatigue.

Hypersplenism refers to nonimmune, indiscriminate destruction of the formed elements of the blood by a spleen that is usually enlarged, affected by portal hypertension, or both. The bone marrow is hyperplastic, and the peripheral blood cell counts are decreased because of destruction of mature formed elements. Splenectomy corrects the cytopenias. Any of the formed elements of the blood—erythrocytes, neutrophils, or platelets—can be affected alone or in combination. Splenic hypertrophy in cirrhosis is due to an increase in splenic macrophages and their activity. Because the normal function of splenic macrophages is to remove senescent cells, this is an exaggeration of a physiologic process.

Hypersplenism develops in patients who receive chronic transfusions, and there are several components that contribute to the development of hypersplenism. The antigenic load of allogeneic transfused cells stimulates the immune system. Additionally, transfused cells have shorter survival than normal red cells (mean of 60 instead of 120 days, unless specially prepared neocytes are used), which increases the work of splenic macrophages. Finally, iron overload causes hemosiderosis of both the spleen and the liver, so that portal hypertension may develop and further increase splenic pathology. Hypersplenism increases the transfusion requirement in patients who are already transfusion dependent.

Interestingly, spleen status at the time of allogeneic hematopoietic stem cell transplantation affects outcomes. Patients with splenomegaly have delayed engraftment while those with prior splenectomy have early engraftment and no difference in mortality.[38] The increased risk in infection may be mitigated by the high-intensity setting in which stem cell transplantation occurs.

TABLE 156.3 Causes of Splenomegaly

Primary Process	Pathogenesis	Examples
Anatomic	Developmental abnormalities	Cysts, pseudocysts, hamartomas, peliosis, hemangiomas
Hematologic	Hemolysis	Intrinsic (membrane, enzyme, hemoglobin disorders), extrinsic (immune)
	Extramedullary hematopoiesis	Myeloproliferative neoplasms/myelodysplasias, myelofibrosis, osteopetrosis
Infectious	Bacteria	Acute and chronic systemic infection, abscesses, subacute bacterial endocarditis
	Mycobacteria	Miliary tuberculosis
	Spirochetes	Syphilis, Lyme disease, leptospirosis
	Viruses	Epstein-Barr virus; cytomegalovirus; human immunodeficiency virus; hepatitis A, B, C
	Rickettsia	Rocky Mountain spotted fever, Q fever, typhus
	Fungi	Disseminated candidiasis, histoplasmosis, South American blastomycosis
	Parasites	Malaria, babesiosis, toxoplasmosis, *Toxocara canis*, *Toxocara cati*, leishmaniasis, schistosomiasis, trypanosomiasis
Immunologic	Collagen vascular diseases	Felty syndrome, systemic lupus erythematosus, mixed connective tissue disorder, systemic vasculitis, Sjögren syndrome, systemic mastocytosis
	Immunodeficiency	Common variable immunodeficiency
	Immune/inflammatory	Graft-versus-host disease, serum sickness, large granular lymphocyte lymphocytosis, Weber-Christian panniculitis
Neoplastic	Primary malignancies	Lymphomas, leukemias
	Metastatic malignancies	Breast, lung, skin, colon
Infiltrative	Storage diseases	Gaucher disease, Niemann-Pick disease, GM_1 gangliosidosis, glycogen storage disease type IV, Tangier disease, Wolman disease, mucopolysaccharidoses, hyperchylomicronemia types I and IV
Congestive	Portal hypertension	Intrahepatic cirrhosis, extrahepatic cirrhosis (Budd-Chiari syndrome)
	Systemic	Congestive heart failure
	Local	Splenic vein thrombosis

SPLENIC IRRADIATION

Indications

Splenic irradiation is considered as a palliative treatment for symptom relief related to splenomegaly, or hypersplenism, in patients who have either declined splenectomy or are high-risk surgical candidates. Symptoms related to splenomegaly that may be palliated with irradiation include left upper quadrant pain, early satiety, and mechanical discomfort related to splenomegaly. These most commonly occur in patients with myeloproliferative, or lymphoproliferative, neoplasms (Chapter 72). However, there are no prospective studies on the use of splenic irradiation to guide its use, or to aid in duration and intensity of treatment. Several retrospective studies have been performed across a variety of diseases with mixed results.

Complications

While splenic irradiation spares the patient from an invasive procedure (discussed in detail below), it carries with its own unique and potentially life-threatening complications.

SPLENECTOMY

Indications and Timing

Splenectomy should be performed for clinical indications rather than for specific diagnoses. In many instances, removal of the spleen will improve the condition of patients with hemolytic anemia due to intrinsic disorders of erythrocyte membranes and enzyme disorders, and of those with chronic conditions, such as storage diseases and portal hypertension. Specific clinical indices that require intervention should be identified, and parameters that can be used to identify clinical improvement (usually an increase in peripheral blood cell counts, growth, or energy level) should be determined before the procedure is performed. For patients with inherited erythrocyte membrane or enzyme disorders, such as hereditary spherocytosis or pyruvate kinase deficiency, marked reticulocytosis indicating significant metabolic energy required for erythropoiesis, somatic growth failure, or lack of exercise tolerance would be potential indications for splenectomy. Avoidance of formation of gallstones, formerly often considered an indication for splenectomy when a diagnosis of hereditary spherocytosis was made, is less important today because minimally invasive surgical procedures have improved the management of cholelithiasis. Patients with storage disorders such as Gaucher disease often develop splenomegaly and hypersplenism, and subsequent cytopenias require intervention. As new therapies are developed, such as eliglustat for Gaucher disease and ruxolitinib for primary myelofibrosis, these patients experience a significant reduction in spleen size and increase in quality of life, which may mitigate the need for splenectomy.[39,40] The clinical benefit to be obtained from splenectomy should at least balance, and preferably outweigh, the potential long-term risks of post-splenectomy septicemia, an increased risk for thrombosis, and the shift of storage cells from the spleen to other organs, such as the bone marrow or liver, where they may do more harm in the absence of the spleen. Not all patients with hemolytic anemias require splenectomy. If such patients develop an aplastic crisis due to parvovirus B19 infection while their spleens are intact, they may require a transfusion. Many patients with mild chronic hemolysis and well-compensated anemia may be better off with their spleens remaining intact. Patients with ITP should undergo surgical splenectomy when the risks of bleeding or of medical therapies (such as long-term corticosteroids or the anti-CD20 monoclonal antibody rituximab) are such that the benefits of splenectomy exceed the risks. The introduction of thrombopoietin mimetics for treatment of chronic ITP has further delayed or eliminated the need for splenectomy in many patients (Chapter 130). The indications for splenectomy are different in adults than in children, and are affected by the presence of underlying disorders, such as systemic lupus erythematosus and HIV. In an attempt to avoid immunologic consequences of a total splenectomy, several centers are performing partial splenectomies for hereditary spherocytosis, although in some cases a second procedure is later required.[41]

Splenectomy for sickle cell disease is usually performed for splenic sequestration that is severe, persistent, or recurrent. In some sickle syndromes, the spleen does not autoinfarct in childhood, and persistent splenomegaly may increase the degree of anemia. The risk for subsequent development of gallstones should be considered in patients with hemoglobinopathies and other hemolytic anemias so that cholecystectomy can be performed simultaneously, if deemed indicated.[35]

The timing of splenectomy (when it is to be performed) should again be chosen to minimize risks and maximize benefits. Immunity to carbohydrate antigens, such as those in the cell walls of encapsulated organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b, develops over the first 2 to 3 years of life. When splenectomy can be delayed until the patient is at least 2 and preferably more than 5 years of age, specific immunity and response to administered polysaccharide vaccines will improve host defenses and lessen the risk for post-splenectomy sepsis. When patients have a disease, such as Gaucher disease, or hemolytic anemia predisposing to iron overload, such as thalassemia, the presence of the spleen as a preferential site for the storage of harmful cellular breakdown products may protect other organs from damage. Delaying splenectomy until a clear clinical indication is present will balance risks and benefits to an optimal degree. The recently developed oral substrate inhibitor, eliglustat, has shown promising success in reducing splenomegaly in patients with Gaucher disease (Chapter 54).[39] As this drug is studied further, it is possible that splenectomy may not be needed as often.

Surgical Options

When splenectomy is clearly indicated, acute complications are rarely a consideration in the decision to perform surgery. Nevertheless, advances in surgical procedures have minimized the short-term risks of the procedure itself and of postoperative complications such as intestinal obstruction from adhesions. Subtotal splenectomy can be performed when total splenectomy is not desirable, such as for the removal of a cyst, a pseudocyst, or tumors, after trauma, or for Gaucher disease. Wedge resection with mattress sutures and cyanoacrylate adhesives and microfibrillar collagen omental packs have greatly improved partial splenectomy procedures in the past decade. Laparotomy is required when extensive peritoneal adhesions are present and for removal of massively enlarged spleens. A sufficiently large incision to permit full visualization and mobilization is essential when the spleen is very large or when inspection is a major part of the surgical procedure. A retroperitoneal approach is useful when the spleen is not massively enlarged but needs to be fully removed, such as when cytopenias are the indication for the procedure. This approach shortens the postoperative recovery time and avoids induction of peritoneal adhesions.

Minimally invasive procedures have become standard for most splenectomies. Laparoscopy is now the procedure of choice for splenectomy. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, risk for damage to the pancreas, likelihood of developing a sub-phrenic abscess and peritoneal adhesions postoperatively, and nutritional and metabolic challenges to the patient are considerably reduced. Laparoscopic splenectomy can be performed even in thrombocytopenic patients. The outcome of laparoscopic splenectomy in ITP is affected by the experience and skill of the surgeon and by the patient's obesity. Prolonged pre-surgical use of corticosteroids may induce obesity and impair tissue healing, resulting in a higher risk for complications from laparoscopic splenectomy than when splenectomy is performed before adverse drug effects develop. In the case of massive splenomegaly, splenic morcellation (division and removal in small pieces) may be necessary prior to laparoscopic retrieval.

Appreciation of the risk for post-splenectomy septicemia and refinements in noninvasive, accurate radiologic monitoring techniques have led to more conservative approaches to splenic injury. Nonoperative management has increased over time and has an acceptable mortality and complication rate in selected patients, although early discharge may put patients at risk for the later complications.[42] Noninvasive imaging and minimally invasive surgical procedures have greatly affected these trends. After traumatic rupture, splenic tissue may regenerate as both micro- and macroscopic ectopic implants in the peritoneal cavity, a process termed *splenosis*. Although splenosis appears to be partially protective against overwhelming post-splenectomy infection in animals, its protective value in humans is not known and may depend on the adequacy of splenic tissue perfusion. If poorly vascularized, the ectopic splenic tissue may not provide adequate contact between macrophages and the antigens of the infecting organism. It is generally valuable to attempt preservation of splenic function when possible after traumatic rupture. Some surgeons attempt to induce splenosis when traumatic splenectomy is unavoidable, in the hope of minimizing late complications.

As the late complications of splenectomy are better appreciated, surgeons have become increasingly creative at performing procedures that preserve or restore splenic function. Even large cysts that were indications for splenectomy until recently have been managed with spleen-conserving procedures, such as partial or total cyst removal, which can often be performed laparoscopically.[43] Pancreatic surgery often requires sacrifice of the spleen; however, increasing numbers of procedures are being performed with salvage of the spleen.

Splenic transplantation is being used as a means of developing immune tolerance, as well as a means of reducing the risk for infection following organ transplantation.[44] Allogeneic spleens have been transplanted within multivisceral grafts with only minimal graft-versus-host disease. To date, there are more animal than human data, and it is unclear how large an impact this approach will have on visceral, especially small-bowel and pancreatic, allotransplantation.[45] If protection against infection is the main consideration, an intact spleen is superior to a repaired or autotransplanted spleen, whereas accessory spleens and splenosis may be only marginally better than asplenia.[32]

Complications After Splenectomy

Acute complications in the perioperative period include rupture of the spleen, the development of a sub-phrenic abscess, and injury to the pancreas during the operative procedure. In a healthy patient, the immediate risk of splenectomy is limited.[46] The degree of splenomegaly greatly affects the risk for rupture and pancreatic injury. The technical difficulty of performing a splenectomy is much greater when the spleen is massively enlarged than when the spleen is small. Once the arterial supply is ligated, rupture of the spleen is rarely a problem. The splenic hilum is retroperitoneal, so if the spleen is very large, mobilization to gain access to the splenic artery and vein can be difficult. After recovery from surgery, intestinal obstruction due to formation of peritoneal adhesions is a complication that, if it is to occur at all, usually occurs within the first few months.

Several late complications of splenectomy give cause for concern, including severe infection, increased risk for venous thromboembolism, coronary artery disease, and possibly malignancy (Fig. 156.9).[47] However, the precise risk is not known, as there have been conflicting data on the risk of malignancy, particularly in those with traumatic causes for splenectomy.[47,48] Age-appropriate cancer and cardiovascular screening with evaluation of symptoms are essential preventive interventions that are probably underused because patients may not be aware of the risks of splenectomy performed early in life.

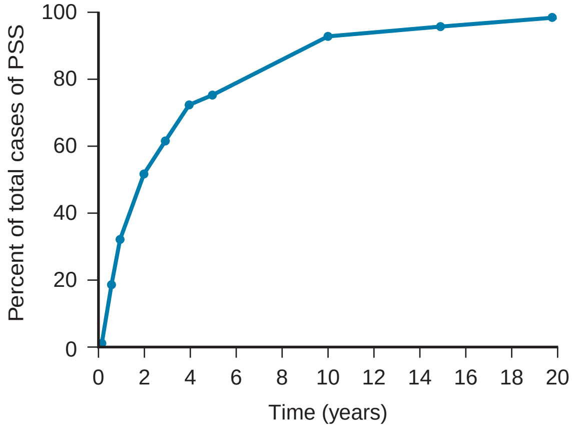

Figure 156.9 THE INTERVAL FROM SPLENECTOMY TO POST-SPLENECTOMY SEPSIS. Of the total (n = 288), 3.1% occurred more than 20 years after splenectomy. *PSS*, Post-splenectomy sepsis. *(Used, with permission, from Lutwick LI. Infections in asplenic patients. In: Mandell GL, Bennett JE, Dolin R, eds. Principles and Practice of Infectious Diseases. 7th ed. Philadelphia: Churchill Livingstone; 2009.)*

Post-splenectomy septicemia is rare but may be rapidly lethal.[49] In the absence of protective levels of opsonic IgG antibodies produced in the spleen, hepatic and pulmonary macrophages are unable to effectively clear organisms from the bloodstream. Organisms that enter the bloodstream and would ordinarily be removed by splenic macrophages are able to evade recognition by macrophages whose Fc and C3b receptors appear to be less avid than those of splenic macrophages. Circulation of the blood through the liver and lung is more rapid than through the spleen, and there is little opportunity for macrophages to recognize organisms with surfaces containing little IgG and only small amounts of C3bi. The important filtration function of the venous sinus endothelial cells is absent following splenectomy. The generation of cytokines, including TNF-α and bacterial endotoxins, leads to cardiovascular collapse and shock. It is difficult to rescue an asplenic patient once shock develops, even with effective antibiotic therapy. The risk that this will happen varies with the indication for splenectomy (Table 156.4) and the patient's medical condition. Factors that impair host defenses significantly increase the risk for infection. These include deficient opsonins (hypogammaglobulinemia and specific antibody-production deficiency), reticuloendothelial blockade related to increased phagocytic activity of macrophages in other organs, impaired antigen processing or recognition (AIDS, lymphoma, other malignancies, and some collagen vascular diseases), neutropenia, and high iron load (thalassemia). The tetrapeptide tuftsin, primarily produced in the spleen, enhances the phagocytic activity of monocytes and neutrophils; its absence in asplenic patients appears to contribute to depressed neutrophil function and the subsequent increased risk for infection.

Patients at the lowest risk for overwhelming post-splenectomy sepsis are those in whom splenectomy cures the underlying problem, such as isolated ITP, hereditary spherocytosis, and trauma. Patients undergoing splenectomy for trauma have a 50-fold greater risk for subsequent septic death than trauma patients with intact spleens, whereas the risk in patients with sickle cell disease is increased 350-fold over that of the general population, and other authors report the risk to be 600 times greater. Similar to using hemodialysis to attempt to replace the function of the kidney, work is ongoing to devise an artificial spleen as a mechanical way to filter pathogens from the blood.

An increased risk for vascular complications may result from splenectomy. Acute portal vein thrombosis occurs within 2 months of splenectomy in 5% to 37% of patients, which is probably the result of local surgical factors. The surgical approach seems to affect the rate of post-splenectomy portal and splenic vein thrombosis, with a laparoscopic approach and morcellation associated with a higher rate of thrombosis compared with open splenectomy (55% vs. 19%, respectively). Patients with thalassemia and prior splenectomy appear to also have an increased incidence of venous thromboembolism beyond the portal venous system. In addition, splenectomy appears to be a risk factor for the development of pulmonary hypertension.

TABLE 156.4 Incidence of Post-Splenectomy Sepsis

Indication for Splenectomy	Cumulative Incidence of Bacterial Sepsis (%)
Trauma	1.5
Hematologic disorders	3.4
Portal hypertension	8.2
Hodgkin disease	10
Sickle cell disease	15
Thalassemia	25

Data from Gorse GJ. The relationship of the spleen to infection. In: Bowlder AJ, ed. *The Spleen: Structure, Function, and Clinical Significance.* New York, NY: Van Nostrand Reinhold; 1990:269, with permission.

Vascular events after splenectomy are likely multifactorial in origin, being attributed to a combination of hypercoagulability, platelet activation, activation of endothelium due to the persistence of particulate matter, and damaged cells in the bloodstream.

Atherosclerosis that develops many years after splenectomy in patients with hereditary spherocytosis or hereditary stomatocytosis may be related to subsequent thrombocytosis that leads to enhancement of plaque formation. Statistically, the increased risk for atherosclerosis is not particularly high, but for individuals with other risk factors such as hypertension, diabetes, high levels of cholesterol or homocysteine, heterozygous protein C or S deficiency, or factor V Leiden deficiency, splenectomy may pose a more significant risk. Although no human data are currently available in this area, some studies have suggested that the spleen might be involved in lipid metabolism in both rats and rabbits.

Prevention of Complications

Post-splenectomy Septicemia

The major risk for post-splenectomy sepsis is infection with encapsulated organisms such as *Staphylococcus pneumoniae*, *H. influenzae* type b, and *N. meningitidis*, which require opsonization for effective phagocytosis. Polysaccharide vaccines are available for all three bacteria.[50,51] The highest risk period for children is in the first 2 years of life, when their ability to mount an antibody response to purified polysaccharides has not developed completely, so protein-conjugated vaccines are now in widespread use. This has significant potential benefit for patients when asplenia is not recognized, because they might then be immunized as part of their routine care. The antibody responses to vaccines, especially the conjugated vaccines, differ in IgG subclasses from those produced following natural infection. Overwhelming post-splenectomy sepsis and death from sepsis in functionally hyposplenic patients should be preventable.[49] It is recommended that immunization be done at least 14 days, but ideally 1 to 12 weeks, prior to the anticipated splenectomy to optimize antigen recognition and processing, and induce more effective immunity.[52] If emergency splenectomy is performed, it is recommended that vaccination be postponed until at least 14 days post-splenectomy to avoid the transient immune suppression often seen with general anesthesia and surgery (see box on Vaccination of a Patient Scheduled for Elective Versus Emergent Splenectomy). Adults with prior vaccination to *H. influenzae* type b are generally presumed to be immune and may receive the pneumococcal and meningococcal vaccines alone. Reimmunization for children is recommended 2 to 5 years after initial immunization. Splenectomized adults should be revaccinated with the PPSV23 once after 5 years, whereas meningococcal revaccination should occur every 5 years. The Advisory Committee on Immunization Practices recommends that adult patients who are vaccine naïve, receive the pneumococcal conjugate vaccine (PCV13) followed 8 weeks later by the pneumococcal polysaccharide vaccine (PPSV23). Because these recommendations change with experience and vaccine use, it is wise to consult current guidelines for individual patients. The US Centers for Disease Control and Prevention website should be consulted for the most up-to-date recommendations. Additional organisms to consider in post-splenectomy sepsis include *Escherichia coli*, *Pseudomonas aeruginosa*, and *Capnocytophaga canimorsus*.[53]

VACCINATION OF A PATIENT SCHEDULED FOR ELECTIVE VERSUS EMERGENT SPLENECTOMY

A 50-year-old man with refractory ITP is scheduled for splenectomy. Having heard there is a risk for different types of infection after splenectomy, he asks about what he can do to reduce his risk.

- Patients scheduled for elective splenectomy should receive the following at least 14 days, ideally 10–12 weeks, prior to the procedure:[52]
- *Streptococcus pneumoniae* vaccines
- PCV13 (Prevnar)
- PPSV23 (Pneumovax)-given AT LEAST 2 months after PCV13; revaccinated 5 years after initial dose and again at age 65 years
- *Haemophilus influenzae type b* (Hib) vaccine: Hib conjugate (Hiberix, Act-HIB), can be omitted for adults with known prior vaccination
- *Neisseria meningitidis* vaccines
- Meningococcal serotypes ACWY: MenACWY (Menactra or Menveo)
- Meningococcal serotype B: MenB (Bexsero or Trumenba)
- Annual seasonal influenza vaccine
- If the procedure is done emergently, wait at least until the 14th postoperative day.

There are fewer data on the efficacy of prophylactic antibiotics for asplenic, or hyposplenic, patients, except for young children with sickle cell disease, in whom antibiotics should be initiated as soon as the diagnosis is established. Present recommendations are that twice-daily oral penicillin V potassium or amoxicillin be continued in sickle cell patients until 5 years of age, or 3 years post-splenectomy. Beyond this, recommendations vary by international organization regarding antimicrobial prophylaxis.[54,55] High-risk patients with surgical or functional asplenia, including those with diagnoses of thalassemia, Hodgkin disease, other malignancies, immunodeficiency disease, or chronic graft-versus-host disease, should receive prophylactic antibiotics unless specific contraindications exist. Patients who have a history of pneumococcal sepsis post-splenectomy may be considered candidates for life-long daily prophylaxis as well. Whether or not such patients receive prophylactic antibiotics, and regardless of their immunization status, they may develop overwhelming infections with other organisms, including gram-negative organisms and *Staphylococcus aureus*. Some experts recommend providing a supply of emergency antibiotics to have "on-hand" (emphasizing that patients will need to check expiration dates regularly) and be immediately available at the time of febrile illness, prior to traveling to an emergency room for prompt evaluation. If the patient already takes a prophylactic antibiotic, the emergency agent should have a broader coverage. There are no randomized trials to guide therapy and experts have recommended the use of amoxicillin-clavulanate, cefuroxime axetil, macrolides, or extended-spectrum fluoroquinolones. Updated recommendations should be consulted for specific circumstances.

The single most important measure to prevent post-splenectomy septicemia is education of the patient, family, and physician. Recognition of the risk, the institution of appropriate preventive measures, and the rapid administration of antibiotics to a patient who is showing signs of infection (fever and chills) can be lifesaving.

Atherosclerosis

The magnitude of the risk for developing atherosclerosis is not clear.[21,56] Appropriate preventive measures include identifying and minimizing concurrent risk factors, such as obesity, dietary patterns, a sedentary lifestyle, and the presence of other hereditary factors that would predispose to thrombosis. Low-dose aspirin could be considered, but no data exist regarding its efficacy in this situation.

CONCLUSIONS AND FUTURE DIRECTIONS

Although very little novel information has emerged about clinical aspects of splenic function in recent years, appreciation of many subtleties of splenic function and advances in supportive care in several fields have had significant impacts on the management of disorders of the spleen. Better education and more effective immunizations have helped prevent serious complications related to splenic disorders. Advances in imaging and surgery have transformed the diagnosis and management of congenital and traumatic splenic disorders.

Enhanced understanding of the complexity of communication interaction between the cells of the immune and hematopoietic system has improved our appreciation of the molecular, cellular, system, and network basis for clinical observations about splenic function. The ability of splenic macrophages, in concert with dendritic cells and B cells, to recognize and ingest a variety of microorganisms—even in patients without previous exposure to the pathogens—provides great insight into the reasons that the spleen provides protection against a variety of very specific infections. More detailed understanding of the impact of the splenic microenvironment on cellular functions, the role of stromal infrastructure on the ability of cells to interact with and respond to invading pathogens, and the integration of components of the immune system has contributed to an appreciation of clinical observations about the role the spleen plays in normal biology. The intersection of hematopoiesis, recycling of aging cells, and iron metabolism is most clearly demonstrated in the spleen.

Although not necessary for life under baseline circumstances, the contribution of the spleen to homeostasis under stress is considerable. Ongoing efforts to preserve and manage splenic function will continue to benefit from enhanced appreciation of the underlying biology.

CHAPTER 157

AGING AND HEMATOLOGIC DISORDERS

Kah Poh Loh, Mazie Tsang, Shakira J. Grant, Richard J. Lin, and Heidi D. Klepin

The population is aging, and it is estimated more than 23.4% of the population in the United States will be older than 65 years by 2060.[1] Many hematologic disorders, including anemia and hematologic malignancies such as myelodysplastic disorders, myeloproliferative neoplasms, chronic lymphocytic leukemia (CLL), acute myeloid leukemia (AML), multiple myeloma, and certain types of lymphoma, are more common with aging. Compared with younger adults, older adults are more likely to have age-related vulnerabilities such as functional and cognitive impairment. Therefore there is a need to personalize management therapies based on age-related vulnerabilities, rather than relying on chronological age alone, to reduce unnecessary testing and to improve outcomes in this population. The consequences of aging on hematopoiesis are reviewed in Chapter 19. The effects of aging on blood stem and progenitor cells likely account for many of the hematological findings observed in the elderly.

ANEMIA

Anemia in older and younger adults is defined by the World Health Organization (WHO) as hemoglobin less than 13 g/dL for men and less than 12 g/dL for women.[2] For adults aged 65 years and older, the prevalence of anemia is approximately 10% to 11% and increases to 20% to 25% for those aged 85 years and older, and to 50% for those in nursing homes.[3,4] Common causes of anemia in the older age group include iron deficiency/bleeding, chronic disease/inflammation, renal insufficiency, and hematologic malignancies.[3,5] Approximately 30% to 40% of older adults with anemia lack a discernible cause despite a thorough investigation. Unexplained anemia has been associated with acquired somatic mutations in genes associated with myeloid malignancies as detected by whole-exome sequencing (see Chapter 19).[6]

The work-up of anemia should include history taking (symptoms and their effect on daily activities and duration), physical examination, and laboratory testing (complete blood count with differential, renal function, and peripheral smear; depending on the white blood cell differential other testing may include reticulocyte count, iron indices, folate, B_{12}, copper, and zinc levels, thyroid function studies, haptoglobin, liver function test and enzymes, fecal occult blood). If primary bone marrow disorders or anemia is unexplained (especially when patients are symptomatic requiring transfusion), a bone marrow aspirate/biopsy is recommended. It is important to consider age-related vulnerabilities in the work-up of anemia. If patients are frail and/or work-up likely will not change management, periodic monitoring may be considered as an alternative to an invasive bone marrow aspirate/biopsy.

GENERAL PRINCIPLES IN OLDER ADULTS WITH HEMATOLOGIC MALIGNANCIES

Chronological age alone does not determine underlying fitness due to heterogeneity in underlying health status. A geriatric assessment encompasses the use of validated tools to assess age-related vulnerabilities, including functional status and physical performance, cognition, nutrition, psychological health, comorbidities, social support, and medications (Table 157.1). Age-related vulnerabilities assessed as part of the geriatric assessment predict both morbidity and mortality in several hematologic malignancies.[7–10]

Geriatric assessment complements standard oncologic assessments and can be used (1) to uncover vulnerabilities in older adults that would not otherwise be captured during routine visits, (2) to predict treatment tolerance and prognosticate, (3) to assign treatment, and (4) to guide supportive care interventions.[11] Studies have shown that geriatric assessment-guided care improves patient and caregiver satisfaction, increases discussion of age-related vulnerabilities, reduces treatment toxicity without worsening survival, improves treatment tolerance, improves quality of life (QOL), and reduces healthcare utilization.[12–15]

Two specific tools based on the geriatric assessment have been developed to predict chemotherapy toxicity—the Chemotherapy Risk Assessment Scale for High-Age Patients (CRASH) and the Cancer Aging and Research Group (CARG) calculators. The CARG toxicity calculator was developed and validated among older patients with solid tumors, whereas the CRASH toxicity calculator was developed and validated in older patients with a variety of cancers, including hematological malignancies. Specific age-related vulnerabilities incorporated in the CRASH toxicity calculator included Instrumental Activities of Daily Living (IADL), Eastern Cooperative Group (ECOG) Performance Status, Mini-Mental State Examination, and Mini-Nutritional Assessment. The risk of both hematologic and nonhematologic toxicities can be estimated using this tool (see Table 157.2 for a case example).

Studies of the use of geriatric assessment for treatment assignment, although limited, have been done in several hematologic malignancies.[16] Geriatric assessment may prevent both undertreatment (providing less than recommended therapy, thereby leading to worse outcomes) and overtreatment (providing intensive treatment where the harms outweigh the benefits or providing intensive treatment for a cancer that is not expected to affect an older adult in his or her remaining lifetime).[17] Based on geriatric assessment, patients are generally classified as fit, vulnerable, or frail. Alternatively, they can be classified as fit or unfit. It is important to note that these classifications are context- and treatment-specific. For example, an older adult may be fit to receive lower-intensive treatment but unfit to receive high-intensity treatment.

Age-related vulnerabilities are dynamic, and an unfit patient may become fit during the disease trajectory or vice versa. Therefore geriatric assessment may guide supportive care interventions to reverse these vulnerabilities.[11] For example, functional impairment is associated with chemotherapy toxicity and poor survival. For these patients, geriatric assessment may inform the need for interventions such as exercise and physical therapy to improve functional status, therefore improving treatment tolerability and prognosis.

Older adults and their caregivers often overestimate chance of cure.[18,19] When appropriate, geriatric assessment may provide an opportunity for hematologists to guide older adults and caregivers toward end-of-life choices that are consistent with their values and preferences. Studies have shown that geriatric assessment-guided care increases discussion of patient goals, healthcare proxy, and advance directive wishes,[20,21] as well as improves completion of advances directives.[15] This may in turn encourage early referral to palliative care, which in the context of AML, has been shown to improve QOL, improve psychological health, and decrease use of chemotherapy in the last 30 days of life.[22]

In the next few sections, the use of geriatric assessment in lymphoma, AML, myelodysplastic syndrome (MDS), multiple myeloma, and hematopoietic stem cell transplantation (HSCT) is described.

TABLE 157.1 Components of Geriatric Assessment and Examples of Validated Tools

Components	
Functional status	• Activities of Daily Living (ADL) • Instrumental Activities of Daily Living (IADL)
Physical performance	• Short Physical Performance Battery (SPPB) • Timed Up and Go (TUG) • Gait speed
Cognition	• Mini-Cog • Mini-Mental Status Exam (MMSE) • Montreal Cognitive Assessment (MoCA)
Nutrition	• Self-reported weight loss in the last 6 months • Mini Nutritional Assessment (MNA)
Psychological health	• Geriatric Depression Scale-15 (GDS-15) • Generalized Anxiety Disorder-7 (GAD-7)
Comorbidities	• Older Americans Resources and Services (OARS) Comorbidity Scale • Cumulative Illness Rating Scale
Social support	• OARS Social Resources Scale
Medications	• Number of medications (for polypharmacy) • Beers Criteria (for high-risk medications)

LYMPHOMA IN OLDER ADULTS

Lymphomas primarily occur in older adults, with at least half of lymphoma cases occurring in patients who are 65 and older.[23] Choosing a treatment regimen for older patients can be challenging because many older patients may not be able to tolerate standard of care regimens due to their comorbidities, functional status, and increased risk for toxicities. This is especially relevant for older patients with aggressive non-Hodgkin lymphomas, which are often treated with intensive, curative anthracycline-containing regimens.[23] While there is no precise definition of frailty to identify those who are unfit for curative treatment, geriatric assessment can be an important guide.

For patients with aggressive lymphomas, a geriatric assessment may help with treatment assignment. In a randomized controlled trial of 224 older patients with diffuse large B-cell lymphoma (DLBCL), a geriatric assessment was used to assign treatment to either standard-dose rituximab, cyclophosphamide, doxorubicin hydrochloride, vincristine, and prednisone (R-CHOP) or the less-intensive rituximab plus cyclophosphamide, etoposide, vincristine, and prednisone (R-miniCEOP). The outcomes were similar between the two groups. However, patients who were older than 72 and had low-risk disease appeared to have a better outcome when treated with R-miniCEOP ($P = .011$).[16] In a systematic review on the use of the geriatric assessment for older patients with DLBCL, four prospective observational studies showed that independent of the treatment regimen, geriatric assessment could predict overall response rates, overall survival, and therapy-related toxicities. Choice of the regimen to be used was left to the discretion of the treating oncologist rather than based on a geriatric assessment.[7] Although there have been other studies investigating less-intensive chemotherapy regimens, geriatric assessment was not used for treatment assignment. When curative treatment is considered for aggressive lymphoma, older adults without impairment on geriatric assessment

TABLE 157.2 Case Example Using the Chemotherapy Risk Assessment Scale for High-Age Patients Tool to Estimate Hematologic and Nonhematologic Toxicities

Case Example

A 75-year-old male is diagnosed with diffuse large B-cell lymphoma and standard-dose R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone) is considered. He requires some help with getting to places, shopping, preparing meals, doing housework, doing handyman work, laundry, taking medications, and managing money. He can use the telephone independently. On Mini-Mental State Exam, he lost two points for recall and two points in attention and calculation. Based on the CRASH tool, his estimated risk of hematologic and nonhematologic toxicities is 23%–35% and 66%–67%, respectively.

For individual risk score and risk category, please refer to https://moffitt.org/media/4238/crash_scoring_analysis.pdf

	Case	**Score**
Hematologic risk factors		
Diastolic blood pressure (>72 = 1)	90	1
Instrumental Activities of Daily Living (<26 = 1)[a]	22	1
LDH (>459=2)	180	0
HEME SCORE		**2 (ranges from 0 to 5); translates to 23%–35% or intermediate-low risk**
Nonhematologic risk factors		
Eastern Cooperative Group Performance Status (1 – 2 = 1; 3 – 4 = 2)	1	1
Mini-Mental State Exam (<30 = 2)[b]	26	2
Mini Nutritional Assessment (<28 = 2)[c]	23.5	2
NONHEME SCORE		**5 (ranges from 0 to 6); translates to 66%–67% or intermediate high risk**
COMBINED SCORE		**7 (ranges from 0 to 11); translates to 58%–72% or intermediate high risk**

[a] Assesses ability to use the telephone, get to places beyond walking distance, go shopping for groceries, prepare meals, do housework, do handyman work, do laundry, take medications, and manage money; ranges from 10 to 28 (https://moffitt.org/media/4240/instrumental_activities_of_daily_living.pdf).
[b] Assesses orientation, registration, attention, calculation, recall, and language; ranges from 0 to 30 (https://moffitt.org/media/4241/mini_mental_state_examination.pdf).
[c] Ranges from 0 to 30 (https://moffitt.org/media/4243/mna_english-full_new.pdf).
CRASH, Chemotherapy Risk Assessment Scale for High-Age Patients.

should be strongly considered for standard treatments regardless of age. Older patients with vulnerabilities may benefit from modified treatment plans.

Components of a geriatric assessment can independently assist with prognostication. In older patients with CLL, physical performance was the best predictor of outcome when compared with comorbidities, cognition, and functional status. Seventy-five patients, out of 97 enrolled in a clinical trial of the German CLL Study Group, underwent a geriatric assessment before initiation of low-dose fludarabine. Components of a geriatric assessment in this study included the cumulative illness rating scale (CIRS) to measure comorbidities, timed up-and-go (TUG) to measure objective physical function also called "physical performance," the dementia detection (DEMTECT) test, and IADL for self-reported functional status. Although there was little correlation between the CIRS, TUG, DEMTECT, and IADL results with treatment toxicity, decreased performance in TUG (i.e., slower speed) or DEMTECT test was strongly associated with decreased survival. Overall survival was remarkably poor in patients who underperformed in either TUG or DEMTECT test (median overall survival 53.8 vs. 40.5 vs. 18.2 months for TUG test $\leq$10 s vs. 11 to 19 s vs. $\geq$20 s; median overall survival 53.8 vs. 57.8 vs. 17.0 months for DEMTECT test >12 vs. 9 to 12 vs. <9 points, respectively, $P < .05$). The differences were significant after adjusting for age and disease-specific factors that are known to be of use in determining prognosis.[8] These results are supported by a recent study in 448 patients with hematologic malignancies that showed that for every 0.1-m/s decrease in measured usual gait speed, there was an associated higher mortality, odds of unplanned hospitalizations, and emergency department visits.[24] Therefore gait speed should be routinely used to assess frailty in older adults with blood cancers.

In summary, geriatric assessment is an important tool in the prognostication and assignment of treatment for patients with lymphoma and CLL. Geriatric assessment is underutilized in clinical practice because of its perceived complexity. Additional prospective, randomized studies are warranted to validate the use of geriatric assessment in determining treatment approaches and uncovering vulnerabilities.

MYELODYSPLASTIC SYNDROMES

MDSs (see Chapter 61) are a heterogeneous group of clonal hematopoietic disorders that are characterized by ineffective hematopoiesis and peripheral blood cytopenias. Patients diagnosed with MDSs often experience morbidity associated with cytopenias and are at risk for progression to AML. MDS is associated with impairments in QOL, functional decline, and high healthcare use with a 5-year survival rate estimated at less than 50%. The majority of people diagnosed with MDS (proximately 80%) are older than 70 years of age. Diagnosis and risk stratification are described in Chapter 61. The disease can be indolent, having minimal effect on QOL and survival or aggressive with a high risk of progression to AML and posing morbidity risk due to anemia, neutropenia, and/or thrombocytopenia. The commonly used revised International Prognostic Scoring System (R-IPSS) is applicable to older adults and was developed in an older age cohort (median age 71 years). In the development cohort, age was a prognostic factor for survival but not for progression to AML, having more impact on lower-risk (indolent disease) versus higher-risk disease.

Treatment for MDS is guided by risk stratification and symptoms as described in Chapter 61. For older adults, particularly those older than the age of 75 years, treatment decisions must also take into account a patient's overall fitness and competing comorbid conditions. Most patients with MDS have additional comorbidities; a higher comorbidity burden affects non-MDS life expectancy as well as treatment tolerance. Comorbidity burden has been associated with shorter survival independent of age and disease risk.[25] Comorbidity is not static in this population, but comorbid conditions accumulate over time, requiring reassessment during ongoing management.[26]

In general, supportive care remains the mainstay of treatment for patients with low-risk disease regardless of fitness level and in many cases for those who are frail regardless of disease-risk stratification. Patients in the higher-risk IPSS categories are more likely to experience morbidity-related cytopenias and progress to acute leukemia in a shorter time interval from the time of diagnosis. For these patients, hypomethylating agents represent the mainstay of treatment. Randomized studies have shown improvements in survival, QOL, and longer time to progression to AML, including among those age 75 and older.[27] Challenges for older adults using hypomethylating therapy include myelosuppression, which often worsens for several months before a response is achieved, and the duration of therapy, with most clinical trials treating for more than 6 months for all patients and more than 12 months for responders.

Few older adults are candidates for high-intensity therapy with curative intent (see the section on Stem Cell Transplantation and Cellular Therapy).

Assessment of fitness is critical during initial treatment decision-making and during ongoing management to maximize the opportunity for benefit and to guide supportive care. Although data form large prospective trials remain limited, use of geriatric assessment can identify those who are fit (i.e., no impairments detected in geriatric domains) and who are most likely to tolerate guideline-based therapies. Several studies have specifically evaluated strategies for assessing frailty among patients with MDSs. Frailty is a state of decreased physiologic reserve associated with morbidity and mortality and commonly arising from decreased organ reserve, lack of activity, poor nutritional intake, stress, and/or physiologic changes of aging. The two most common methods for characterizing frailty are the phenotype method (weight loss, weakness, slow gait speed, low physical activity, and exhaustion)[28] or the cumulative deficit burden strategy.[29] Investigators leading the Canadian MDS registry have shown that frailty is independently associated with a worse overall survival using several assessment methods.[30] First, the Clinical Frailty Scale (nine-item descriptive scale assigned by physician judgement) was evaluated among 445 patients with MDS and shown to be independently prognostic of overall survival adjusting for R-IPSS and comorbidity.[30] This scale represents an efficient, practical screening tool to incorporate frailty screening into practice. The investigators further evaluated a deficit accumulation frailty index which included 42 variables inclusive of comorbid conditions, laboratory tests, symptoms, self-reported function, and physical performance tests. This MDS-specific frailty index was associated with survival adjusting for age, IPSS score, and transfusion dependence. It improved discrimination of survival by 37%.[31] To enhance usability of the index, a 15-item MDS-specific frailty index was developed using machine learning techniques. This index is weighted toward readily available laboratory data and includes three easy to obtain patient characteristics (fatigue score, assistance with food preparation, and 4-meter walk time). While validation of this tool is needed in other settings, it is a useful tool and an online calculator is available for predicting overall survival at the following link: https://qxcalc.app.link/mdsfrailty.

Finally, a prospective study investigating use of geriatric assessment among older adults with MDS demonstrated a high prevalence of vulnerabilities (78%) at the time of diagnosis and showed that those requiring assistance with IADL and with higher comorbidity burden had shorter survival independent of disease-related factors or treatment.[32] In addition, requiring assistance with IADL, impaired cognition, or mobility limitation were each associated with significantly fewer azacitidine cycles received compared with those without deficits.

In summary, assessing fitness or frailty is relevant to assist initial treatment decision-making, inform expected benefits of therapy, and identify vulnerabilities that can direct supportive care interventions such as referral for physical therapy. Highest yield assessments include frailty screening tools, self-reported function (i.e., activities of daily living [ADL], IADL), gait speed, cognition screening, and evaluation of comorbidity burden. Future studies will help move beyond prognostication and toward intervention on vulnerabilities to improve quality and extent of survivorship.

ACUTE MYELOID LEUKEMIA

There are approximately 20,000 new cases of AML diagnosed in the United States annually, and the majority of those are among adults older than age 65. Although outcomes for patients with AML have improved in recent years, a persistent age-related outcome disparity exists with 5-year survival rates less than 10% for those older than 65 years of age. Due to concerns regarding poor treatment outcomes, many older adults receive no therapy after AML diagnosis. Recently, as described in Chapter 60, treatment options, including isocitrate dehydrogenase (IDH) inhibitors (enasidenib and ivosidenib), FLT-3 inhibitors (midostaurin and gliteritinib), Hedgehog inhibitor (glasdegib), BCL-2 inhibitor (venetoclax), and others (gemtuzumab, CPX-351), have expanded for older and less fit adults. Current guideline recommendations emphasize treatment over best supportive care with more intensive treatment for those who are fit and likely to withstand the stress of treatment versus less-intensive strategies for those who are not considered "fit" to optimize the risk to benefit estimation.[33]

A key unresolved issue in these recommendations are the criteria for "fitness" for intensive therapy. To date, no validated set of criteria have been prospectively evaluated, and this decision is largely based on a provider's subjective estimation and rely on chronologic age. Recent drug approvals for "unfit" older adults with AML have used age 75 years or older as the most consistent criteria, followed by presence of comorbidities (i.e., cardiac and renal disease) and oncology performance status to define the population treated. Use of more refined strategies are needed to ensure fit patients, particularly those older than age 75 years, are appropriately identified.

Several nonrandomized studies have shown that geriatric assessment can inform estimation of fitness in the setting of therapy for AML. Geriatric assessment detects vulnerabilities not otherwise captured.[34,35] A prospective study assessing older patients with good ECOG performance status considered fit to receive intensive therapy identified the following impairments at the time of treatment initiation: cognitive impairment (24%), depression (26%), distress (50%), ADL dependence (34%), impaired objectively measured physical performance (31%), and comorbidity burden (40%).[35] In this cohort study (N=74) evaluating inpatient geriatric assessment prior to intensive chemotherapy, two measures were independently associated with survival: objectively measured physical performance (assessed using the short physical performance battery [SPPB]) and cognitive impairment.[36] The SPPB is a validated measure of lower extremity function that predicts future disability, hospitalizations, and mortality among older adults in varied settings. The SPPB is composed of a short walk (4 meters), repeated chair stands, and balance tests and is more sensitive to change in function than self-report measures.

Geriatric assessment has also been studied to a limited extent in the nonintensive treatment setting.[34,37] A multisite observational study evaluated pretreatment geriatric assessment among patients with MDS or AML who received best supportive care, hypomethylating agents, and intensive therapy per clinician discretion. Among those who received either best supportive care or low-intensity therapy dependence in ADL, high fatigue score and impaired oncology performance status were independently associated with inferior survival.[34] A frailty score was created from these variables, ranging from 0 (low risk), 1 to 2 (intermediate), and 3 impairments (high risk) that predicted survival. A multisite study validating this frailty score has been completed in the setting of nonintensive chemotherapy in Europe, and published results are pending.[38]

In addition to providing useful information at the time of initial treatment decision-making, geriatric assessment measures can provide important information during the course of treatment due to the dynamic nature of measured vulnerabilities. For example, in older adults receiving intensive therapy, short-term declines in physical function can be expected.[39,40] Symptom burden may also change during treatment. These acquired vulnerabilities can impact longer-term outcomes and candidacy for subsequent therapies such as stem cell transplantation. A recent analysis demonstrated that objectively measured physical function (SPPB score) and depressive symptoms measured at the time of postremission therapy evaluation are independently associated with survival among older adults treated intensively for AML.[41] These observations suggest that repeat geriatric assessment at key decision intervals during the course of treatment and survivorship can provide prognostic information and guide supportive care targeting those vulnerabilities to improve "fitness."

Another important consideration when evaluating older adults with AML is alignment of treatment choices to patient values and the importance of providing information on both disease control and QOL. Age-related differences in health-related QOL have been evaluated in an observational study comparing older and younger patients treated intensively for AML.[42] As expected, most patients report a significant symptom burden at diagnosis with similar improvements in QOL in both older and younger age groups over time for those who survive. Compared with younger patients, older adults had less recovery in measures of physical function than younger patients did. Several studies have evaluated differences in QOL between those treated with different regimens. In a randomized trial comparing azacitidine to conventional therapy (standard induction chemotherapy, low-dose ara-c, or supportive care only) for newly diagnosed older adults with AML, global QOL was similar between treatments, although comparisons were limited over time due to attrition.[43] Observational studies have also shown no clear difference in QOL between those treated with azacitidine or conventional therapy and no clear indication that QOL was associated with treatment allocation.[44,45] The inclusion of well-designed QOL objectives in randomized treatment trials will be important to inform patients on how they will feel and function during and after treatment to guide personalized decision-making as therapeutic options evolve.

In summary, most older adults with AML should be offered therapy. Initial treatment decision-making should be informed by both tumor biology and careful assessment of patient characteristics to inform "fitness." Although there is no gold standard definition of fitness, older adults with adequate physical performance (SPPB score $\geq$9), normal cognition, independence in ADL, and lack of significant comorbidity can be considered fit for intensive therapy. Use of geriatric assessment can inform treatment decision-making and management during the course of treatment with emphasis on identifying modifiable vulnerabilities (i.e., physical function, symptoms) that can guide supportive care.

MULTIPLE MYELOMA IN OLDER ADULTS

Multiple myeloma is a disease of older adults, with a median age at diagnosis of 70 years (Chapter 91). With approximately 32,000 new cases diagnosed annually in the United States, multiple myeloma is the second most common hematologic malignancy following leukemia.[46] As therapies for multiple myeloma continue to evolve rapidly to include novel agents and targeted therapies, improved survival has resulted in multiple myeloma becoming a chronic disease for some. This trend toward improved survival is less apparent for older adults (age $>$ 70 years) due to their increased risk of early mortality (death within 6 to 12 months following diagnosis).[47,48] The observed survival differences are partly due to the higher prevalence of cognitive and functional impairments and multimorbidity detected with advancing age.[49] Recognizing the heterogeneity of aging and the limitations associated with use of chronologic age and performance status as proxies for an older adult's fitness level, geriatric assessment has become an essential component of the care for older adults with cancer.

In the multiple myeloma setting, various tools are available to detect vulnerabilities and shape clinicians' decision-making around treatment intensity and treatment-related toxicity risk prediction. Palumbo and colleagues developed the International Myeloma Working Group's frailty tool, which incorporates age, performance status, functional status (IADL, and ADL), and comorbid burden (Charlson comorbidity index [CCI]).[9] In this pooled analysis of

869 newly diagnosed older adults with multiple myeloma enrolled in three prospective trials, patients were classified as fit, intermediate fit, and frail using an additive score; scores were predictive of death, survival, treatment discontinuation, and nonhematologic toxicities.[9] The Revised Myeloma Comorbidity Index (R-MCI) is an expansion of the previously described Freiburg Comorbidity index[50] that incorporates frailty status along with age, comorbid burden, disease cytogenetics, performance status, and the presence of lung or renal disease. In this prospective study of 552 patients, 13% (*n* = 74) were classified as frail using the R-MCI. Frailty was associated with an inferior overall survival.[51] Further attempts to streamline assessments of geriatric domains in adults with multiple myeloma have been retrospectively explored using data from the Frontline Investigation of Revlimid and Dexamethasone versus Standard Thalidomide (FIRST) (MM-020) trial.[52,53] Among 1618 newly diagnosed, transplant-ineligible multiple myeloma patients, frailty status was defined by age, presence of comorbidities (CCI), and ECOG Performance Status. Forty-nine percent of patients were found to be frail, with frail patients experiencing worse overall survival compared with nonfrail patients (median overall survival 42.1 vs. 70.1 months; $P < .0001$).[53]

Further attempts to describe the predictive and prognostic value of deficits in age-related vulnerabilities using administrative and claims data have been pursued. Using the Rockwood Accumulation of Deficits approach for the Medicare Health Outcomes Survey (MHOS), a frailty index was developed and applied to 305 patients with multiple myeloma.[54] Using the MHOS-based frailty index, 53% of patients were considered frail. Furthermore, each 10% increase in frailty index was associated with a 16% increased risk for a poor outcome.[54] Recently investigators applied an accumulation of deficits approach frailty index to a large (*n* = 3807) database of US veterans with multiple myeloma. Thirty percent of the cohort were considered frail, with higher frailty scores associated with worse overall survival, with hazard ratios of 1.33, 1.97, 2.86, and 3.22 for prefrail, mildly frail, moderately frail, and severely frail, respectively.[55]

Assessment of vulnerabilities using a geriatric assessment remains essential in the care of adults with multiple myeloma. However, whether personalization of therapy based on geriatric assessment–detected vulnerabilities could improve the outcomes of older adults remains unanswered. The planned phase 3 Myeloma XIV (FiTNEss) trial will address this question in transplant-ineligible older adults.[56] The results of this and other prospective trials could shape future treatment approaches, ultimately leading to improved outcomes for older adults with multiple myeloma.

HEMATOPOIETIC STEM CELL TRANSPLANTATION AND CELLULAR THERAPY IN OLDER ADULTS

HSCT is more frequently considered for older patients with hematologic malignancies, and studies from the Center for International Blood and Marrow Transplant Research (CIBMTR) have shown improved long-term outcomes in recipients receiving autologous and allogeneic grafts.[57] The increased use of HSCT is likely the result of advances in reduced-intensity conditioning regimens, broadened donor pools, improved supportive care including antimicrobials, and better selection of appropriate older candidates using validated geriatric assessment tools.[57]

Traditionally, the Hematopoietic Cell Transplant-Comorbidity Index (HCT-CI) is used in combination with chronologic age to risk stratify older adults prior to HSCT.[58] Recognizing increased geriatric vulnerabilities and heightened sensitivity to therapeutic toxicities among older adults, Muffly and colleagues conducted the first prospective study of geriatric assessment in older allogeneic HSCT patients.[10] They found that several geriatric deficits, including functional and physical limitation, mental health impairment, and multimorbidity, significantly reduced post-HSCT survival beyond chronologic age or performance status alone. These findings were subsequently validated in several small prospective and retrospective studies[57] and laid the foundation for the larger ongoing Blood and Marrow Transplant Clinical Trials Network (BMTCTN-1704) study: Composite Health Assessment Model for Older Adults: Applying Pre-transplant Comorbidity, Geriatric Assessment, and Biomarkers to Predict Non-Relapse Mortality after Allogeneic Transplantation (CHARM, NCT03992352).

The use of a geriatric assessment for autologous HSCT decision-making has shown promise, with initial data suggesting a role for the geriatric assessment in predicting the likelihood of receiving HSCT.[59] In a prospective study of 40 newly diagnosed older adults with multiple myeloma, the administration of a pretransplant geriatric assessment identified 62% with at least one measurable IADL deficit, 76.9% with polypharmacy, and 47.5% with one or greater comorbid conditions. Patients with fewer geriatric assessment–detected vulnerabilities were also more likely to undergo transplantation (*n* = 26). In addition, age and IADL dependence were strongly associated with receipt of HSCT.[59] Use of a pre- and post-stem cell transplantation geriatric assessment was also found to predict length of stay and event-free survival in multiple myeloma.[60]

Beyond risk stratification for HSCT outcomes, geriatric assessment may uncover additional geriatric vulnerabilities for targeted interventions. Derman and colleagues published results from a single institution pre–post implementation study of a transplant optimization program.[61] They found that a geriatric assessment–guided, multidisciplinary team clinic composed of interprofessional providers reliably provided targeted rehabilitation and optimization for older, vulnerable patients pre-HSCT. The geriatric assessment–selected, optimized postintervention cohort had fewer inpatient deaths, shorter length of stay, and lower 1-year nonrelapse mortality and higher overall survival compared with the preintervention cohort. These results provided support for geriatric assessment–guided interventions to improve HSCT and cellular therapy outcomes.

More recently, novel cellular immunotherapy such as chimeric antigen receptor T-cell (CAR-T) therapy is revolutionizing the treatment of hematologic malignancies. However, it remains unknown how older, vulnerable patients will tolerate these intensive therapies with unique toxicity profiles. In a recent single institution study with prospectively collected geriatric assessment data, Lin and colleagues showed that older lymphoma patients had similar outcomes after CAR-T therapy compared with younger patients, suggesting that chronologic age alone should not exclude older patients.[62] Moreover, CAR-T could be safely administrated to older patients with preexisting functional limitation and cognitive impairment. Larger studies with longer follow-up are needed to evaluate prognostically important geriatric assessment domains among older CAR-T patients.

In summary, geriatric assessment is playing an increasingly important role to risk stratify and to identify potential modifiable deficits for older patients undergoing HSCT and cellular therapies. It is likely that incorporating geriatric assessment tools to assess HSCT candidacy will become the standard of care based on the CHARM study. However, prospective, randomized, multicenter studies are needed to evaluate whether geriatric assessment tools can guide HSCT cellular therapy decision-making and treatment intensity; and to determine the impact of targeted geriatric interventions on HSCT and cellular therapy outcomes for older, vulnerable patients with hematologic malignancies.

CONCLUSION

With the growing number of older adults with cancer, a geriatric assessment provides a way to personalize management in this population. However, this approach is underutilized and not routinely incorporated in clinical practice due to various barriers such as perceived lack of time, resources, and evidence to support its use. Increasing numbers of studies on the utility of geriatric assessment in hematologic malignancies are emerging and, along with continued education of hematologists, will facilitate its dissemination and implementation.

CHAPTER 158

ONCO-CARDIOLOGY: FOCUS ON CARDIAC COMPLICATIONS OF HEMATOLOGIC TREATMENTS

Andrea Gallardo-Grajedau and Gagan Sahni

Recent progress in chemotherapy and immunotherapy for hematological malignancies has improved cancer survivorship over the past few decades. However, cardiovascular disease is a prominent cause of death in many cancer survivors, with emerging cardiotoxicity from cancer therapies being a significant contributor to the morbidity and mortality of this population.

Onco-cardiology as a subspecialty of cardiology that seeks to identify, prevent, diagnose and manage the cardiovascular complications of cancer therapies, which may be related to both cancer itself and the adverse effects of cancer therapies. Among the myriad cardiovascular complications of cancer therapies, chemotherapy-induced left ventricular dysfunction or cancer therapy-related cardiac dysfunction (CTRCD) as per 2014 guidelines from the American Society of Echocardiography is among the commonest.[1] However, the spectrum of cardiotoxicity includes other cardiovascular conditions including and not limited to atrial fibrillation and other arrhythmias, hypertension, acute coronary syndromes (ACSs), venous thromboembolism, pericardial syndromes, and valvular disease.

This chapter aims at a discussion of cardiotoxicity due to chemotherapy, immunotherapy, radiation therapy, and bone marrow transplantation, all of which are commonly used therapies for hematological malignancies.

CARDIOTOXICITY FROM CHEMOTHERAPY USED IN HEMATOLOGICAL MALIGNANCIES (TABLE 158.1)

Anthracyclines

Oncological Indication

Anthracyclines are cytostatic antibiotics discovered in the 1960s and encompass several anthracyclines including doxorubicin, epirubicin, idarubicin, daunorubicin, and liposomal encapsulated doxorubicin, used for a broad range of solid tumors, sarcomas, and hematological malignancies.

Cardiotoxicity

Anthracycline-induced cardiotoxicity (AIC) can develop in an acute, subacute, or chronic manner. Injury to the myocyte may begin as early as the initial exposure, with some studies detecting a rise in troponin levels immediately after the first dose is administered.[2] This occurs in less than 1% of patients and manifests as an acute, transient decline in myocardial contractility, which is usually reversible.

The subacute form occurs in 1.6% to 2.1% of patients within the first year after treatment whereas the late-onset chronic form presents at least 1 year after completion of therapy in 1.6% to 5% of patients receiving lower doses. Both the subacute and chronic forms tend not to be reversible.[2–4]

AIC occurs in a dose-dependent manner, increasing with a cumulative dose. Studies evaluating cumulative probability of doxorubicin-induced heart failure have found rates in the range of 3% to 5% at doses less than 400 mg/m^2, 7% to 26% at 550 mg/m^2, and 18% to 48% at 700 mg/m^2.[5] However, subclinical cardiotoxicity defined by troponin rise, strain imaging, and MRI studies has been shown with doses less than 250 mg/m^2 (Fig. 158.1).

Mechanism of Cardiotoxicity

Previously, the most commonly accepted hypothesis for AIC was the generation of reactive oxygen species (ROS) by electron exchange between the anthracycline and oxygen molecules and the formation of complexes with iron that undergo redox cycling and generate oxygen radicals. Although in vivo and in vitro studies confirmed increased ROS production in cardiomyocytes after anthracycline therapy, neither antioxidants nor iron chelation have prevented the development of cardiomyopathy (Fig. 158.2).

More recent studies demonstrate topoisomerase (Top) 2b as the primary mediator of AIC. Top2b is present in all quiescent cells, including cardiomyocytes and is responsible for unwinding deoxyribonucleic acid (DNA) chains during normal DNA replication, transcription, or recombination. Anthracycline inhibition of Top2b results in double-stranded breaks in DNA, production of ROS, and mitochondrial dysfunction which leads to cardiomyocyte apoptosis.[6] Mice models have shown Top2b deletion from the heart protects cardiomyocytes from anthracycline-induced cardiomyopathy, which strongly implicates Top2b as the key mediator of AIC.[7]

Prevention and Treatment

Anthracycline cardiotoxicity should be mitigated without compromising oncological efficacy. The strategies may include dose limitation, altering infusions schedules, use of alternative molecules such as liposomal encapsulated doxorubicin, using less cardiotoxic derivatives (e.g., epirubicin or idarubicin), and cardio-protection using targeted cardioprotective agent (e.g., dexrazoxane) in conjunction with treatment.

Dexrazoxane is the only FDA-approved, targeted, cardioprotective agent for AIC. It changes Top2's configuration to a closed-clamp form through tight binding to Top2's ATP-binding sites, thus preventing anthracyclines from binding to the Top2 complex.[8] Even though in some pediatric studies it has shown a relative risk reduction of up to 79% in cardiotoxicity, there have been adult studies suggesting myelosuppression, secondary malignancy, and reduced anthracycline efficacy which has not been validated in any randomized controlled trials. However, currently dexrazoxane is only approved by the FDA for adults needing additional anthracyclines after an initial dose of greater than 300 mg/m^2.

Other cardioprotective agents including beta-blockers, angiotensin-converting enzyme inhibitors (ACEi), and angiotensin receptor blockers (ARBs) have been studied for both primary and secondary prevention in smaller studies.[9] Stringent control of concomitant risk factors such as diabetes, dyslipidemia, hypertension, and avoiding combination cardiotoxic chemo and concomitant radiotherapy to the mediastinum/left chest are other ways to mitigate AIC.[10]

TABLE 158.1 Cardiotoxicity From Therapies Used in Hematological Malignancies

Agent		Hematological Indications	Cardiovascular Toxicity	Prevention and Treatment
Anthracyclines	Doxorubicin Epirubicin Idarubicin Daunorubicin Liposomal encapsulated doxorubicin	Bone marrow transplant Leukemias Lymphomas	Acute and chronic heart failure [3%–26%]	• Cardioprotection with dexrazoxane [Top 2b inhibitor] • Dose limitation and avoiding combination radiation/cardiotoxic chemo • Altering infusions schedules • Use of alternative molecules such as liposomal encapsulated doxorubicin • Use of less cardiotoxic derivatives (e.g., epirubicin or idarubicin) • Role of ACE-I, ARBs and beta-blockers in primary prevention
Tyrosine kinase inhibitors		Chronic myelogenous leukemia (CML) Acute lymphoblastic leukemia (ALL)	Heart failure Arrhythmias/QT prolongation Hypertension Myocardial ischemia/ACS	
	Imatinib		Heart failure (0.5%–1.7%)	• Use of cardioprotective agents such as beta-blockers and ACE-I if indicated
	Dasatinib		Pulmonary hypertension (0.45–12.1%) Pleural effusion	• Screening for PAH with transthoracic echocardiogram • Combination therapy of vasodilators (phosphodiesterase-5 inhibitor, endothelin receptor antagonists, etc.)
	Nilotinib		QT prolongation Vascular events (PVD, CVD)	• Baseline ECG • Correct electrolyte abnormalities • Check drug-drug interactions for QT prolongation • Stop therapy or reduce dose if QTc >480 • Screening for PVD with ABI
	Ponatinib		Vascular events, venous and arterial thrombosis	• Controlling risk factors such as diabetes and hypertension • Use of ACE-I, statins, aspirin • Screening for PVD
	Ibrutinib	Refractory chronic lymphocytic leukemia (CLL) Waldenstrom macroglobulinemia Mantle cell lymphoma (MCL)	Atrial fibrillation	• Strategy of immediate rhythm control • Interactions with antiarrhythmic drugs: amiodarone, diltiazem, and verapamil, digoxin • Interactions with anticoagulants: apixaban and rivaroxaban, dabigatran • Close monitoring during anticoagulation • Alternatives left atrial appendage closure devices, vena cava filter
Arsenic trioxide		Relapsed or refractory acute promyelocytic leukemia (APL) Myelodysplastic syndrome Multiple myeloma Non-Hodgkin lymphoma	QT prolongation, Ventricular arrhythmias, torsades de pointes and sudden cardiac death	• ECG surveillance • Monitoring and supplementation of electrolytes • ROS scavengers and antioxidants (experimental role of (vit C, vit E, glutathione, carotenoids, flavonoids and antioxidants)
Immune checkpoint inhibitors		Plasma cell myeloma Myelodysplastic syndrome Acute myeloid leukemia	Myocarditis	• Measure hs-cTnT and perform periodic EKG especially in first 3 months • Transthoracic echocardiogram if clinical suspicion of myocarditis • Withhold therapy if ICI-myocarditis suspected and admit patient • CMR gold standard for diagnosis of ICI-myocarditis, if not, EMB • Treatment with steroids or aggressive immunosuppressive regimens as required
CAR-T therapy		Highly refractory and relapsing hematological malignancies	Sinus tachycardia, arrhythmias, QT prolongation, ST changes, LVSD, profound hypotension, shock during CRS	• Tocilizumab, steroids, pressors • Echocardiogram to assess LVSD during CRS • Ace-I / ARBs when blood pressure is stable • Hold anticoagulation and dual antiplatelet therapy prior to CAR-T therapy to avoid intracranial hemorrhage

Continued

TABLE 158.1 **Cardiotoxicity From Therapies Used in Hematological Malignancies—cont'd**

Agent	Hematological Indications	Cardiovascular Toxicity	Prevention and Treatment
Radiation therapy	Hodgkin and non-Hodgkin lymphoma	Pericarditis (acute and constrictive) CAD (late) Valvular dysfunction (late) Restrictive heart failure	• Minimizing radiation dose given to left chest and mediastinum • Use of charged particle (e.g., proton or carbon ion) therapy • Prior CT-guided field planning to minimize cardiac involvement • Prone patient position, breast boards, and having the patient hold a deep breath to decrease the involvement of the anterior heart

Tyrosine Kinase Inhibitors

The vast majority of chronic myeloid leukemia (CML) and acute lymphoblastic leukemia (ALL) (Chapters 68 and 69) are treated with a spectrum of tyrosine kinase inhibitors (TKIs) which targets the Abl kinase portion of Bcr-Abl in these hematological malignancies.

Imatinib was the first tyrosine kinase inhibitor to be discovered with high specificity for Bcr-Abl protein; however, more than 30% of patients with CML are either unable to tolerate or will develop resistance to imatinib. Thereby, newer generation BCR-ABL kinase inhibitors—dasatinib, nilotinib, bosutinib, and ponatinib—have been developed as efficacious alternatives or second-line therapy. Of these, only ponatinib inhibits the "gatekeeper" T315I mutation, which is present in up to 20% of patients with resistance to other tyrosine kinase inhibitors. The various TKIs have distinct vascular safety profiles, due to each compound's different kinase inhibition profiles and non-kinase targets.[11]

The spectrum of cardiovascular toxicities associated with TKIs includes heart failure (HF), arrythmia, QT prolongation, hypertension, and ACS/myocardial ischemia. The individual cardiotoxicity of the most common TKIs and their mechanism of cardiac damage is discussed separately as below.

Imatinib

In patients treated with imatinib monotherapy, clinical heart failure is very rare, occurring in 0.5% to 1.7% of patients.[11] Initial studies that used serum B-type natriuretic peptide (BNP) or troponin T levels as a marker of cardiac dysfunction reported no cardiotoxicity with imatinib therapy[12]; however, some noninvasive imaging studies have demonstrated a decline in the left ventricular ejection fraction with this therapy.[13] Although pathological findings characteristic of toxin-induced myopathy have been demonstrated on biopsy in imatinib-treated patients, studies have failed to correlate with clinical heart failure. Which patients are most susceptible to developing cardiac dysfunction with imatinib therapy and are candidates for appropriate preventative and management interventions is currently unknown.

Vascular toxicity is rare with imatinib treatment; in fact, it may actually have beneficial roles on the vasculature, having shown attenuation of in-stent restenosis and diabetes-associated atherosclerosis in mouse models. Interestingly, in a large retrospective cohort, patients with CML on imatinib treatment had lower rates of peripheral vascular events compared with those treated initially with placebo. These favorable effects also extend to the pulmonary vasculature, where pre-clinical data suggesting reversal of pulmonary arterial hypertension (PAH).[14–17]

Figure 158.2 POTENTIAL OPPORTUNITIES FOR CARDIOPROTECTION. Doxorubicin chemotherapy has a range of effects on cardiomyocytes. It induces lipid peroxidation at the cell and mitochondrial membranes by way of complexing with Fe^{2+} and induces apoptosis, mitochondrial DNA damage, and energy depletion through its production of ROS. Furthermore, it impairs Ca^{2+} processing in the sarcoplasmic reticulum and inhibits the transcription of important muscle elements, weakening the heart muscle. It also downregulates adrenergic receptors and interrupts cell signaling. (1) Administration of dexrazoxane can prevent Fe^{2+} complex formation. (2) Intravenous immunoglobulin therapy can reduce inflammatory cytokines. (3) l-Carnitine can bolster mitochondrial function. (4) Anti-heart-failure therapies, such as angiotensin-converting enzyme inhibitors and beta-blockers, can prevent further damage. *cTn*, Cardiac troponin; *MLC2*, myosin light chain 2; *MM-CK*, myofibrillar isoform of the CK enzyme; *ROS*, reactive oxygen species; *TOPII*, topoisomerase 2. *(From Lipshultz SE, Sambatakos P, Maguire M, et al. Dasatinib

Dasatinib frequently causes pulmonary hypertension (PAH), the incidence varying from 0.45% to 12.1% in different series.[18,19] One-third of these cases have irreversible PAH that persists even on discontinuation of the drug. The mechanism of dasatinib-associated PAH remains unclear.

A French PAH registry reported a series of 9 dasatinib-associated PAH cases, the median time between initiation of dasatinib therapy and PAH diagnosis being 8 to 48 months. At diagnosis, most patients had severe clinical, functional, and hemodynamic impairment with minimal acute vasodilator response, suggesting that isolated acute vasoconstriction is not the main mechanism of dasatinib-induced PAH, which seems to be a delayed and sometimes irreversible phenomenon.[18]

Interestingly, dasatinib is associated with a higher incidence of pleural effusion, from 14% to 35%. The mechanisms underlying development of pleural effusion are probably immune-mediated.[20]

Nilotinib

QT prolongation and vascular events are the main CV adverse events seen with nilotinib. Nilotinib prolongs the QT interval more commonly than other tyrosine kinase inhibitors with an incidence of 1% to 10%. The mechanism behind this action potential delay is an inhibition of phosphoinositide-3-kinase due to “on-target” effects of nilotinib.[21]

A baseline ECG should be obtained in all patients prior to starting TKI’s such as nilotinib. Electrolyte abnormalities must be corrected and drug-drug interactions that influence QTc interval (antibiotics, antiemetic, antipsychotic or antidepressant drugs) must be evaluated prior to beginning treatment. ECGs should be repeated a few days after initiation/modification of anticancer therapy. Strict monitoring and repletion of magnesium and electrolyte levels are warranted when using this agent and a corrected QT of greater than 480 ms is an indication to hold therapy or ΔQTc greater than 60 ms during monitoring.[11,21]

Vascular events have been reported in up to 6.15% of patients who received nilotinib, including severe peripheral atherosclerosis needing angioplasty and limb amputation.[22] In fact, a prospective study of 129 patients with CML screened for peripheral vascular disease (PVD) with ankle-brachial index (ABI) during therapy demonstrated PVD in 26% of patients treated with first-line nilotinib, and 35.7% with second-line nilotinib—far higher than previously reported.[23]

Nilotinib also affects coronary arteries causing vasospasm, direct antiangiogenic, and pro-atherogenic effects on endothelial cells, procoagulant effects, and acceleration of atherosclerotic processes in the coronary and peripheral vasculature. Therefore, it is necessary to have rigorous metabolic control, modification of cardiovascular risk factors, and is to get baseline screening for CAD with stress testing and PVD with ABI in high-risk patients.[22]

Besides VEGF inhibition, an accelerated metabolic dysregulation may be involved in accelerated vascular atherosclerosis, since nilotinib may cause increases in glucose, total cholesterol and LDL, insulin resistance, and compensatory hyperinsulinemia. Nilotinib treatment is also associated with hypothyroidism, which can affect lipid and glucose metabolism, which are all risk factors for developing atherosclerosis.[24,25]

Ponatinib

Ponatinib is highly effective in CML patients who are resistant to other TKIs. However, in a study with a median follow-up of 27.9 months, serious arterial thrombotic events occurred in 19% of ponatinib-treated patients, including CV events (10%), cerebrovascular events (7%), and peripheral vascular events (7%), with some patients having greater than 1 event. In addition, 5% of patients experienced VTE and at least five patients died from vascular events (VE) thought to be due to ponatinib.[26] Other studies have shown a high incidence of HTN in up to 26% of patients treated with ponatinib.[27] Subsequently, ponatinib now has a black box warning about increased risk of arterial and venous occlusive events which occur earlier and more frequently than even nilotinib.

The underlying mechanisms of ponatinib-induced VE are largely unknown. Ponatinib inhibits numerous tyrosine kinases such as SRC, FGFR, PDGFR, and VEGFR1–3 which result in nitrous oxide depletion, platelet aggregation, endothelial dysfunction, and vasospasm that eventually lead to a high incidence of vascular events.[28]

Controlling risk factors such as diabetes and hypertension, use of ACE-inhibitors, statins, aspirin, and screening for PVD are thereby essential in prevention and treatment of ponatinib and nilotinib induced cardiotoxicities.

Ibrutinib

Ibrutinib is an irreversible inhibitor of Bruton tyrosine kinase (BTK), which has become an important part of the therapeutic approach in patients with refractory chronic lymphocytic leukemia (CLL), Waldenstrom macroglobulinemia, and mantle cell lymphoma (MCL) (Chapters 76, 86, and 92). However, ibrutinib use is associated with an almost fourfold increase in the risk of atrial fibrillation (AF). The reported incidence of new-onset AF in patients treated with ibrutinib can be as high as 16%, most occurring in the first 2 years of its use. The mechanism of AF may be induced via inhibition of cardiac PI3K-Akt signaling by inhibition of cardioprotective BTK and TEC kinases by ibrutinib according to a preclinical mouse model theory.[29,30]

Due to the interactions between ibrutinib and both antiarrhythmic and anticoagulant drugs, the management of ibrutinib-related AF is particularly challenging. Amiodarone, diltiazem, and verapamil, which are inhibitors of CYP3A4, a primary site for ibrutinib metabolism, increase ibrutinib exposure and should not be co-administered, while digoxin interacts with ibrutinib through inhibition of P-glycoprotein. A strategy of immediate rhythm control with cardioversion followed by a short course of anticoagulation, during which ibrutinib can be administered at decreased doses, seems to be preferable over rate control in patients who present with new-onset AF.[31]

There are also drug interactions between ibrutinib and the oral anticoagulants, apixaban and rivaroxaban through CYP3A interaction, and dabigatran through P-glycoprotein interaction. Also, ibrutinib has significant intrinsic anticoagulant activity due to unclear mechanisms; because of this anticoagulant activity with the increased risk of bleeding, additional platelet inhibition is generally contraindicated during the ibrutinib therapy course.[31] Close monitoring is warranted during anticoagulation therapy. In case of failed cardioversion or recurrent AF with a high risk of bleeding, additional treatment alternatives could be the use of left atrial appendage closure devices or placement of a vena cava filter.

Therapy decisions need to be individualized, based on feasibility of rate or rhythm control, patients' risk factors for thromboembolism and bleeding, and the availability of effective alternative antineoplastic treatments for the underlying hematologic malignancy.

Arsenic Trioxide

Oncological Indication

Arsenic trioxide (ATO) has been recommended as the front-line agent for treatment of relapsed or refractory acute promyelocytic leukemia (APL). It has also been found to be effective in other hematologic malignancies, such as myelodysplastic syndrome, multiple myeloma, and non-Hodgkin lymphoma.

Cardiotoxicity

Chronic ATO use can result in cardiac toxicities including QT prolongation, ventricular arrhythmias, torsades de pointes, and sudden cardiac death. Lesser reported CV events include other EKG changes, myocarditis, pericarditis, myocardial infarction, and heart failure. Myocardial damage might be irreversible and sometimes even lethal.

Mechanism of Cardiotoxicity

Apoptosis induced by arsenic depends on cell type, time, and concentration of exposure. When arsenic concentrations reach 0.5 to 2.0 mol/L, apoptosis is triggered by different pathways: ROS-mitochondrial disruption, caspase activation (especially caspase 3), MAPK signaling and p53. Depletion of nitric oxide by increase in synthesis of inflammatory mediators like leukotriene E4 and prostacyclin, tumor necrosis factor alpha (TNF-α), and NF-κB in vascular endothelial cells is another mechanism for the other cardiac toxicities caused by ATO.

The mechanism underlying QT prolongation is prolongation of the cardiomyocyte action potential duration via (1) increasing cardiac Ca^{2+} currents with up-regulation of Ica and L channels (L type calcium current) and (2) reducing surface expression of the cardiac K+ current human related gene (hERG) that encodes for cardiomyocyte K+ channels causing a down-regulation of Ik1 (inward rectifier potassium current). Also, ATO induces cardiac fibrosis because it increases TGF-B1 secretion leading to adverse cardiac electrical events.[32,33]

Arsenic-induced atherosclerosis can be attributed to different mechanisms, such as increasing mRNA transcripts of growth factors such as GM-CSF, TGF beta and the inflammatory cytokines like tumor necrosis factor-alpha and interleukin-6. Importantly, arsenic exposure enhances the aggregation of platelets and increases plasminogen activator inhibitor type-1 (PAI-1) expression, thus leading to reduced fibrinolysis.

Prevention and Treatment

ROS scavengers and antioxidants (ascorbic acid [vitamin C]; alpha-tocopherol [vitamin E]; glutathione [GSH]; carotenoids, flavonoids, and antioxidant enzymes such as glutathione reductase, glutathione peroxidase, and glutathione S-transferase) could provide a possible approach to treat arsenic-mediated heart injuries.

In addition, some valuable medicinal plants have demonstrated cardio-protection effect against ATO-induced toxicity such as *Boerhavia diffusa*, *Corchorus olitorius*, *Salvia miltiorrhiza*, *Silibum marianum*, and *Terminalia arjuna* in smaller studies.[34]

Regular ECG surveillance, monitoring and supplementation of electrolytes and use of cardioprotective agents such as beta-blockers and ACE-I (if indicated) are strategies to detect and circumvent CV events caused by ATO.

CARDIOTOXICITY FROM IMMUNOTHERAPY USED IN HEMATOLOGICAL MALIGNANCIES

Immune Checkpoint Inhibitors

Oncological Indication

Immune checkpoint inhibitors (ICIs) improve survival outcomes in patients with non-hematologic malignancies including prostate, lung, urothelial, and renal cancers, as well as melanoma. However, these agents have shown the ability to reestablish immune function in patients with certain hematologic malignancies, including multiple Hodgkin disease and B-cell lymphomas.

Cardiac Toxicity

The remarkable efficacy of ICIs as antineoplastic therapies is shadowed by their potential for inducing autoimmune or inflammatory side effects, termed immune-related adverse events (irAEs). Cardiovascular irAEs, particularly myocarditis, are increasingly recognized with a prevalence reported from 0.06% to 2.4%. Other manifestations include pericardial disease, vasculitis, Takotsubo syndrome, destabilization of atherosclerotic lesions, venous thromboembolism, or conduction abnormalities.[35]

Mechanism of Cardiotoxicity

The therapeutic mechanisms of the most commonly used ICIs are based on blocking either the cytotoxic T-lymphocyte associated antigen-4 (CTLA-4) or programmed cell death protein-1 (PD-1) pathways. Cardiac irAEs appear more frequently in patients treated with CTLA-4 antagonists as compared with PD-1 inhibitors, and the risk increases with combination therapy, sometimes even leading to ICI's discontinuation in up to 50% of patients.[36,37]

The mechanism of ICI-induced myocarditis has been hypothesized to be due to a loss of the inhibitors of T-cell inactivation, leading to an autoimmune T-cell infiltration of the myocardium causing autoimmune myocarditis, release of biomarkers such as troponin signaling cardiac injury and eventually dilated cardiomyopathy and death due to heart failure. There is a suggestion that patients with autoimmune diseases, diabetes mellitus, pre-existing CV disease, and those who did not receive a flu vaccine in the preceding 6 months are at highest risk.[38]

The onset of ICI-associated myocarditis has been primarily reported within 3 months of treatment initiation in 81% of cases in registry data with a median time of 17 to 65 days after the first dose of the ICI. Symptoms are non-specific and may include dyspnea, chest pain, fatigue, myalgia, palpitations, syncope, dizziness, or altered mental status. Subclinical myocarditis has also been described, posing management challenges.

Prevention and Treatment

Baseline and serial measurements of serum high-sensitivity cardiac troponin T (hs-cTnT) and the performance of EKGs is reasonable in patients undergoing ICI therapy, especially during the first 3 months. A transthoracic echocardiogram and cardiac MRI (cMR) should be performed in patients suspected of ICI-induced cardiotoxicity, with cardiac biopsy reserved for cases with equivocal imaging findings or presentation. ICI therapy should be withheld in patients presenting with overt heart failure, significant myocardial injury with high levels of troponin, and those presenting with malignant arrhythmias such as heart block and ventricular tachyarrhythmias, according to the practice guideline for the management of ICI-associated myocarditis by the American Society of Clinical Oncology.[39]

Almost all patients (94%) will have increased serum troponin levels, which should immediately prompt suspicion of ICI-associated myocarditis. The ECG is frequently abnormal, ranging from nonspecific changes to ACSs in up to 89% of patients.[40] Echocardiography is useful for determining cardiac function, but the gold standard is cardiac magnetic resonance imaging (cMR). However, cMR changes demonstrating myocardial inflammation or necrosis through late gadolinium enhancement (LGE) may not be present in the early phases of immune mediated myocarditis. Registry data has shown that presence of LGE varied with the timing of cMR being present in only 21% patients if done before 4 days from admission and in up to 72% patients if performed after day 4 of admission for suspected immune mediated myocarditis.[41]

In symptomatic but clinically stable cases with abnormal tests, treatment should be initiated promptly with high dose prednisone or methylprednisolone. Decompensated cases require more aggressive and early immunosuppressive regimens, such as 2 mg/kg prednisone + mycophenolate, anti-thymocyte globulin, or infliximab (to be avoided in cases of heart failure); these cases may also require advanced heart failure support (Fig. 158.3).[42]

CAR-T Therapy

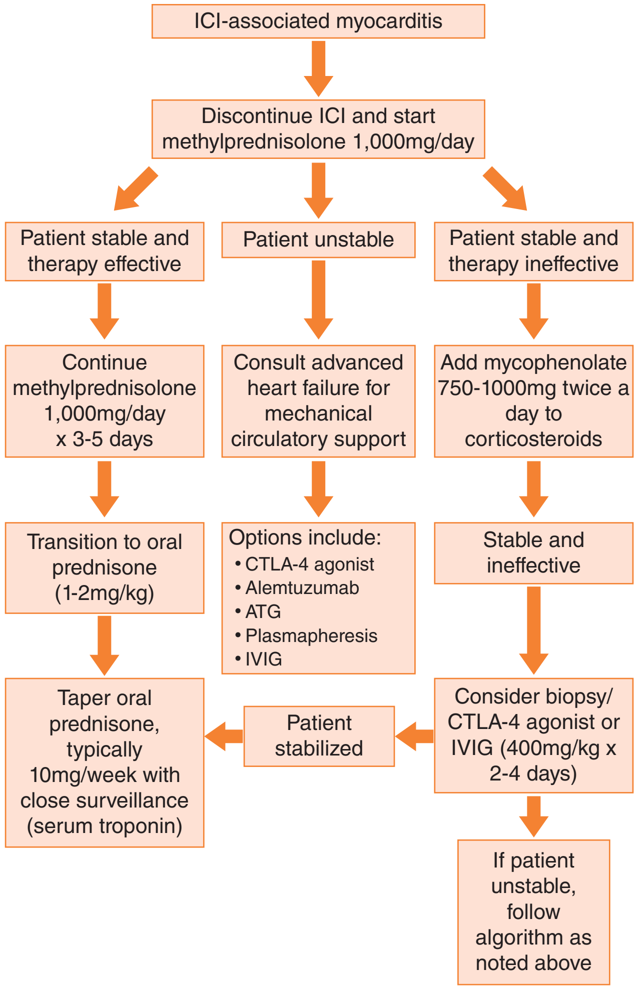
Oncological Indication

Chimeric antigen receptor T cells (CAR-T) are genetically engineered T cells that express artificial receptors that can bind to tumor associated antigens and augment T-cell-mediated killing of target cancer cells. CAR-T-cell therapies expressing CD19 receptors have shown remarkable early success in highly refractory and relapsing hematological malignancies such as ALL in children and young adults, large B-cell lymphoma, and multiple myeloma.[43]

Cardiac Toxicity

Cytokine release syndrome (CRS) is a frequent adverse effect of CAR-T-cell therapy, which may result in cardiotoxicity in the form of cardiomyopathy, heart failure, capillary leak syndrome, myocardial injury with troponin elevations and arrhythmias.[44]

Though CRS usually develops earlier in the course of CAR-T therapy (median time 2.2 days), the cardiomyopathy usually develops after a median duration of 12.5 days (2 to 24 days range). The reported incidence of cardiomyopathy has been variable in several retrospective studies but was as high as 10.3% in some studies where



ICI-associated myocarditis
Discontinue ICI and start methylprednisolone 1,000mg/day
Patient stable and therapy effective
Patient unstable
Patient stable and therapy ineffective
Continue methylprednisolone 1,000mg/day x 3-5 days
Consult advanced heart failure for mechanical circulatory support
Add mycophenolate 750-1000mg twice a day to corticosteroids
Transition to oral prednisone (1-2mg/kg)
Options include:
• CTLA-4 agonist
• Alemtuzumab
• ATG
• Plasmapheresis
• IVIG
Stable and ineffective
Taper oral prednisone, typically 10mg/week with close surveillance (serum troponin)
Patient stabilized
Consider biopsy/ CTLA-4 agonist or IVIG (400mg/kg x 2-4 days)
If patient unstable, follow algorithm as noted above

Figure 158.3 PROPOSED TREATMENT ALGORITHM FOR IMMUNE CHECKPOINT INHIBITOR-ASSOCIATED MYOCARDITIS. *(From Zhang L, Reynolds KL, Lyon AR, et al. The evolving immunotherapy landscape and the epidemiology, diagnosis, and management of cardiotoxicity: JACC: CardioOncology Primer. JACC CardioOncol. 2021;3(1):35–47.)*

serial echocardiograms were performed at baseline and after development of grade greater than 2 CRS.[45]

Mechanism of Cardiac Toxicity

The pathophysiology of cardiac dysfunction during CRS is unclear but is likely mediated by interleukin-6 (IL-6), which is known to cause myocardial depression in infectious and inflammatory states. The refractory hypotension and vascular leak syndrome seen in CRS could contribute to the LV dysfunction,[46–49] as could a non-specific stress induced or Takotsubo cardiomyopathy not directly caused by the CAR-T cells.[50] Another plausible theory is direct cardiotoxicity through an autoimmune cross-reactivity of CAR-T cells against Titin, a striated muscle protein.[51]

Prevention and Treatment

Prompt recognition of CRS is crucial since the vast majority of cardiotoxicity occurs in patients with grade 2 CRS. Patients should have a baseline echocardiogram prior to CAR-T and inflammatory markers such as IL-6, CRP, and ferritin should be routinely checked during CAR-T therapy. If grade greater than 2 CRS does occur, patients should have a repeat echocardiogram.

Supportive hemodynamic care with judicious use of intravenous fluids and vasopressors, targeted anti-IL-6 therapy, as well as possibly broader immunosuppression with corticosteroids, are the cornerstones of the management.

Anti IL-6 therapy with tocilizumab is first line therapy approved by FDA for management of CRS related toxicity, especially in the setting of hemodynamic compromise, unstable arrhythmias, myocardial damage with troponin elevation or new cardiomyopathy with LVEF less than 40%. Siltuximab is another monoclonal antibody that blocks IL-6 with a higher affinity, not yet FDA approved for CRS, but may be considered in patients not responding to tocilizumab and corticosteroids.[52]

Corticosteroids are also effective in the treatment of CRS. However, given concerns of reduced CAR-T cell efficacy with their use, though not yet proven, corticosteroids are considered a second-line therapy for the management of CRS refractory to tocilizumab. If neurotoxicity occurs as part of the CRS, dual antiplatelet therapy and anticoagulation should be held to avoid intracranial bleeding with a friable blood brain barrier, though there are no established guidelines regarding this.

CARDIOTOXICITY OF RADIATION TREATMENT

Radiotherapy used to treat carcinomas, especially thoracic cancers such as Hodgkin lymphoma or lung and breast cancer, carries a high risk of developing cardiovascular side effects. Major cardiac side effects include pericarditis, coronary artery diseases, cardiomyopathy, valvular dysfunction, and heart failure (Table 158.2).

In general, radiation-related cardiovascular disease is a chronic concern, with a median time to diagnosis of 19 years (10 to 40 years range). The heart is affected by radiation in a dose-dependent manner. Cardiomyocyte toxicity and cardiomyopathy are most common in radiation doses greater than 30 Gy. However, damaging effects can also be seen even after using doses as low as 2 Gy.

Risk factors associated with radiation-induced heart disease include an earlier age of treatment (such as young children with mediastinal Hodgkin lymphoma), concomitant therapy with trastuzumab (which binds to the extracellular segment of the HER2/neu receptor) or anthracyclines, irradiation of the left side of the heart, prior coronary artery disease or other heart diseases, or the presence of other cardiovascular risk factors.

Radiation-induced cardiac (RIC) effects are mediated primarily by the generation of free radicals, pro-inflammatory cytokines that cause DNA strand disruption, resulting in a spectrum of structural changes in the heart; these include pericardial inflammation, chronic development of fibrosis in the myocardium, valvular heart diseases, fibrosis of conduction system, and endothelial damage in the coronary vessels. This eventually leads to clinical manifestations such as constrictive pericarditis, pericardial effusion, restrictive cardiomyopathy, valvular stenosis and regurgitation, and accelerated coronary atherosclerosis.

Pericardial manifestations occur the earliest in 8% to 30% of patients, radiation-induced coronary vasculopathy occurs in up to 85% of patients typically affecting the ostia or proximal segments of the coronary arteries, and valvular disease occurs in 7% to 39% of patients at 10 years and 12% to 60% of patients at 20 years, with mitral and aortic valves the most affected.[53]

Prevention of cardiac damage during radiation therapy involves minimizing the radiation dose given, use of charged-particle (e.g., proton or carbon ion) therapy, and prior CT-guided field planning to minimize cardiac involvement. The use of prone patient position, breast boards, and having the patient hold a deep breath to decrease the involvement of the anterior heart have also been suggested to minimize cardiac damage.

To date, no treatment is available to reverse or treat the effects of RIC. The focus of treatment paradigms has been to optimize medical management of other cardiac risk factors, such as hypertension and diabetes, and prevent disease through education toward a smoke-free

TABLE 158.2 **RACD Is a Spectrum of Deleterious Effects, Ranging From Preclinical Findings to Symptomatic Clinical Disease**

Component of the Heart	Effects of Radiation Therapy	Examples of Clinical Sequelae
Myocardium	Myocardial edema, myocardial inflammation, myocardial fibrosis	Cardiomyopathy, systolic dysfunction, diastolic dysfunction, congestive heart failure
Heart valves	Valvular, subvalvular, annular, and aortic-mitral curtain thickening and/or calcification restricted leaflet mobility, reduced size of valve orifice	Valve regurgitation, valve stenosis, volume, or pressure overload
Pericardium	Pericardial thickening, pericardial calcification, pericardial constriction	Pericarditis (acute or chronic), pericardial effusion, chronic pericardial disease, cardiac tamponade
Coronary arteries	Myofibroblast replacement and enhanced platelet deposition, plaque rupture	Coronary artery disease, accelerated atherosclerosis, coronary stenosis, angina pectoris, ischemic heart disease, myocardial infarction, resting and inducible regional wall abnormalities
Vascular	Narrowing of capillary lumens, thrombosis rupture of vessel walls, damage to endothelial cell membranes, reduced capillary density	Reduced collateral flow, reduced vascular reserve, microvascular disease, myocardial infarction, systemic embolization
Conduction system	Fibrosis of conduction pathways, compression from adjacent calcification	Conduction defects including arrhythmias, heart block, and sick sinus syndrome; autonomic dysfunction

and heart-healthy lifestyle. Smoking cessation and counseling have played critical roles in reducing risk. It is also important to identify prior risk factors of heart disease in cancer patients before administering thoracic radiation therapy. This intervention includes smoking cessation and treatment of hypertension, hyperlipidemia, and diabetes.[54]

CARDIAC CONSIDERATIONS DURING HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation (HSCT) is a potential cure for various hematologic malignancies with the number of survivors having undergone HSCT projected to reach 500,000 patients by the year 2030. It involves administration of myelosuppressive chemotherapy with or without total body irradiation (TBI) followed by infusion of a hematopoietic stem cell graft that induces immunologic response on malignant cells. The preparative regimen and the immune response are the major sources of treatment-related toxicity.[55]

Cardiovascular disease and cardiovascular complications are one of the most common complications associated with HSCT, reported in 0.9% to 43% of patients. These complications can occur acutely within the first 100 days or several years after the initial transplantation period. These cardiotoxicities include cardiomyopathy, arrhythmias, ischemic events, CHF, pericarditis, tamponade, and cardiac arrest. Many factors, including cyclophosphamide, anthracyclines, TBI, prior mediastinal radiotherapy, and transfusion-associated iron overload, increase the risk of post-HSCT cardiac complications.

Acute Cardiac Complications

Studies have shown that the overall incidence of acute cardiotoxicity during HCT is moderate (0.9% to 8.9% range) depending on the study.

A median of 5.2% (4% to 9.4% range) of persons receiving HSCT develop arrhythmias, including AF, atrial flutter, and supraventricular tachycardia. Risk factors are advanced age, obesity, prior anthracycline use, lower ejection fraction at baseline, prior history of arrhythmias (especially AF), renal dysfunction, chronic CAD, and acute weight gain of greater than 7% over baseline due to fluid overload during HSCT. Ventricular arrhythmias are rare, occurring in less than 1% of recipients. Developing post-transplant arrhythmias is also predictive of longer periods of hospitalization, increased likelihood of needing intensive care, and an increased risk of death (OR 3.5) at 1-year post-transplant.[56]

Other cardiac complications include congestive heart failure. Most preparative regimens for allogeneic HSCT use cyclophosphamide (CY). High-dose CY can induce myocardial necrosis which clinically presents with dyspnea, tachycardia, hypotension, decreased QRS voltage on electrocardiogram, and pericardial effusion within 10 days of drug administration. The histology shows a unique pattern of fibrin microthrombi in capillaries, fibrin strands in the interstitium, and fibrin strands in myocytes with higher rates of heart failure in those receiving doses $\geq 170\ \mathrm{mg/m^2}$. However, with reduced CY dose employed in contemporary regimens, heart failure appears less frequent (<2%).

Reduced intensity conditioning (RIC) regimens that spare some of the toxicity of a myeloablative preparative regimen have been developed in recent years. Melphalan and fludarabine are agents used in some RIC regimens and have been reported to cause cardiovascular complications. Melphalan has been associated with AF, atrial flutter, and supraventricular tachycardia in up to 9% of cases. The combination of melphalan and fludarabine has been reported in some case series to cause heart failure ranging in severity from minor and reversible systolic dysfunction to fatal heart failure.

The development of RIC made HSCT a treatment option for patients with comorbidities and who are older. Now patients with a cardiac comorbidity, defined as the presence of coronary artery disease, congestive heart failure, myocardial infarction, or an ejection fraction greater than 50% are considered as having a low-risk comorbidity. Furthermore, recent data suggests that those patients with an ejection fraction less than 50% are still eligible for HSCT and patients with borderline left ventricular systolic dysfunction can safely undergo HSCT without alterations in overall survival or treatment-related complications.[57]

Long-Term Cardiac Complications

Individuals who survive the first 100 days following HSCT remain at an increased risk for cardiovascular complications many years after transplantation. Ten-year cumulative incidence of hypertension is 37.7%, diabetes (18.1%), hyperlipidemia (46.7%), and having more than one of these cardiac risk factors at 31.4%. Most of these risk factors are seen in allogeneic HSCT survivors with the risk being highest in older and obese patients and those with a history of acute graft-versus-host disease. The risk of cardiovascular anthracycline-induced cardiomyopathy complications in autologous HSCT survivors, however, also remains of concern with the cumulative incidence of HF at 4.8% 5 years after HSCT and increasing to 9.1% at 15 years. Overall, this cardiovascular risk is 4.5-fold higher than that seen in the general population. Prior anthracycline use and chest radiation also increases this risk.[58]

Evaluation of cardiac systolic function by multiple gated acquisition scan (MUGA), echocardiogram, or cMR is a recommended part of a pre-transplantation evaluation. Attention to any signs of left ventricular dysfunction or premature supraventricular complexes on screening electrocardiogram should be reviewed carefully; consideration of preventative therapy with beta-blockers and angiotensin-converting enzyme (ACE) inhibitors should be considered in this population, given their higher risk for arrhythmias during transplantation. Referral to a cardio-oncology clinic, for those with any cardiovascular risk factors or prior cardiac disease or arrhythmias, is recommended.

Preventive and therapeutic strategies for cardiovascular complications in the HSCT population are poorly studied. To our knowledge there has only been one randomized controlled trial (OVERCOME trial) evaluating the benefit of cardioprotective strategies in patients undergoing HCT; however, this study only looked at autologous HCT patients with a short-term follow-up of 6 months. This study reported that ACE inhibitors and beta-blockers might prevent against LVEF reduction in patients with hematologic malignancies receiving intensive chemotherapy.[59]

Lifestyle modifications should be encouraged in patients who are undergoing HSCT, including abstinence from tobacco use, low fat diet, regular exercise, control of diabetes, baseline testing of lipids, electrocardiogram screening, and imaging with transthoracic echocardiography.

CONCLUSION

Contemporary anticancer therapies, particularly stem cell transplantation and immunotherapy, including ICI and chimeric antigen receptor (CAR) T-cell therapy, have changed the landscape of treatment for patients with hematological malignancies. However, each of these emerging interventions along with traditional chemotherapeutics, including anthracyclines and the spectrum of tyrosine kinase inhibitors, are associated with serious cardiovascular-adverse effects. The prevention and treatment of cardiotoxicities resulting from each of these therapies is variable, and studies validating these are still lacking robust data. Regardless, the identification of high-risk patients with preexisting cardiovascular risk factors and disease is important, and pre-treatment control of these risk factors and emerging imaging and biomarker modalities are the cornerstone of reduction of cardiac complications of hematological treatments.

CHAPTER 159

RESOURCES FOR THE HEMATOLOGIST: INTERPRETIVE COMMENTS AND SELECTED REFERENCE VALUES FOR NEONATAL, PEDIATRIC, AND ADULT POPULATIONS

Andrea N. Marcogliese and Lisa Hensch[a]

APPENDIX CONTENTS

Red Blood Cell Testing

- Estimated Blood Volumes (Plasma Volume and Red Blood Cell Mass)
- Complete Blood Count (Red Blood Cell) Parameters
- Red Blood Cell Distribution Width
- Reticulocyte Count (Absolute and Percentage)
- Immature Reticulocyte Fraction
- Reticulocyte Hemoglobin Equivalent
- Haptoglobin
- Plasma Hemoglobin
- Hemoglobin F and Hemoglobin A2
- Sickle Cell Screen (Hemoglobin S Solubility Test)
- Ferritin
- Total Iron-Binding Capacity, Transferrin Saturation
- Iron
- Erythropoietin
- Folate (RBC or Serum/Plasma)
- Vitamin B_{12} (Cobalamin)
- Homocysteine
- Methylmalonic Acid
- Osmotic Fragility
- Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants

White Blood Cell and Immunologic Testing

- Leukocyte Counts (Absolute and Percentage)
- Lymphocyte Subsets
- Immunoglobulin A
- Immunoglobulin E
- Immunoglobulin G
- Immunoglobulin G Subclasses
- Immunoglobulin M
- Immunoglobulin Light Chains
- Complement Fractions C3 and C4

Platelet and Coagulation Testing

- Platelet Count and Mean Platelet Volume
- Immature Platelet Fraction
- Prothrombin Time/International Normalized Ratio (PT/INR)
- Activated Partial Thromboplastin Time (aPTT)
- Fibrinogen
- Mixing Studies
- Lupus Anticoagulant
- Coagulation Factor Levels (II, V, VII, VIII, IX, X, XI, XII, Contact Pathway Factors)
- Bethesda Assay/Nijmegen-Bethesda Assay
- von Willebrand Antigen/Activity
- Natural Anticoagulants (Antithrombin, Protein C, Protein S, Tissue Factor Pathway Inhibitor)
- D-dimer
- Anti-Xa Assay
- PFA-100
- Platelet Aggregometry

This appendix is intended to provide useful supplemental information to clinicians in selecting, obtaining, and interpreting certain key laboratory tests relevant to hematology. Reference values are given in Tables and interpretive comments appear in associated Boxes. The most appropriate reference range for a particular test is dependent on the specific testing methods employed (including reagents and instrumentation), patient age and gender, testing conditions, preanalytical variables, and other concurrent medical conditions and is determined and validated by the laboratory performing the test. The listed reference ranges thus provide only a rough guide to differentiating normal from abnormal results. Clinicians are encouraged to seek out the most applicable and appropriate reference range for a particular test, preferably using reference data that are specific to the performing laboratory and the patient population being tested. Although the tables herein provide some age-specific information, caution is particularly emphasized in interpreting results obtained from testing infants and children.

RED BLOOD CELL TESTING

Estimated Blood Volumes (Includes Plasma Volume, Red Blood Cell Mass)

The red cell volume, plasma volume, and total blood volume are calculated from hematocrit (packed cell volume) and isotope dilution after reinjection of red cells labeled with a radioactive isotope. Performance of a red cell mass determination is occasionally indicated in the investigation of polycythemia to differentiate primary or secondary polycythemia (elevated red cell mass) from relative polycythemia (normal red cell mass). Table 159.1 provides typical reference ranges.

Total blood volume can be roughly estimated using the following:
Preterm Neonates: 100 mL/kg
Term Neonates: 85 mL/kg
Infants: 80 mL/kg
Adults: 70 mL/kg

Total blood volume can also be estimated by calculation[b]:
Total Blood Volume for Males = $[0.3669 \times (\text{Height in Meters})^3] + [0.03219 \times (\text{Weight in Kilograms})] + 0.6041$;
Total Blood Volume for Females = $[0.3561 \times (\text{Height in Meters})^3] + [0.03308 \times (\text{Weight in Kilograms})] + 0.1833$.

---

TABLE 159.1 Estimated Blood Volumes

			Total Blood Volume (mL/kg)	
Age	**Plasma Volume (mL/kg)**	**Red Blood Cell Mass[a] (mL/kg)**	**From Plasma Volume**	**From Red Blood Cell Mass**
Newborn	41.3 M 46.0 F	43.1 M	82.1 M 78.0 F	86.1M 84.7 F
1–7 days	51–54	37.9	82–86	77.8
1–12 months	46.1	25.5	78.1	72.8
1–3 years	44.4 M 47.2 F	24.9	73.8 M 81.8 F	69.1
4–6 years	48.5 M 49.6 F	25.5	80.0 M 85.6 F	67.5
7–9 years	52.2 M 49.0 F	24.3	87.6 M 86.1 F	67.5
10–12 years M	51.9 M 46.2 F	26.3	87.6 M 83.2 F	67.4
13–15 years	51.2		88.3	
16–18 years	50.1		90.2	
Adults	39–50	20–35	68–88	55–75

[a] Red cell volume is approximately 5 mL/kg less in females compared with males. Increases in plasma volume, red cell volume, and overall blood volume are seen in residents living at high altitude compared to those living at sea level. Red cell volume may be increased up to 80% in residents living at high altitudes (4500 meters) compared to those living at sea level.*

COMPLETE BLOOD COUNT (RED BLOOD CELL) PARAMETERS

Summary points	• Used to identify anemia or polycythemia (RBC count, hemoglobin, hematocrit) • RBC indices (MCV, MCH, MCHC, RDW) can characterize anemia according to RBC size and degrees of hemoglobinization and anisopoikilocytosis
Methodology	Automated hematology analyzer—flow cytometric or impedance methods
Specimen requirements	Whole blood: EDTA
Indications	Evaluation of anemia or polycythemia
Reference range	Tables 159.2, 159.2A and 159.2B

Interpretation	• Anemia (low hemoglobin, hematocrit, RBC count)
	  • Microcytic, hypochromic: iron deficiency (often with high RDW), thalassemia (typically normal RDW but can be high, high RBC count), sideroblastic anemia (may be dimorphic RBCs on peripheral smear), some cases of anemia of chronic disease, hyperthyroidism
	  • Normocytic, normochromic: aplastic anemia, anemia of chronic disease, renal disease, hemolysis, bone marrow infiltration, drugs, lead poisoning, myelodysplastic syndrome
	  • Macrocytic: vitamin B_{12} or folate deficiency, liver disease, antimetabolite drugs, inherited bone marrow failure, some cases of aplastic anemia, myelodysplastic syndrome, hemolysis with high reticulocyte count, hypothyroidism, alcohol
	• Polycythemia (high hemoglobin, hematocrit)
	  • Primary: polycythemia vera, altered erythropoietin receptor
	  • Secondary: pulmonary disease, high-affinity hemoglobin, tumor related

Related tests	• Peripheral smear review, reticulocyte count, bone marrow aspiration/biopsy, tests of renal and hepatic function, hemoglobin fractionation/electrophoresis • Microcytic, hypochromic anemias: iron studies, lead level (children), hemoglobin fractionation/electrophoresis • Macrocytic anemias: vitamin B_{12}, folate, homocysteine, methylmalonic acid • Normocytic anemias: markers of hemolysis (reticulocyte count, haptoglobin, indirect bilirubin, LDH) • Polycythemia: family history, *JAK2* mutation testing, erythropoietin level
Interfering substances	Clotted or hemolyzed sample, cold agglutinin, lipemia, marked turbidity

EDTA, Ethylenediaminetetraacetic acid; *LDH*, lactate dehydrogenase; *MCH*, mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *RBC*, red blood cell; *RDW*, red blood cell distribution width.

TABLE 159.2 Reference Hematologic Values in Children and Adults

	Hemoglobin (g/dL)		Hematocrit (%)		Red Blood Cell Count (10^{12}/L)		MCV (fL)		MCH (pg)		MCHC (g/dL)	
Age	**Mean**	**−2 SD**	**Mean**	**−2 SD**	**Mean**	**−2 SD**	**Mean**	**−2 SD**	**Mean**	**−2 SD**	**Mean**	**−2 SD**
Birth (cord blood)	16.5	13.5	51	42	4.7	3.9	108	98	34	31	33	30
1–3 days (capillary)	18.5	14.5	56	45	5.3	4.0	108	95	34	31	33	29
1 weeks	17.5	13.5	54	42	5.1	3.9	107	88	34	28	33	28
2 weeks	16.5	12.5	51	39	4.9	3.6	105	86	34	28	33	28
1 months	14.0	10.0	43	31	4.2	3.0	104	85	34	28	33	29
2 months	11.5	9.0	35	28	3.8	2.7	96	77	30	26	33	29
3–6 months	11.5	9.5	35	29	3.8	3.1	91	74	30	25	33	30
0.5–2 years	12.0	10.5	36	33	4.5	3.7	78	70	27	23	33	30
2–6 years	12.5	11.5	37	34	4.6	3.9	81	75	27	24	34	31
6–12 years	13.5	11.5	40	35	4.6	4.0	86	77	29	25	34	31
12–18 years												
Female	14.0	12.0	41	36	4.6	4.1	90	78	30	25	34	31
Male	14.5	13.0	43	37	4.9	4.5	88	78	30	25	34	31
18–49 years												
Female	14.0	12.0	41	36	4.6	4.0	90	80	30	26	34	31
Male	15.5	13.5	47	41	5.2	4.5	90	80	30	26	34	31

These data have been compiled from several sources. Emphasis is given to studies employing electronic counters and to the selection of populations that are likely to exclude individuals with iron deficiency. The mean ±2 SDs can be expected to include 95% of the observations in a normal population. Note: Values for RBC, Hemoglobin, and Hematocrit are increased in residents living at higher altitudes. Values for hemoglobin are 11% higher for residents living at high altitudes, with corresponding increases in RBC and Hematocrit.*

MCH, Mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *SD*, standard deviation.

m, Hemoglobin was measured using a HemoCue H6201 DM Analyzer.

Data adapted from Ocas-Córdova S, Tapia V, Gonzales GF. Hemoglobin concentration in children at different altitudes in Peru: proposal for [Hb] correction for altitude to diagnose anemia and polycythemia. *High Alt Med Biol.* 2018;19(4):398–403

TABLE 159.2B Reference Hemoglobin and Hematocrit Values in Adults at High Altitude (4000 meters)

	Male	**Female**
Hemoglobin (g/dL)	13–21	12–19
Hematocrit (%)	45–61	41–56

Data from Vásquez R, Villena M. Normal hematological values for healthy persons living at 4000 meters in Bolivia. *High Alt Med Biol.* 2001;2(3):361–367

RED BLOOD CELL DISTRIBUTION WIDTH

Summary points	• Measures variability of red blood cell size (anisocytosis) • Reported as either CV, SD, or both
Methodology	Automated hematology analyzer
Specimen requirements	Whole blood: EDTA
Indications	Evaluation of anemia
Reference range	RDW-CV: 11%–15% (based on adults)[a]

Interpretation	• Elevated with increased variability in red blood cell size and shape; normal with more uniform, red blood cell size
	• Hypochromic microcytic anemia
	  • Usually elevated with iron deficiency, hereditary sideroblastic anemia, thalassemia intermedia and major, and red blood cell fragmentation
	  • Normal with anemia of chronic disease and thalassemia minor
	• Normocytic or macrocytic anemia
	  • Usually elevated in folate or vitamin B_{12} deficiency, mixed iron and folate or vitamin B_{12} deficiency, some hemoglobinopathies, myelofibrosis, acquired sideroblastic anemia, immune hemolytic anemia, and cold agglutinins
	  • Usually normal in anemia of chronic disease, some hemoglobinopathies, hemorrhage, hereditary spherocytosis, and bone marrow failure
	• RDW-CV = (SD of red cell volume/MCV)(100) reported more commonly than the RDW-SD
	• RDW-SD is less influenced by MCV and may be a more accurate assessment of variability in red blood cell size
	• Reference range will vary with the instrument used—check with laboratory

Related tests	• RBC, Hgb, Hct, MCV, MCH, MCHC, peripheral blood smear
Interfering substances	• Hemolyzed or clotted specimen
References	• Briggs C. Quality counts: new parameters in blood cell counting. *Int J Lab Hematol*. 2009;31:277. • [a]Evans TC, Jehle D. The red blood cell distribution width. *J Emerg Med*. 1991;9:71.

CV, Coefficient of variation; *EDTA*, ethylenediaminetetraacetic acid; *Hgb*, hemoglobin; *Hct*, hematocrit; *MCH*, mean corpuscular hemoglobin; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *RBC*, red blood cell count; *RDW*, red blood cell distribution width; *SD*, standard deviation.

RETICULOCYTE COUNT (ABSOLUTE AND PERCENTAGE)

Summary points	• Used to assess erythroid production • In the setting of anemia, can aid in distinguishing between destructive process (hemolysis) and marrow production problem
Methodology	Automated hematology analyzer, flow cytometry
Specimen requirements	Whole blood: EDTA
Indications	Differential diagnosis of anemia (destruction versus marrow production problem); evaluate marrow response to anemia; monitor response to therapy (treatment of nutritional anemias, post immunosuppressive therapy for aplastic anemia, post growth factor therapy, post chemotherapy, or bone marrow transplant)
Reference range	Table 159.3
Interpretation	• Elevated with marrow response to anemia, implying decreased RBC life span (hemolysis), marrow recovery (post injury, chemotherapy, or bone marrow transplant), or response to treatment (immunosuppressive therapy in aplastic anemia, nutritional replacement in iron, B_{12}, or folate deficiency) • Decreased (or inadequately elevated) in nutritional anemias, marrow suppression (infections, toxic exposures, malignancy), marrow failure • Corrected reticulocyte count (absolute reticulocyte count/reticulocyte maturation time) and RPI [reticulocyte percentage × (hematocrit/45) × (1/reticulocyte maturation time)] adjust for the degree of anemia and account for reticulocyte maturation time in assessing the appropriateness of the marrow responseAbsolute count is more meaningful than the percentage in some settings (aplastic anemia)
Related tests	Complete blood count, reticulocyte hemoglobin, immature reticulocyte fraction, mean reticulocyte volume, corrected reticulocyte count, RPI, direct antiglobulin test, markers of hemolysis
Interfering substances	Clotted or hemolyzed sample

EDTA, Ethylenediaminetetraacetic acid; *RBC*, red blood cell; *RPI*, reticulocyte production index.

TABLE 159.3 Reticulocyte Counts in Infants and Children by Flow Cytometry

Age	Number	Percentage	Absolute Count (10^9/L)
0–14 days[a]	21	5.33 + 1.99	318.44 + 50.04
		(1.61/8.28)	(238.9/404.1)
14 days–1 year[a]	32	2.03 + 0.52	89.00 + 22.94
		(1.09/3.00)	(45.8/137.8)
1–3 years[a]	63	2.01 + 0.72	88.38 + 20.49
		(1.11/5.00)	(50.2/141.0)
3–8 years[a]	60	2.19 + 0.66	98.83 + 27.97
		(0.95/4.03)	(45.4/163.1)
8–12 years[a]	18	2.07 + 0.78	90.20 + 27.16
		(1.18/3.78)	(54.8/154.4)
12–adult[a]	14	2.25 + 0.99	91.62 + 24.80
		(1.32/4.91)	(58.6/146.2)
Age	**Number**	**Percentage**	**Absolute Count (10^4/µL)**
Term newborns[b]	150	2.44 + 1.15	7.42 + 2.50
		(1.1/5.5)	(4.9/15.0)
Preterm newborns[b]	30	2.55 + 1.01	7.18 + 2.88
		(0.9/6.5)	(4.0/17.1)
1 week–16 years[b]	750	1.16 + 0.39	5.87 + 1.23
		(0.6/1.9)	(5.0/6.5)

Note: Flow cytometry may yield results 0.5%–1.0% higher than microscopy following supravital staining.

[a] Data from 188 pediatric outpatients (0–18 years of age) for whom all hematologic parameters are within age-appropriate reference ranges. Unpublished data from Lucile Packard Children's Hospital at Stanford. Analysis was performed on the Becton Dickinson FACSCalibur flow cytometer. Results are expressed as mean +1 SD (min/max).

[b] Data from Herkner KR, Bock A, Muhl A, et al. Reticulocyte counting and maturity grading in pediatrics using the Sysmex R-1000 automated reticulocyte analyzer. *Sysmex Int J.* 1992;2:4.

IMMATURE RETICULOCYTE FRACTION

Summary points	• Indicator of marrow response to anemia • May be useful to follow engraftment after bone marrow transplant
Methodology	Automated hematology analyzer—flow cytometric method
Specimen requirements	Whole blood: EDTA
Indications	Suspected anemia, differential diagnosis of anemia, assess marrow response to anemia, after marrow injury, chemotherapy, growth factor treatment, or bone marrow transplant
Reference range	Table 159.4
Interpretation	• Decreased in marrow failure or suppression states, increased with marrow response to anemia • Increased levels after bone marrow transplant appear to correlate with engraftment and precede other cell counts
Related tests	Complete blood count, reticulocyte count, reticulocyte hemoglobin, mean corpuscular volume reticulocyte
Interfering substances	Clotted or hemolyzed sample
Reference	Piva E, Brugnara C, Chiandetti L, et al. Automated reticulocyte counting: state of the art and clinical applications in the evaluation of erythropoiesis. *Clin Chem Lab Med.* 2010;48:1369.

EDTA, Ethylenediaminetetraacetic acid.

RETICULOCYTE HEMOGLOBIN EQUIVALENT (RET-HE)

Summary points	• May be useful in the early detection of iron deficiency • CHr is a similar but not identical parameter; whether Ret-He or CHr is reported depends on the hematology analyzer used Can be used to monitor response to therapy
Methodology	Automated hematology analyzer—flow cytometric method
Specimen requirements	Whole blood: EDTA
Indications	Suspected anemia, assessment of iron status, differential diagnosis of anemia, assess response to growth factor therapy
Reference range	Table 159.5
Interpretation	• Decreased in iron deficiency and may be decreased in thalassemia • Decreased levels in renal failure may suggest functional iron deficiency
Related tests	Complete blood count, reticulocyte count, immature reticulocyte fraction, mean corpuscular volume reticulocyte, iron studies
Interfering substances	Hemolyzed or clotted specimen

HAPTOGLOBIN

Summary points	• Binds free hemoglobin in plasma • Haptoglobin-hemoglobin complex removed by the reticuloendothelial system • Often used to evaluate for intravascular hemolysis but has low sensitivity and specificity • Acute-phase reactant
Methodology	Immunoassay
Specimen requirements	Lithium heparin, EDTA, or plain tube
Indications	Evaluation of hemolysis, especially intravascular
Reference range	Table 159.6
Interpretation	• Levels low in neonates and young infants, severe extravascular hemolysis, liver disease, massive tissue hemorrhage, and congenital deficiency states • High levels occur with pregnancy, steroids, estrogen, and acute-phase responses Preexisting high levels may mask hemolysis
Related tests	Plasma-free hemoglobin concentration, LDH, bilirubin, reticulocyte count
Interfering substances	Lipemia
Reference	Owen JA, Better FC, Hoban J. A simple method for the determination of serum haptoglobins. *J Clin Pathol*. 1960;13:163.

EDTA, Ethylenediaminetetraacetic acid; *LDH*, lactate dehydrogenase.

TABLE 159.6 Reference Values for Serum Haptoglobin by Age

Age	Hemoglobin-Binding Capacity (mg/dL)	
	Mean	Range (95%)
Cord blood	0	0
1–7 days	10	0–41
1–4 weeks	28	0–45
1–3 months	59	41–95
3–6 months	91	64–134
6–12 months	115	43–160
1–5 years	109	51–160
5–10 years	107	62–186
>10 years	110	41–165

PLASMA HEMOGLOBIN

Summary points	• Disruption of red cells will cause elevations in plasma hemoglobin • Useful to assess for intravascular hemolysis and for following patients on ECMO or with a VAD • Sensitive to traumatic blood draws and artifactual red cell disruption and may cause false positives • Also known as plasma-free hemoglobin
Methodology	Colorimetric or quantitative spectrophotometry
Specimen requirements	Whole blood: EDTA, heparin (sodium or lithium)
Indications	• Evaluation of hemolysis, especially acute intravascular (transfusion reactions, mechanical destruction of red cells) • Evaluation of patients on ECMO or VAD to assess pump function and disruption of red cells from the pump
Reference range	< 30 mg/dL (Institutional reference range may vary)
Interpretation	• Elevated with intravascular red cell destruction • Increasing levels over baseline for patients on ECMO or VAD may indicate a problem with pump function and may herald renal injury
Related tests	LDH, bilirubin, reticulocyte count, haptoglobin, creatinine
Interfering substances	• Lipemia, hyperbilirubinemia, other causes of turbidity • Artifactually hemolyzed specimen • Delay in the separation of plasma from red cells (> 2 h from specimen collection)

EDTA, Ethylenediaminetetraacetic acid; *LDH*, lactate dehydrogenase; *ECMO*, extracorporeal membrane oxygenation; *VAD*, ventricular assist device.

HEMOGLOBIN F AND HEMOGLOBIN A_2

Summary points	• Hemoglobin F is composed of two α and two γ chains—the dominant hemoglobin during gestation and early infancy • Hemoglobin A_2 is composed of two α and two δ chains—a normal minor hemoglobin in adulthood • Hemoglobin A_2 present at very low levels at birth, gradually increasing to adult levels over the first 1–2 years of life
Methodology	Gel electrophoresis, capillary electrophoresis, or high-performance liquid chromatography
Specimen requirements	Whole blood: EDTA
Indications	• Assess for β-thalassemia (including trait) or other hemoglobinopathy • Evaluate for bone marrow failure syndromes or juvenile myelomonocytic leukemia (elevated hemoglobin F); evaluate patients being treated with hydroxyurea for hemoglobin F response (e.g., sickle cell anemia)
Reference range	Tables 159.7 and 159.8
Interpretation	• Hemoglobin F is elevated in β-thalassemia, δβ-thalassemia, hereditary persistence of fetal hemoglobin, sickle cell anemia, other hemoglobin disorders, some bone marrow failure syndromes, and juvenile myelomonocytic leukemia • Hemoglobin A_2 is elevated in β-thalassemia, unstable β-chain variants, megaloblastic anemia, thyrotoxicosis • Hemoglobin A_2 is decreased in δβ-thalassemia and at times in iron deficiency, lead poisoning, anemia of chronic disease, sideroblastic anemia, and hypothyroidism • Infants with suspected β-thalassemia disorders may require repeat testing at 6 months to 1 year of age to reliably evaluate hemoglobin A_2 levels
Related tests	Complete blood count, peripheral smear review, isoelectric focusing, molecular diagnostic testing for β-chain mutations

EDTA, Ethylenediaminetetraacetic acid.

TABLE 159.7 Reference Values for Hemoglobin F and Hemoglobin A_2 in the First 2 Years of Life

SICKLE CELL SCREEN (HEMOGLOBIN S SOLUBILITY TEST)

Summary points	• Rapid test to evaluate for the presence of hemoglobin S >30% • Also known as a *sickle prep* or by the brand name of a commonly used test kit—*Sickledex*
Methodology	Differential solubility
Specimen requirements	Whole blood: EDTA, some laboratories accept heparin or ACD anticoagulants
Indications	Suspected hemoglobin S disorder
Reference range	Negative
Interpretation	• Positive when hemoglobin S >30%, negative when hemoglobin S <20% • Hemoglobin S between 20% and 30% may be positive or negative • False positive with cryoglobulinemia, multiple myeloma, dysglobulinemia, certain rare hemoglobinopathies (C Harlem or C Georgetown); false negative with severe anemia, high hemoglobin F, infants under 6 months • Recent transfusion may give false-positive or false-negative results • Does not distinguish between sickle cell trait and sickle cell disease or compound heterozygotes for hemoglobin S and another hemoglobinopathy • Positive results should be confirmed by another method
Related tests	Hemoglobin fractionation/electrophoresis
Interfering substances	Hemolyzed sample

FERRITIN

Summary points	• Ferritin concentration reflects body iron stores; decreased in iron deficiency, increased in iron overload • Useful in distinguishing between iron deficiency anemia and anemia of chronic disease, thalassemia minor • Assessment of iron deficiency may be confounded by infection, inflammation, malignancy, and liver disease, all of which raise ferritin concentration • More sensitive and reliable than serum iron, transferrin (total iron-binding capacity), and transferrin saturation for detecting iron deficiency • Is an acute-phase reactant
Methodology	Immunoassay
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency or iron overload
Reference range	Table 159.9
Interpretation	• Levels are age and gender dependent. Levels in adult females are generally lower than in adult males, but following menopause, the levels progressively approach those of males • Levels elevated with iron overload, Gaucher disease, acute hepatitis, malignancies, hemophagocytic lymphohistiocytosis, other highly inflammatory states
Related tests	Iron, transferrin (total iron-binding capacity), transferrin saturation, soluble transferrin receptor
Interfering substances	Anti-animal antigen antibodies

TABLE 159.9 Serum Ferritin in Children and Adults

Age- and sex-specific pediatric reference intervals and correlations for zinc, copper, selenium, iron, vitamins A and E, and related proteins. *Clin Chem.* 1988;34:1625. Study was based on healthy children; children with anemia, microcytosis, and thalassemia syndromes were excluded. Values represent the 0.025th–0.975th fractiles.

[d] No significant differences between males and females; range derived from combined data.

SOLUBLE TRANSFERRIN RECEPTOR

Summary points	• Transferrin receptor derived mainly from erythroid marrow cells • Reflects iron status independent of concurrent inflammation
Methodology	Immunoassay
Specimen requirements	Lithium heparin or plain tube
Indications	Assess for iron deficiency, especially in the setting of inflammation
Reference range	Table 159.10
Interpretation	• Levels decreased with erythroid hypoplasia states, increased with increased iron demand (erythroid hyperplasia [hemolysis, recent blood loss, thalassemia], iron deficiency) • Unaffected by inflammation or liver disease • African Americans and individuals at high altitude may have slightly higher values
Related tests	Iron, transferrin (total iron-binding capacity), transferrin saturation, ferritin
Interfering substances	Lipemia

TABLE 159.10 Soluble Transferrin Receptor Levels in Infants, Children, and Adults

Soluble Transferrin Receptor Levels in Infants and Children[a]

Age (Years)	Number	sTfR (mg/L)
0.05–0.5	13	1.26–3.17
0.5–1	17	1.12–2.91
1–1.5	16	1.37–2.52
1.5–2	20	1.33–2.93
2–3	46	0.98–2.91
3–4	38	1.08–2.55
4–6	76	1.10–2.74

12–18	85	0.91–1.91

Soluble Transferrin Receptor Levels in Adults[b]

Age (Years)	sTfR (mg/L)
13–17	1.75 ± 0.39
18–30	1.65 ± 0.34
31–40	1.60 ± 0.39
41–50	1.54 ± 0.39
51–65	1.59 ± 0.34

sTfR, Soluble transferrin receptor.
From Ooi CL, Lepage N, Nieuwenhuys E, et al. Pediatric reference intervals for soluble transferrin receptor and transferrin receptor-ferritin index. *World J Pediatr.* 2009;5:122.
SD, Standard deviation; *sTfR*, soluble transferrin receptor.
From von Schmiesing A, Schmidt SA, Kratzer W, et al. Determination of reference values for the soluble transferrin receptor (sTfR) on a cross sectional population sample. *Clin Lab.* 2009;55:193.
[a] Values are expressed in mg/L. Data were obtained from a total of 436 apparently healthy children. Values are 2.5th–97.5th percentiles.
[b] Values are expressed as means ± SD based on testing of 2050 adults (1060 males).

TOTAL IRON-BINDING CAPACITY, TRANSFERRIN SATURATION

Summary points	• Transferrin—the major iron transporter protein in plasma • TIBC—often measured as transferrin concentration, especially in pediatrics, because of the smaller specimen volume required for children • One molecule of transferrin can bind two molecules of iron • TIBC and transferrin concentration—typically elevated in iron deficiency due to increased transferrin gene expression • Transferrin saturation—calculated as serum iron concentration divided by the iron-binding capacity; low in iron deficiency, elevated in iron overload
Methodology	Immunoassay and calculation
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency, iron overload, and acute iron poisoning (transferrin saturation elevated in the latter)
Reference range	Table 159.11
Interpretation	• Pregnancy and oral contraceptives increase transferrin concentration, leading to low transferrin saturation • Acute-phase response can decrease transferrin and TIBC • Spuriously high TIBC can occur with acute hepatitis and after iron dextran injection
Related tests	Iron, ferritin, soluble transferrin receptor
Interfering substances	Lipemia

TIBC, Total iron-binding capacity.

TABLE 159.11 Serum Iron-Binding Capacity, Transferrin, and Transferrin Saturation Reference Values

Iron-Binding Capacity[a]

	Male Subjects		Female Subjects	
Age	**µg/dL**	**µmol/L**	**µg/dL**	**µmol/L**
1–30 days	94–232	16.8–41.5	94–236	16.8–42.2
31–182 days	116–322	20.8–57.6	89–311	15.9–55.7
182–365 days	176–384	31.5–68.7	138–365	24.7–65.3
1–3 years	204–382	36.5–68.3	184–377	32.9–67.5
4–6 years	180–390	32.2–69.8	162–352	29.0–63.0
7–9 years	183–369	32.8–66.1	167–336	29.9–60.1
10–12 years	173–356	31.0–63.7	198–383	35.4–68.6
13–15 years	193–377	34.5–67.5	169–358	30.3–64.1
16–18 years	174–351	31.1–62.8	194–372	34.7–66.6

Age	Male Subjects (g/L)	Female Subjects (g/L)
1–30 days	0.97–2.05	0.92–2.08
31–182 days	1.06–3.25	1.28–3.09
182–365 days	1.78–3.57	1.46–3.64
1–3 years	1.96–3.65	1.49–3.82
4–6 years	2.02–3.50	1.74–3.99
7–9 years	1.49–3.53	1.86–3.68
10–12 years	1.73–3.80	1.85–3.77
13–15 years	1.71–3.74	1.93–3.91
16–18 years	1.94–3.48	1.81–4.16

Transferrin Saturation[b,c,d]

Age	Male Subjects (ng/mL)	Female Subjects (ng/mL)
1–5 years	0.07–0.44	0.07–0.44
6–9 years	0.17–0.42	0.17–0.42
10–14 years	0.11–0.36	0.02–0.40
14–19 years	0.06–0.33	0.06–0.33

[a] From Soldin SJ, Brugnara C, Gunter KC, et al. *Pediatric Reference Ranges*. 2nd ed. Washington, DC: AACC Press; 1997:100, 101, 143.

[b] From Lockitch G, Halstead AC, Wadsworth L, et al. Age- and sex-specific pediatric reference intervals and correlations for zinc, copper, selenium, iron, vitamins A and E, and related proteins. *Clin Chem* 34:1625, 1988. Study was based on healthy children; children with anemia, microcytosis, and thalassemia syndromes were excluded. Values represent the 0.025th–0.975th fractiles.

[c] No significant differences between males and females; range derived from combined data.

[d] Transferrin saturation calculated from iron (µmol/L)/total iron-binding capacity. Transferrin, transferrin saturation, and total iron-binding capacity results may be misleading in patients receiving iron therapy. Note that the lower reference limits for serum iron and transferrin saturation in this study are below the limits used to define acceptable levels for nutritional health for these two analytes (see O'Neal RM, Johnson OC, Schaefer AE: Guidelines for classification and interpretation of group blood and urine data collected as part of the National Nutrition Survey. *Pediatr Res.* 1970;4:103).

IRON

Summary points	- Reflects recent iron ingestion and absorption - Undergoes circadian variation - Less reliable than ferritin for assessing iron deficiency
Methodology	Spectrophotometry
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency, iron overload, acute iron poisoning, iron absorption (iron challenge test)
Reference range	Table 159.12
Interpretation	- Acute-phase response, malignancy, and ascorbate deficiency can decrease iron concentration, whereas liver disease, ineffective erythropoiesis, and aplastic and sideroblastic anemias can increase it - For oral iron challenge testing, an increase of at least 100 μg/dL 1–4 h after ingestion of 65 mg elemental iron is thought to indicate adequate absorption
Related tests	Ferritin, transferrin (total iron-binding capacity), transferrin saturation, soluble transferrin receptor
Reference	Cook JD. Diagnosis and management of iron-deficiency anaemia. *Best Pract Res Clin Haematol.* 18:319, 2005.

TABLE 159.12 Serum Iron Reference Values

	Male Subjects		Female Subjects	
Age	**μg/dL**	**μmol/L**	**μg/dL**	**μmol/L**
1–30 days	32–112	5.7–20.0	29–127	5.2–22.7
31–365 days	27–109	4.8–19.5	25–126	4.5–22.6
1–3 years	29–91	5.2–16.3	25–101	4.5–18.1
4–6 years	25–115	4.5–20.6	28–93	5.0–16.7
7–9 years	27–96	4.8–17.2	30–104	5.4–18.6
10–12 years	28–112	5.0–20.0	32–104	5.7–18.6
13–15 years	26–110	4.7–19.7	30–109	5.4–19.5
16–18 years	27–138	4.8–24.7	33–102	5.9–18.3

From Soldin SJ, Brugnara C, Gunter KC, et al. *Pediatric Reference Ranges.* 2nd ed. Washington, DC: AACC Press; 1997:100, 101, 143.

ERYTHROPOIETIN

Summary points	- Glycoprotein hormone secreted mostly by the kidney but also by the liver - Level varies inversely with hematocrit, stimulated by hypoxia - May be secreted by certain tumors, leading to polycythemia - Results obtained with one method may differ significantly from those obtained with another—any serial testing over time should be performed using the same test method
Methodology	Immunoassay
Specimen requirements	Lithium heparin, EDTA, or plain tube
Indications	Can differentiate primary (decreased concentration) from secondary erythrocytosis (elevated), but testing may be problematic given the broad overlap between the two groups. Levels are usually increased in anemia except in chronic renal failure patients, in whom levels may be used to monitor erythropoietin therapy
Reference range	Adult values approximately 3–16 milli–International Unit/mL; Table 159.13
Interpretation	Normal or low levels with primary polycythemia; elevated levels with most forms of secondary polycythemia
Interfering substances	Lipemia
Reference	Cotes PM, Doré CJ, Yin JA, et al. Determination of serum immunoreactive erythropoietin in the investigation of erythrocytosis. *N Engl J Med.* 1986;315:283.

EDTA, Ethylenediaminetetraacetic acid.

TABLE 159.13 Erythropoietin Reference Values in Infants and Children

Serum Erythropoietin Levels in Term Infants During the First Year of Life[a]

Days After Birth	Erythropoietin (Milli–International Unit/mL)	Hemoglobin (g/dL)	RBC ($\times 10^6/\mu L$)
0–6	33.0 ± 31.4 (11)	15.6 ± 2.2 (11)	4.51 ± 0.74 (11)
7–50	11.7 ± 3.6 (7)	12.8 ± 1.1 (5)	3.92 ± 0.35 (5)
51–100	21.1 ± 5.5 (13)	11.4 ± 1.0 (10)	4.09 ± 0.51 (10)
101–150	15.1 ± 3.9 (5)	11.2 ± 1.1 (3)	4.21 ± 0.31 (3)
151–200	17.8 ± 6.3 (6)	–	–
>201	23.1 ± 9.7 (10)	11.8 ± 0.8 (9)	4.57 ± 0.24 (9)

Plasma Erythropoietin Reference Ranges in Children[b]

Age (Years)	Number	Male Subjects	Number	Female Subjects
1–3	122	1.7–17.9	97	2.1–15.9
4–6	89	3.5–21.9	76	2.9–8.5
7–9	79	1.0–13.5	80	2.1–8.2
10–12	98	1.0–14.0	90	1.1–9.1
13–15	100	2.2–14.4	148	3.8–20.5
16–18	66	1.5–15.2	77	2.0–14.2

[a] Values are expressed as means ± SD; parentheses enclose the number of specimens. Patients were not transfused and weighed 2500 g or more.

[b] Values are expressed in milli–International Unit/mL. Data were obtained from a total of 1122 hospitalized and outpatient children ages 1–18 years, using a commercially available enzyme-linked immunosorbent assay methodology. Values are 2.5th–97.5th percentiles.

FOLATE (RBC OR SERUM/PLASMA)

Summary points	• Folate—commonly assessed in the setting of macrocytic anemia along with vitamin B_{12} (should be done concurrently) • RBC folate less sensitive to short-term dietary changes than serum folate; more reflective of tissue folate stores, more specific for folate deficiency • Folate deficiency usually nutritional in origin or due to inadequate intake in the setting of increased demand (pregnancy, hemolytic anemias, liver disease)
Methodology	Immunoassay
Specimen requirements	RBC: whole blood: EDTA; protect from light for RBC Serum: plain or serum separator tube (fasting state preferred)
Indications	Macrocytic or megaloblastic anemia, workup of possible nutritional deficiencies or myelodysplastic syndrome, unexplained neurologic symptoms, or dementia
Reference range	Table 159.14

Interpretation	• Decreased in nutritional deficiencies (pregnancy, alcoholism, older adults), antimetabolite therapy (methotrexate, for example), rarely due to inherited metabolic disorders
	• May be decreased in vitamin B_{12} (cobalamin) deficiency
	• Additional testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients who have borderline levels of either
	  ◦ Homocysteine—elevated in both folate and vitamin B_{12} deficiency
	  ◦ MMA—elevated in vitamin B_{12} but not folate deficiency

Related tests	Vitamin B_{12}, homocysteine, MMA, complete blood count
Interfering substances	Excessive light exposure before testing, hemolysis, lipemia
Reference	Kaferle J, Strzoda CE. Evaluation of macrocytosis. *Am Fam Physician*. 2009;79:203.

EDTA, Ethylenediaminetetraacetic acid; *MMA*, methylmalonic acid; *RBC*, red blood cell.

TABLE 159.14 Folate Reference Values

RBC Folate Thresholds[a]		
<305 nmol/L (140 ng/mL)	Folate deficiency	
305–340 nmol/L	Subclinical deficiency (with elevated homocysteine)	
>900 nmol/L (400 ng/mL)	Reduced risk for neural tube defect in pregnancy	
Plasma Levels of Folic Acid in Children[b]		
Age	**Males (nmol/L)**	**Females (nmol/L)**
0–1 year	16.3–50.8	14.3–51.5
2–3 years	5.7–34.0	3.9–35.6
4–6 years	1.1–29.4	6.1–31.9
7–9 years	5.2–27.0	5.4–30.4
10–12 years	3.4–24.5	2.3–23.1
13–18 years	2.7–19.9	2.7–16.3

[a] Data from Green R. Indicators for assessing folate and vitamin B-12 status and for monitoring the efficacy of intervention strategies. *Am J Clin Nutr*. 2011;94:666S.
[b] From Hicks JM, Cook J, Godwin ID, et al. Vitamin B12 and folate. Pediatric reference ranges. *Arch Pathol Lab Med*. 1993;117:704. Data were collected from hospitalized patients; 2.5th–97.5th percentile values adapted from the Hoffman technique. Specimens from more than 100 patients in each age-group were analyzed by radioimmunoassay.

VITAMIN B_{12} (COBALAMIN)

Summary points	• Commonly assessed in the setting of macrocytic anemia along with folate (should be done concurrently to avoid undiagnosed vitamin B_{12} deficiency) • Deficiency often due to inadequate gastric absorption (pernicious anemia, gastric bypass) or lack of small bowel reabsorption (malabsorption, Crohn disease, small intestinal surgery) • Nutritional deficiency is uncommon, but strict vegans are at risk (vitamin B_{12} available only from animal sources); also seen in alcoholics, older adults, malnutrition • Elevated vitamin B_{12} may accompany severe disease states and warrants consideration of additional evaluation
Methodology	Immunoassay
Specimen requirements	Plain or serum separator tube
Indications	Macrocytic or megaloblastic anemia, pancytopenia, workup of possible nutritional deficiencies or myelodysplastic syndrome, unexplained neurologic symptoms or dementia, hypersegmented neutrophils on peripheral smear
Reference range	Table 159.15

Interpretation	• Low levels diagnostic of deficiency; pregnancy lowers vitamin B_{12} level
	• Follow-up testing for low levels to diagnose pernicious anemia: parietal cell antibodies, anti-intrinsic factor antibodies
	• Additional testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients with borderline levels of either
	  • Homocysteine—elevated in both folate and vitamin B_{12} deficiency
	  • MMA—elevated in vitamin B_{12} but not folate deficiency
	• High vitamin B_{12} may accompany solid neoplasms, hematologic malignancy, liver or kidney disease, functional B_{12} deficiency, and autoimmune lymphoproliferative syndrome

Related tests	Folate, homocysteine, MMA, complete blood count, parietal cell antibodies, anti-intrinsic factor antibodies, serum gastrin
Interfering substances	Excessive light exposure before testing, hemolyzed sample
References	Andrès E, Serraj K, Zhu J, et al. The pathophysiology of elevated vitamin B_{12} in clinical practice. *Q J Med*. 2013;106:505. Kaferle J, Strzoda CE. Evaluation of macrocytosis. *Am Fam Physician*. 2009;79:203.

MMA, Methylmalonic acid.

TABLE 159.15 Plasma Levels of Vitamin B_{12} in Children

Age	Males (pmol/L)	Females (pmol/L)
0–1 year	216–891	168–1117
2–3 years	195–897	307–892
4–6 years	181–795	231–1038
7–9 years	200–863	182–866
10–12 years	135–803	145–752
13–18 years	158–638	134–605

From Hicks JM, Cook J, Godwin ID, et al. Vitamin B12 and folate. Pediatric reference ranges. *Arch Pathol Lab Med*. 1993;117:704. Data were collected from hospitalized patients; 2.5th–97.5th percentile values adapted from the Hoffman technique. Specimens from more than 100 patients in each age-group were analyzed by radioimmunoassay.

HOMOCYSTEINE

Summary points	- Used in differentiating vitamin B_{12} from folate deficiency, evaluating hereditary metabolic disorders, and assessing cardiovascular risk
Methodology	Liquid chromatography—tandem mass spectrometry, stable isotope dilution analysis, quantitative enzymatic
Specimen requirements	Plain, EDTA, heparin, or serum separator tube (fasting state preferred)
Indications	Suspected B_{12} or folate deficiency with equivocal initial testing (folate, vitamin B_{12} level), disorder of methionine metabolism, assess cardiovascular or prothrombotic risk
Reference range	Table 159.16

Interpretation	- Testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients with borderline levels of either
	  - Homocysteine—elevated in both folate and vitamin B_{12} deficiency
	  - MMA—elevated in vitamin B_{12} but not folate deficiency
	- Levels decrease with vitamin supplementation
	- May be elevated due to age, medications, smoking, renal disease, poor nutrition, thyroid disease, MTHFR 677 C→T polymorphism
	- Serum/plasma should be separated quickly from red blood cells to prevent false elevations
	- Recent consumption of high-protein meal may falsely elevate the level

Related tests	Folate, vitamin B_{12}, MMA, complete blood count, methionine, plasma amino acids, urine organic acids
Reference	Refsum H, Smith AD, Ueland PM, et al. Facts and recommendations about total homocysteine determinations: an expert opinion. *Clin Chem*. 2004;50(1):3.

TABLE 159.16 **Homocysteine Reference Values in Infants and Children**

Age	Median (µmol/L)	Range (µmol/L)
Newborn[a]	5.2	0.8–10.9
4 days[b]	6.22	5.0–7.48
6 weeks–6 months[b]	7.47	6.1–9.22
1–10 years[b]	5.24	4.68–5.97
10.5–15 years[b]	6.52	5.7–7.75
15.5–19 years[b]	7.75	6.61–9.12

[a] Data from blood spots from 200 normal newborns using tandem mass spectrometry. Data from Turgeon CT, Magera MJ, Cuthbert CD, et al. Determination of total homocysteine, methylmalonic acid, and 2-methylcitric acid in dried blood spots by tandem mass spectrometry. *Clin Chem*. 2010;56:1686.
[b] Data from cross-sectional study of 700 children; range in interquartile. Data from Bjørke Monsen AL, Refsum H, Markestad T, et al. Cobalamin status and its biochemical markers methylmalonic acid and homocysteine in different age groups from 4 days to 19 years. *Clin Chem*. 2003;49:2067.

METHYLMALONIC ACID

Summary points	• Used in differentiating vitamin B_{12} from folate deficiency and evaluating hereditary metabolic disorders
Methodology	Liquid chromatography—tandem mass spectrometry
Specimen requirements	Plain, EDTA, heparin, or serum separator tube; urine levels may also be measured
Indications	Suspected vitamin B_{12} or folate deficiency with equivocal initial testing (folate, vitamin B_{12} level), metabolic disorder (methylmalonic acidemia)
Reference range	Table 159.17

Interpretation	• Testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B_{12} deficiency in patients with borderline levels of either
	  • Homocysteine—elevated in both folate and vitamin B_{12} deficiency
	  • MMA—elevated in vitamin B_{12} but not folate deficiency
	• Elevated in vitamin B_{12} deficiency, renal failure, thyroid disease, bacterial overgrowth of small bowel
	• Markedly elevated levels in a child suggest hereditary metabolic disorder but must be confirmed

Related tests	Folate, vitamin B_{12}, homocysteine, complete blood count
Interfering substances	Hemolyzed sample, lipemia

EDTA, Ethylenediaminetetraacetic acid; *MMA*, methylmalonic acid.

TABLE 159.17 Reference Values for Methylmalonic Acid

Age	Median (Range) µmol/L

4 days[b]	0.29 (0.24–0.39)
6 weeks–6 months[b]	0.78 (0.36–1.51)
1–10 years[b]	0.13 (0.11–0.17)
10.5–15 years[b]	0.17 (0.13–0.22)
15.5–19 years[b]	0.14 (0.12–0.18)
Adult[c]	<0.4

[a] Data from blood spots from 200 normal newborns using tandem mass spectrometry, median value, and range given. Data from Turgeon CT, Magera MJ, Cuthbert CD, et al. Determination of total homocysteine, methylmalonic acid, and 2-methylcitric acid in dried blood spots by tandem mass spectrometry. *Clin Chem*. 2010;56:1686.

[b] Data from cross-sectional study of 700 children; range in interquartile. Data from Bjørke Monsen AL, Refsum H, Markestad T, et al. Cobalamin status and its biochemical markers methylmalonic acid and homocysteine in different age groups from 4 days to 19 years. *Clin Chem*. 2003;49:2067.

[c] Data from Bjørke Monsen AL, Ueland PM. Homocysteine and methylmalonic acid in diagnosis and risk assessment from infancy to adolescence. *Am J Clin Nutr*. 2003;78:7.

OSMOTIC FRAGILITY

Summary points	• Used in the differential diagnosis of hemolytic anemia • Usually increased osmotic fragility with hereditary spherocytosis • Increased osmotic fragility can be seen in other conditions with increased spherocytes and other hematologic disorders
Methodology	Lysis of erythrocytes in a gradient of hypoosmolar solutions; degree of hemolysis commonly measured by spectrophotometry
Specimen requirements	Whole blood: EDTA or heparin
Indications	Hemolytic anemia, suspected hereditary spherocytosis
Reference range	Normal curves generated by individual laboratories; patient results are plotted against a normal curve
Interpretation	• Patients with hereditary spherocytosis will show increased lysis of red blood cells in hypoosmolar solutions compared with normal controls • Increased osmotic fragility also seen in other causes of spherocytosis (autoimmune hemolytic anemia, posttransfusion), other hematologic disorders (pyruvate kinase deficiency, G6PD deficiency, hereditary stomatocytosis, hereditary pyropoikilocytosis), Rh-null phenotype • Decreased osmotic fragility seen in sickle cell disease, thalassemia, iron deficiency • Normal test does not exclude hereditary spherocytosis (the most fragile cells may have already lysed)—repeat testing at a time when the patient is at baseline state and hematologically stable may be useful as may perform the test with incubation overnight (increases sensitivity) • Measurements taken either immediately or after incubation for 24 h at 37°C enhance assay sensitivity • Results may vary depending on patient age, gender, medication history, and presence or absence of active hemolysis • Flow cytometry for band 3 using EMA is more sensitive and specific for hereditary spherocytosis and related hereditary disorders than osmotic fragility
Related tests	Flow cytometry for band 3 using EMA, peripheral smear, direct antiglobulin test, complete blood count, red cell glycolytic intermediate metabolites (Table 159.18)
Interfering substances	Hemolyzed specimen, specimen age may falsely increase background hemolysis (laboratory may require submitting a concurrent sample from normal nonrelative to control for this)

TABLE 159.18 Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants[a]

Metabolite	Normal Adults (n =10)	Term Infants (n =10)	Premature Infants (n =11)
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9
Fructose-1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ± 1.6	6.5 ± 3.2
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15
2,3-Diphosphoglycerate	4423 ± 1907	3609 ± 800	3152 ± 2133

Units per 100 mL of red blood cells.

[a] Premature infants had birth weight below 2200 g and gestational age of less than 37 weeks and were clinically healthy at the time of investigation.

Reproduced with permission from Oski FA. Red cell metabolism in the newborn infant. V. Glycolytic intermediates and glycolytic enzymes. *Pediatrics*. 1969;44:84; Beutler E. G6PD deficiency. *Blood*. 1994;84:3613.

WHITE BLOOD CELL AND IMMUNOLOGIC TESTING

LEUKOCYTE COUNTS (ABSOLUTE AND PERCENTAGE)

Summary points	• Also called *WBC count and differential* • Part of complete blood count
Methodology	Automated hematology analyzer—flow cytometric or impedance methods, may use myeloperoxidase staining for granulocytes, differential may be performed by automated or manual methods
Specimen requirements	Whole blood: EDTA
Indications	Suspected infection, hematologic disorder, or immune deficiency
Reference range	Table 159.19

Interpretation	• Results can vary with time of day, hormonal status, ethnicity (e.g., lower neutrophil counts in persons of African descent)
	• With infection, total white blood cell (leukocyte) count is often elevated, but may be normal or low
	  • Predominance of neutrophils with left shift (immature myeloid precursors) suggests bacterial infection or sepsis but nonspecific; also seen with physical or emotional stress, growth factor treatment
	  • Predominance of lymphocytes and/or monocytes suggests a viral or atypical bacterial infection
	  • Eosinophilia suggests allergy, drug effect, or invasive parasitic infection
	• Abnormal cells suggest leukemia, lymphoma, or myelodysplastic syndrome but can also be seen after growth factor treatment
	• Low counts suggest marrow suppression due to infection, medication, autoimmunity, toxic exposure, metabolic disorder, bone marrow failure, myelodysplastic syndrome, leukemia, or immune deficiency
	• Generally, automated differentials are more accurate, but a manual differential may be indicated if abnormal or immature cells are present

Related tests	Manual differential, peripheral smear, lymphocyte subsets
Interfering substances	Clotted or hemolyzed sample

EDTA, Ethylenediaminetetraacetic acid; WBC, white blood cell.

LYMPHOCYTE SUBSETS

Summary points	• B-, T-, and NK-cell subsets used to diagnose and characterize immunodeficiency along with other lymphocyte function testing
Methodology	Flow cytometry
Specimen requirements	Whole blood: EDTA or heparin
Indications	Suspected or known immune deficiency; monitor status of HIV disease or immunomodulatory/immunosuppressive therapy
Reference range	Table 159.20
Interpretation	• Absolute declines in lymphocyte subsets can aid diagnosis and characterization of immune deficiencies: primarily B cell, T cell, or combined • T- and B-cell subsets may decline with immunomodulatory or immunosuppressive therapy • Absolute CD4 counts—monitored in patients with HIV; may define therapy thresholds or risks for specific pathogens • Results may vary with diurnal rhythm
Related tests	Complete blood count, lymphocyte mitogen testing, lymphocyte antigen response testing, antigen-specific IgG/IgM titers after vaccination, PPD testing for the delayed type of hypersensitivity response
Interfering substances	Hemolyzed sample, lipemia

EDTA, Ethylenediaminetetraacetic acid; *HIV*, human immunodeficiency virus; *Ig*, immunoglobulin; *NK*, natural killer; *PPD*, purified protein derivative.

Basophils[c]	
Absolute range	3–100/mm^3
Percentage range	0.10%–1.47%

[a] Numbers of leukocytes are in thousands per cubic millimeter, ranges are estimates of 95% confidence limits, and percentages refer to differential counts. Neutrophils include band cells at all ages and a small number of metamyelocytes and myelocytes in the first few days of life.

[b] Normal ranges vary slightly depending on automated analyzer used. The total leukocyte count is used to convert percentage values to absolute counts. Some automated hematology analyzers provide a full or limited differential. aValues are expressed in mg/L. Data were obtained from a total of 436 apparently healthy children. Values are 2.5th–97.5th percentiles.

[c] Data based on 668 normal individuals ages 5–74 years; range reflects 2.5th–97.5th percentiles; counts obtained using a Hemalog D cytochemical automated counter. From Simmons A, Leaverton P, Elbert G. Normal laboratory values for differential white cell counts established by manual and automated cytochemical methods (Hemalog D™). *J Clin Pathol.* 1974;27:55.

Samples analyzed by Epics Profile (Coulter) flow cytometer following whole blood lysis.
%, Relative percentage; A, absolute cell count × 10^9/L.
Data from Kotylo PK, Fineberg NS, Freeman KS, et al. Reference ranges for lymphocyte subsets in pediatric patients. *Am J Clin Pathol.* 1993;100:111. See also Denny T, Yogev R, Gelman R, et al. Lymphocyte subsets in healthy children during the first 5 years of life. *JAMA.* 1992;267:1484. Copyright 1992, American Medical Association.
[a] Values are expressed as 95th percentile reference range.
[b] Data represent median value, 10th-90th percentiles; based on studies from healthy human immunodeficiency virus (HIV)-negative HIV-nonexposed children using flow cytometry at multiple core laboratories. Approximately 700 children per age group.
[c] Modified from Shearer WT, Rosenblatt HM, Gelman RS, et al. Lymphocyte subsets in healthy children from birth through 18 years of age: The Pediatric AIDS Clinical Trials Group P1009 study. *J Allergy Clin Immunol.* 2003;112:973.

IMMUNOGLOBULIN A

Summary points	• Important component of mucosal immunity—dimeric form in mucosal secretions, monomeric form in serum • IgA deficiency may occur asymptomatically and may or may not confer increased infection risk • Elevated levels may be seen in monoclonal gammopathies or in the setting of chronic inflammation or infection (liver disease, collagen vascular disease, autoimmune disease, chronic infections) leading to polyclonal gammopathy
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency (recurrent infections), monoclonal gammopathy, isolated IgA deficiency, anaphylactic transfusion reaction to plasma
Reference range	Table 159.21
Interpretation	• Decreased with immune deficiency, celiac disease, some autoimmune diseases, medications, protein loss (nephrotic syndrome, protein-losing enteropathy), non-IgA monoclonal gammopathy • Increased in polyclonal hypergammaglobulinemia, monoclonal gammopathies, infections (tuberculosis, sepsis), chronic liver disease, collagen vascular disease, autoimmune disease, IgA nephropathy • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgG, IgM, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe specimen turbidity, microbial contamination
Reference	Woof JM, Kerr MA. The function of immunoglobulin A in immunity. *J Pathol*. 2006;208:270.

IMMUNOGLOBULIN E

Summary points	• Important in immune response to deep parasitic (nematode) infections • Important mediator of allergic response; level often elevated in patients with bronchial asthma or atopic dermatitis
Methodology	Nephelometry, immunoassay
Specimen requirements	Plain or serum separator tube
Indications	Suspected allergic disease; monitoring allergic bronchopulmonary aspergillosis
Reference range	Table 159.22
Interpretation	• Low levels in hypogammaglobulinemia and selective IgE deficiency • Elevated levels in allergic diseases, deep parasitic infections, malignancy, drug allergy, immune deficiency, some infections, and inflammatory disorders; rarely monoclonal IgE gammopathies • IgE measurement has limited value in diagnosing atopy given the large overlap between atopic and nonatopic individuals • Normal levels do not exclude allergy
Related tests	IgA, IgG
Interfering substances	Lipemia, other causes of extreme turbidity, microbial contamination
References	Bacharier LB, Geha RS. Regulation of IgE synthesis: the molecular basis and implications for clinical modulation. *Allergy Asthma Proc*. 1999;20:1. Hamilton RG, Adkinson NF Jr. Clinical laboratory assessment of IgE-dependent hypersensitivity. *J Allergy Clin Immunol*. 2003;111:S687.

IMMUNOGLOBULIN G

Summary points	• Largest fraction of serum immunoglobulins; important component of secondary humoral immunity • Elevation seen in monoclonal gammopathies and many polyclonal infectious or inflammatory conditions
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency (primary or secondary) or monoclonal gammopathy, assess response to immunization or recent or previous infection when antigen-specific IgM and IgG are tested
Reference range	Table 159.23
Interpretation	• Polyclonal elevations seen in hypergammaglobulinemia, chronic liver disease, collagen vascular diseases, autoimmune diseases, some infections • Monoclonal elevations seen in monoclonal gammopathies (plasma cell dyscrasias); confirmed by serum protein electrophoresis with immunofixation • Decreased in immune deficiencies, hypogammaglobulinemia, states of protein loss (protein-losing enteropathy, nephrotic syndrome), some malignancies, medications • Normal IgG levels do not exclude humoral immunodeficiency—further functional studies (assessment of antibody response post vaccine administration), and/or IgG subclasses may be required if high degree of clinical suspicion • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgM, IgA, lymphocyte subsets, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination

IMMUNOGLOBULIN G SUBCLASSES

Summary points	• IgG subclass deficiencies are uncommon but may be associated with recurrent bacterial infections • Total serum IgG may be normal, even with a subclass deficiency
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected humoral or combined immune deficiency with normal total serum IgG levels, recurrent respiratory, or sinus infections. Testing IgG subclasses has a limited role in the assessment of antibody-mediated immune function in patients with recurrent sinusitis and respiratory infections
Reference range	Table 159.24
Interpretation	• Decreased levels in hypogammaglobulinemia • Most frequent abnormality: IgG2 deficiency or combined IgG2–IgG4 deficiency. IgG2 deficiency may be associated with IgA deficiency in patients with chronic respiratory infection • Decreased IgG3 levels may be seen in primary immunodeficiencies (Wiskott–Aldrich syndrome) and type 1 diabetes mellitus • 70% of serum IgG is IgG1—selective IgG1 deficiency is rare • Significance of decreased IgG4 in absence of IgG2 deficiency uncertain
Related tests	IgG, IgM, IgA
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Reference	Maguire G. Are there any clinical indications for measuring IgG subclasses? *Ann Clin Biochem*. 2002;39:374.

Adults	4.8–9.5	1.1–6.9	0.3–0.8	0.2–1.1

[a] Values for males and females, expressed in g/L. Twenty schoolchildren from each age-group were tested. Only samples with C-reactive protein within the reference range were included. Enzyme-linked immunosorbent assay methodology was used on serum.

From Miles J, Riches P. The determination of IgG subclass concentrations in serum by enzyme-linked immunosorbent assay: establishment of age-related reference ranges for cord blood samples, children aged 5–13 years and adults. *Ann Clin Biochem*. 1994;31:245.

IMMUNOGLOBULIN M

Summary points	• Important component of the adaptive humoral immune response as initial antibody type produced after antigen exposure • Measurement of antigen-specific IgM and IgG can be useful in the diagnosis of recent or previous infection • Most common monoclonal immunoglobulin subtype elevated in Waldenström macroglobulinemia; associated with hyperviscosity syndrome
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency, monoclonal gammopathy, assess response to immunization or recent or previous infection when antigen-specific IgM and IgG are tested
Reference range	Table 159.25
Interpretation	• Elevated in polyclonal hypergammaglobulinemia, chronic liver disease, collagen vascular disease, autoimmune disease, some infections, some immune deficiencies, monoclonal gammopathy (lymphoplasmacytic lymphoma and Waldenström macroglobulinemia), cryoglobulinemia • Decreases in immune deficiencies, hypogammaglobulinemia, chronic protein loss (protein-losing enteropathy, malnutrition), some malignancies • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgG, IgA, lymphocyte subsets, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Ig, Immunoglobulin.

[b] From Lockitch G, Halstead AC, Quigley G, et al. Age- and sex-specific pediatric reference intervals: study design and methods illustrated by measurement of serum proteins with the Behring LN nephelometer. *Clin Chem.* 1988;34:1618. Results are 0.025th–0.975th fractiles. Plasma or serum.

IMMUNOGLOBULIN LIGHT CHAINS

Summary points	• Measurement of free light chains is done for diagnosis and monitoring of amyloid, nonsecretory myeloma, and light chain myeloma • Kappa/lambda ratio is critical—excess of kappa versus lambda or excess of lambda versus kappa light chains is consistent with a plasma cell dyscrasia
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected monoclonal gammopathy, amyloidosis, other plasma cell dyscrasia
Reference range	Table 159.26
Interpretation	Elevated free light chain with either kappa or lambda light chain restriction consistent with amyloidosis or another plasma cell dyscrasia
Related tests	Urine free light chains, urine protein electrophoresis with immunofixation, serum protein electrophoresis with immunofixation, serum immunoglobulin levels (IgG, IgA, IgM)
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Comments	May be more sensitive than serum protein electrophoresis with immunofixation for diagnosis of light chain disease

Ig, Immunoglobulin.

COMPLEMENT FRACTIONS C3 AND C4

Summary points	• Used to measure complement activation or deficiency • C3 and C4, measured together, examine both classical and alternative complement pathways
Methodology	Nephelometry, quantitative immunoturbidimetric, radioimmunodiffusion, electroimmunodiffusion
Specimen requirements	Plain or serum separator tube
Indications	Measure activity in collagen vascular diseases (systemic lupus erythematosus), complement deficiency, immune complex disease, glomerulonephritis, hereditary angioedema
Reference range	Table 159.27
Interpretation	• Reduced C4 with or without reduced C3 implies classical pathway activation as seen in lupus, immune complex disease, hereditary angioedema due to C1 inhibitor deficiency, chronic liver disease • Reduced C3 with normal C4 implies activation by the alternative pathway (e.g., sepsis) • Elevated C3 and/or C4 implies an acute-phase response • Primary deficiency is rare and requires functional assay
Related tests	Total complement CH50, C1q inhibitor
Interfering substances	Lipemia, microbial contamination
Reference	Wen L, Atkinson JP, Giclas PC. Clinical and laboratory evaluation of complement deficiency. *J Allergy Clin Immunol.* 113:585, 2004.

TABLE 159.26 Serum Levels of Immunoglobulin Light Chains in Males and Females[a]

Age	Kappa (g/L)	Lambda (g/L)	Kappa/Lambda Ratio
Newborn	8.10 (7.7–8.7)	4.70 (4.5–5.0)	1.74 (1.7–1.9)
Premature	4.29 (3.1–4.9)	2.91 (2.6–3.1)	1.70 (1.6–1.9)
1 month	4.46 (3.6–4.8)	2.32 (1.9–3.5)	1.80 (1.6–2.0)
2 months	2.58 (2.4–2.7)	1.88 (1.8–2.0)	1.66 (1.6–1.7)
3 months	2.07 (1.7–2.5)	2.25 (2.0–2.3)	1.09 (1.0–1.3)
4 months	2.09 (1.9–2.4)	2.40 (1.6–2.6)	0.98 (0.8–1.0)
5 months	2.36 (2.0–3.2)	2.54 (2.4–2.9)	1.02 (1.0–1.1)
1 year	4.46 (3.0–5.3)	3.91 (2.7–4.8)	0.99 (0.9–1.2)
2 years	5.32 (3.6–6.4)	3.82 (2.8–4.0)	1.42 (1.3–1.5)
3 years	4.98 (4.1–5.4)	3.67 (3.1–4.8)	1.31 (1.1–1.4)
4 years	6.78 (4.8–8.3)	4.87 (4.0–5.5)	1.51 (1.2–1.7)
5 years	6.58 (5.4–7.1)	4.01 (3.8–4.7)	1.55 (1.3–1.7)
6 years	8.02 (6.0–8.5)	4.01 (3.0–6.0)	1.61 (1.6–1.7)
7 years	5.90 (4.6–7.5)	4.08 (3.9–4.5)	1.64 (1.4–1.8)
8 years	8.34 (7.3–9.1)	4.64 (5.1–6.4)	1.50 (1.4–1.7)
9 years	8.26 (7.1–9.6)	4.95 (3.3–5.5)	1.69 (1.5–1.8)
10 years	9.03 (8.2–9.6)	5.32 (4.9–5.7)	1.80 (1.3–1.9)
11 years	7.18 (6.0–8.3)	4.10 (3.8–4.8)	1.67 (1.4–1.8)
12 years	9.17 (8.2–9.6)	4.90 (4.1–6.0)	1.82 (1.7–2.0)
13 years	9.59 (8.2–10.5)	5.86 (5.3–6.1)	1.64 (1.4–1.7)
14 years	9.45 (8.0–10.8)	5.50 (4.9–5.8)	2.09 (1.9–2.2)
15 years	10.18 (7.2–11.0)	4.75 (4.1–5.0)	2.25 (1.7–2.3)
16 years	9.37 (7.0–11.2)	5.09 (4.6–5.6)	1.89 (1.5–2.2)

[a] Median and ranges given as 10th–90th percentiles.

TABLE 159.27 Complement Fractions C3 and C4 in Males and Females, by Age

Study	Age	g/L
C3		
Zillow et al. (1993)[a]	Healthy neonates	0.30–0.98
Lockitch et al. (1988)[b]	0–5 days	0.26–1.04
	1–19 years	0.51–0.95
	Adult	0.45–1.8
C4		
Lockitch et al. (1988)[b]	0–5 days	0.06–0.37
	1–19 years	0.08–0.44
	Adult	0.11–0.5

[a] From Zillow G, Zillow EP, Burger R, et al. Complement activation in newborn infants with early onset infection. *Pediatr Res.* 1993;34:199. Results are 0–100th percentiles. Thirty-two healthy full-term newborns, birth weights between 2500 and 4020 g, were tested. All mothers (vagina, rectum) and infants (ear, gastric) were culture negative.

[b] Lockitch G, Halstead AC, Quigley G, et al. Age- and sex-specific pediatric reference intervals: study design and methods illustrated by measurement of serum proteins with the Behring LN nephelometer. *Clin Chem.* 1988;34:1618. Results are 0.025th–0.975th fractiles.

PLATELET AND COAGULATION TESTING

PLATELET COUNT AND MEAN PLATELET VOLUME

Summary points	• Used to assess the integrity of hematopoietic and hemostatic systems
Methodology[a]	Automated hematology analyzer—flow cytometric or impedance methods
Specimen requirements	Whole blood: EDTA
Indications	Suspected thrombocytopenia or thrombocytosis
Reference range	Table 159.28

Interpretation	• Thrombocytopenia
	  • Primary marrow process: infiltration by tumor or fibrosis, bone marrow failure, marrow suppression (drugs, toxins, infections), myelodysplasia
	  • Secondary consumptive or destructive process: immunologic destruction, hypersplenism, microangiopathy, disseminated intravascular coagulopathy
	• Thrombocytosis
	  • Primary: essential thrombocythemia, other MPNs
	  • Secondary: acute-phase reactant, splenectomy, iron deficiency
	• MPV may increase in destructive processes when larger, immature platelets prevail
	• MPV is elevated in hereditary macrothrombocytopenia (Bernard-Soulier syndrome, MYH9 disorders) and ITP
	• MPV is low in Wiskott-Aldrich syndrome

Related tests	Peripheral smear, complete blood count, platelet aggregometry
Interfering substances	Clotted or hemolyzed sample; difficult or prolonged collections may activate platelets and artifactually decrease the count

[a] Platelet count may also be estimated by peripheral smear review (count platelets in five fields using a 100× oil-immersion lens, take the average count, and multiply by 15,000) or manually counted using phase contrast microscopy and a hemocytometer. Automated methods using a hematology analyzer are usually more accurate and preferred.

EDTA, Ethylenediaminetetraacetic acid; *ITP*, immune thrombocytopenic purpura; *MPV*, mean platelet volume; *MYH9*, myosin heavy chain 9; MPNs, myeloproliferative neoplasms.

TABLE 159.28 **Platelet Counts and Mean Platelet Volumes in Children and Adults**

Age (Years)	Platelet Count (10^9/L)	Mean Platelet Volume (fL)
1–10	220–422	8.3–10.9
10–18	165–396	8.6–12.1
18–45	159–376	8.5–12.8
45–65 (males)	156–300	8.6–12.0
45–65 (females)	156–351	9.0–12.9
>65	139–363	8.8–12.4

Data from Giacomini A, Legovini P, Gessoni G, et al. Platelet count and parameters determined by the Bayer ADVIA 120 in reference subjects and patients. *Clin Lab Haematol.* 2001;23:181. Fifty male and 50 female subjects per age range were tested. Range represents 95% confidence limits.

IMMATURE PLATELET FRACTION

Summary points	• Similar to reticulated platelet count by flow cytometry, but available on automated hematology analyzers • Analogous to reticulocyte count for erythropoiesis, IPF assesses the rate of thrombopoiesis, can help distinguish decreased marrow production versus peripheral destruction as likely cause of thrombocytopenia
Methodology	Automated hematology analyzer—flow cytometric method using light scatter and fluorescence dyes that stain RNA
Specimen requirements	Whole blood: EDTA
Indications	Aid in the differential diagnosis of thrombocytopenia, assess marrow response after marrow injury, chemotherapy, or bone marrow transplant
Reference range	Table 159.29
Interpretation	• Increased with increased platelet production as seen in thrombocytopenia due to peripheral destruction (ITP, TTP; assuming normally functioning marrow) • Rise in IPF occurs with marrow engraftment posttransplant; precedes a rise in platelet count by a couple of days • Normal or decreased with impaired thrombopoiesis (bone marrow failure, suppression) • Increased in patients with macrothrombocytopenia • May be artifactually elevated with platelet clumping
Related tests	Platelet count, mean platelet volume, complete blood count
Interfering substances	Clotted or hemolyzed specimen
References	Briggs C. Quality counts: new parameters in blood cell counting. *Int J Lab Hematol.* 2009;31:277. Miyazaki K, Koike Y, Kunishima S, et al. Immature platelet fraction measurement is influenced by platelet size and is a useful parameter for discrimination of macrothrombocytopenia. *Hematology.* 2015;20:587.

EDTA, Ethylenediaminetetraacetic acid; *IPF*, immature platelet fraction; *ITP*, immune thrombocytopenic purpura; *RNA*, ribonucleic acid; *TTP*, thrombotic thrombocytopenic purpura.

TABLE 159.29 **Immature Platelet Fraction Reference Values in Healthy Adults**

N	Mean (%)	Range (%)
50	3.4	1.1–6.1[a]
142	1.7	0.4–5.4[b]
129	3.3	1.0–10.3[c]

Coagulation Screening Tests

PROTHROMBIN TIME (PT) AND INTERNATIONAL NORMALIZED RATIO (INR)

Summary points	• PT is used to screen for extrinsic or common clotting factor deficiencies INR is used as a universal standard to monitor warfarin therapy
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Suspected congenital or acquired coagulopathy involving the extrinsic and/or common pathways, monitor anticoagulation
Reference range	Table 159.30
Interpretation	• Reference ranges dependent on reagents and instrumentation, requiring laboratory-specific and population-specific ascertainment • Prolonged PT suggests a deficiency of one or more factors (II, V, VII, X) or the presence of a coagulation inhibitor • A prolonged PT with normal aPTT could suggest vitamin K deficiency, early liver failure, early disseminated intravascular coagulation, or FVII deficiency • PT can also be prolonged in the setting of markedly low fibrinogen • Mild common pathway factor deficiencies may appear with a prolonged PT and normal aPTT depending on the sensitivity of each assay • INR is intended to normalize PT reagents so that PT measured at any center worldwide yields comparable INR values • INR is a calculated value determined by the International Sensitivity Index (ISI) which is specific to the instrument and reagent used • Calculation of INR: $\mathrm{INR} = \left\{\frac{\mathrm{PT}^{\mathrm{Patient}}}{\mathrm{PT}^{\mathrm{Mean}}}\right\}^{\mathrm{ISI}}$ $\mathrm{PT}^{\mathrm{Patient}} = \text{Patient's PT}$ $\mathrm{PT}^{\mathrm{Patient}} = \text{Mean PT of Normal Range}$ $\mathrm{ISI} = \text{International Sensitivity Index}$ • The INR was only intended to be used to monitor therapy for patients taking Vitamin K (VKA) antagonists, though it is frequently employed outside of this setting, particularly in liver disease
Related tests	aPTT, thrombin time, coagulation factor levels, fibrinogen, factors II, V, VII, VIII, IX, X, XI, other contact pathway factors, lupus anticoagulant, mixing studies
Interfering substances	High hematocrit (>55%) can lead to false prolongation of the PT Direct oral anticoagulants can have variable effects on PT Clotted or hemolyzed sample
References	Ng VL. Prothrombin time and partial thromboplastin time assay considerations. *Clin Lab Med.* 2009;29(2):253–263. Ten Cate H, Henskens YM, Lancé MD. aPTT, Activated partial thromboplastin time; *HMWK*, high-molecular-weight kininogen; *INR*, international normalized ratio; *PT*, prothrombin time; *vWF*, von Willebrand factor. For each assay mean and boundaries including 95% of the population are shown. All factor levels except fibrinogen are expressed as percentages where 100% = 1.0 unit/mL.

[a] Denotes values that are significantly different from adult values ($p < .05$). Data from Monagle P, Barnes C, Ignjatovic V, et al. Developmental haemostasis. Impact for clinical haemostasis laboratories. *Thromb Haemost.* 2006;95:362.

[b] From Andrew M, Vegh P, Johnston M, et al. Maturation of the hemostatic system during childhood. *Blood.* 1992;80:1998.

ACTIVATED PARTIAL THROMBOPLASTIN TIME

Summary points	• aPTT is primarily used to screen for intrinsic clotting factor deficiencies, but also picks up common pathway deficiencies and may be prolonged in von Willebrand disease • aPTT is one method used to monitor unfractionated heparin therapy
Methodology	Clot detection
Specimen requirements	Citrate
Indications	• Suspected congenital or acquired coagulopathy involving the intrinsic and/or common pathways, monitor anticoagulation
Reference range	See Table 159.30
Interpretation	• Reference ranges dependent on reagents and instrumentation, requiring laboratory-specific and population-specific ascertainment (e.g., aPTT is normally prolonged during the neonatal period) • Normal aPTT does not exclude mild, but clinically significant, factor deficiency (especially hemophilia B and von Willebrand disease) • Prolonged aPTT with normal PT suggests a deficiency of one or more factors (VIII, IX, XI, or other contact pathway factors) or the presence of inhibitors such as lupus anticoagulant or heparin (consider heparin contamination in specimen drawn from a heparinized line) • Prolonged PT and aPTT suggests moderate to severe vitamin K deficiency, liver disease, disseminated intravascular coagulation, common pathway factor deficiency • Markedly low fibrinogen can prolong the aPTT • Factor XII, HMWK, and prekallikrein deficiencies can prolong the aPTT but are not associated with clinical bleeding • Lupus anticoagulant can prolong the aPTT but is associated with risk for thrombosis rather than bleeding • High circulating factor VIII and/or thrombin can shorten the aPTT and may be useful for assessing thrombotic risk
Related tests	PT, thrombin time, coagulation factor levels, fibrinogen, factors II, V, VII, VIII, IX, X, XI, other contact pathway factors, lupus anticoagulant, mixing studies
Interfering substances	High hematocrit (>55%) can lead to false prolongation of the aPTT Direct oral anticoagulants can have variable effects on aPTT Contamination from lines containing heparin or direct thrombin inhibitors Elevated C-reactive protein leads to false prolongation Clotted or hemolyzed sample

aPTT, Activated partial thromboplastin time; *HMWK*, high-molecular-weight kininogen; *PT*, prothrombin time

FIBRINOGEN

Summary points	• Used to detect acquired or congenital afibrinogenemia, hypofibrinogenemia, dysfibrinogenemia • Can be used for the detection and assessment of both hemorrhagic and thrombotic diatheses • Fibrinogen should be carefully monitored in fibrinolytic therapy and DIC
Methodology	Clot detection (functional, Clauss and PT-derived), Immunoassay (antigenic)
Specimen requirements	Citrate
Indications	Investigation of bleeding due to suspected decrease or dysfunction of fibrinogen Assessment of thrombotic risk (hyperfibrinogenemia) Monitoring during thrombolytic therapy
Reference range	Tables 159.30 and 159.32
Interpretation	• Fibrinogen is decreased in the setting of congenital afibrinogenemia, congenital hypofibrinogenemia, hemodilution, disseminated intravascular coagulation, fibrinolysis, and liver disease. • Dysfibrinogenemia (abnormal fibrinogen function) can be detected by discrepancies between functional and antigenic levels of fibrinogen • Acquired dysfibrinogenemia can occur in the setting of liver disease • Systemic thrombolytic therapy can rapidly reduce fibrinogen levels, monitoring fibrinogen levels during therapy is recommended • Fibrinogen is an acute-phase reactant, and levels can become increased in response to a variety of physiologic stimuli including: inflammation, pregnancy/oral contraceptives, and disseminated malignancy • Elevated fibrinogen is a risk factor for thrombosis
Related tests	PT, aPTT, thrombin time, reptilase time, thromboelastography/thromboelastogram
Interfering substances	High levels of fibrin degradation products or paraproteins can inhibit fibrin polymerization High levels of heparin (if surpass the heparin neutralization limits of the assay) Icteric or hemolyzed specimens (optical methods), turbid or lipemic specimens (mechanical clot detection)

For each assay the first two rows show mean and boundaries including 95% of the population. The next row shows the number of individual samples.

TABLE 159.32 Comparison of Selected Coagulation Factor Values in Newborns[a]

Study	Fibrinogen (mg/dL)	Factor II (units/mL)	Factor VIII (units/mL)	Factor IX (units/mL)	Factor XII (units/mL)	Antithrombin (units/mL)	Protein C (units/mL)
Term							
Hathaway and Bonnar (1987) and Manco-Johnson et al. (1988)[b]	240 (150)	0.52 (0.25)	1.5 (0.55)	0.35 (0.15)	0.44 (0.16)	0.56 (0.32)	0.32 (0.16)
Andrews et al. (1987, 1988)[c]	283 (177)	0.48 (0.26)	1.0 (0.50)	0.53 (0.25)	0.53 (0.20)	0.63 (0.25)	0.35 (0.17)
Corrigan (1992)[d]	246 (150)	0.45 (0.22)	1.68 (0.50)	0.40 (0.20)	0.44 (0.16)	0.52 (0.20)	0.31 (0.17)
Preterm							
Hathaway and Bonnar (1987) and Manco-Johnson et al. (1988)[b]	300 (120)	0.45 (0.26)	0.93 (0.54)	0.41 (0.20)	0.33 (0.23)	0.40 (0.25)	0.24 (0.18)
Andrews et al. (1987, 1988)[c]	243 (150)	0.45 (0.20)	1.1 (0.50)	0.35 (0.19)	0.38 (0.10)	0.38 (0.14)	0.28 (0.12)
Corrigan (1992)[d]	240 (150)	0.35 (0.21)	1.36 (0.21)	0.35 (0.10)	0.22 (0.09)	0.35 (0.10)	0.28 (0.12)

Note: In summary, plasma levels of the vitamin K–dependent factors (including proteins C and S), contact factors, and antithrombin are decreased at birth.

[a]Data are expressed as mean and lower limit of normal (in parentheses). Preterm, 30–36 weeks' gestational age.

[b]Data from Hathaway WE, Bonnar J. *Hemostatic Disorders of the Pregnant Woman and Newborn Infant.* New York: Elsevier Science; 1987; Manco-Johnson M, Marlar R, Jacobson L, et al. Severe protein C deficiency in newborn infants. *J Pediatr.* 1988;113:359.

MIXING STUDIES

Summary points	• Performed by mixing 1:1 normal pooled plasma (NPP) with patient sample with PT and/or aPTT measured immediately and after incubation for 1–2 h • Used to determine if PT or aPTT is prolonged due to factor deficiency or inhibitor
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Suspected congenital or acquired factor deficiency or inhibitor involving the intrinsic, extrinsic, and/or common pathways Evaluation for lupus anticoagulant
Reference range	Institutional reference range for PT and/or aPTT

Interpretation	• PT mixing study:
	  • Corrected immediately: FVII deficiency, common factor pathway deficiency (factors II, V, X) if aPTT also prolonged. Corrected PT mixing study most frequently suggests multiple factor deficiency
	  • Incompletely corrected: Lupus anticoagulant or extrinsic/common factor pathway inhibitor
	• aPTT mixing study:
	  • Corrected immediately: Intrinsic pathway factor deficiency (factors VIII, IX, XI, XII) if only aPTT prolonged, common pathway factor deficiency (factors II, V, X) if PT also prolonged
	  • Corrected immediately, incompletely corrected after incubation: FVIII inhibitor
	  • Incompletely corrected: Lupus anticoagulant or intrinsic/common pathway factor inhibitor
	• Mixing studies are difficult to standardize, consultation with the performing lab is recommended when only partial correction occurs
	• Weak inhibitors may be completely corrected by mixing study
	• Generally should not be performed on patients with known anticoagulant therapy and can be of some utility when the type of anticoagulant is unknown
	• When clinical suspicion is high for the deficiency of a particular factor, performing directed factor studies may be more efficient

Related tests	Lupus anticoagulant, factor studies, PT, aPTT
Interfering substances	High hematocrit (>55%) can lead to false prolongation Anticoagulant therapy (heparin, direct thrombin inhibitors, direct oral anticoagulants) Clot or hemolysis
References	Favaloro EJ. Coagulation mixing studies: utility, algorithmic strategies and limitations for lupus anticoagulant testing or follow up of abnormal coagulation tests. *Am J Hematol.* 2020;95(1):117–128. doi:10.1002/ajh.25669

aPTT, Activated partial thromboplastin time; *FVII*, factor VII; *FVIII*, factor VIII; *NPP*, normal pooled plasma; *PT*, prothrombin time

LUPUS ANTICOAGULANT

Summary points	• A variety of different assays can be utilized for the detection of lupus anticoagulant (LA) and are based on identifying phospholipid-dependent inhibition • Guidelines recommend two tests be performed; the dRVVT and a sensitive aPTT are generally used • Repeat testing should be performed >12 weeks after initial testing for confirmation of lupus anticoagulant
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Performed for patients suspected of having antiphospholipid antibody syndrome or those found to have unexpectedly prolonged aPTT on routine coagulation testing
Reference range	Cut-off determined by each institution and should be >99th percentile of the distribution of healthy donors. A dRVVT ratio of >1.2 is generally considered to be positive
Interpretation	• LA is a misnomer. While the presence of LA can prolong routine coagulation tests, particularly the aPTT, it is a risk factor for thrombosis rather than bleeding • dRVVT is the first test considered, while the second test is commonly a sensitive aPTT-based assay (low phospholipid content using a silica activator) • A screening test is performed first and is determined to be positive when the clotting time is longer than the institutional reference range • The confirmatory test is performed by increasing the concentration of phospholipids in the assay. Demonstration of correction (greater than the local cut-off) following the addition of excess phospholipids confirms the presence of LA • LA is determined to be present when at least one of the two assays performed is positive, though this must be confirmed with repeat testing >12 weeks after initial testing • Samples should be obtained in the absence of anticoagulation therapy whenever possible, as the various anticoagulants have variable effects on lupus anticoagulant testing. Notably, the dRVVT is particularly sensitive to anti-Xa therapies
Related tests	aPTT, mixing studies, antiphospholipid assays
Interfering substances	Anticoagulants: heparin, direct thrombin inhibitors, direct oral anticoagulants, VKA Clotted or hemolyzed specimens
References	Pengo V, Tripodi A, Reber G, et al. Update of the guidelines for lupus anticoagulant detection. Subcommittee on Lupus Anticoagulant/Antiphospholipid Antibody of the Scientific and Standardisation Committee of the International Society on Thrombosis and Haemostasis. *J Thromb Haemost.* 2009;7(10):1737–1740. doi:10.1111/j.1538-7836.2009.03555.x Favaloro EJ. aPTT, Activated; *dRVVT*, dilute Russell Viper Venom time; *LA*, lupus anticoagulant; *VKA*, vitamin K antagonist

COAGULATION FACTOR LEVELS (II, V, VII, VIII, IX, X, XI, XII, CONTACT PATHWAY FACTORS)

Summary points	• Choice of which specific factor(s) to measure driven by clinical scenario and screening test results (e.g., isolated prolonged PT suggests FVII deficiency, isolated preoperative aPTT suggests measurement of at least FVIII, FIX, and FXI, to assess bleeding risk)
Methodology	Clot detection, chromogenic (factors VIII and IX)
Specimen requirements	Citrate
Indications	Suspected coagulation factor deficiency, especially as suggested by prolonged coagulation screening test and subsequent mixing study that corrects, assessment of risk factors for thrombosis (e.g., high FVIII), monitoring of factor-replacement therapy in patients with coagulopathy
Reference range	Tables 159.30 and 159.32
Interpretation	• No definitive threshold for what constitutes a hemostatically adequate factor level, but the criteria for diagnosing mild factor deficiency are often set at 40%–50% • FVIII and von Willebrand factor are acute-phase reactants • Factor deficiency may be due to reduced production (hereditary factor deficiency, liver disease, vitamin K deficiency), increased consumption (disseminated intravascular coagulation), or specific inhibitor (FVIII) • Acquired deficiency of multiple factors occurs with liver disease, vitamin K deficiency (including vitamin K–antagonist therapy or toxicity), disseminated intravascular coagulation—FV, FVII, and FVIII may aid in distinguishing between these • Rare inherited combined factor deficiencies exist (combined FV/FVIII, vitamin K–dependent factors) • With exception of FXI, contact factor deficiencies (FXII, high-molecular-weight kininogen, prekallikrein) may cause prolonged aPTT but are not associated with increased bleeding risk • Vitamin K–dependent and contact factors are physiologically low in early infancy • FV and FVIII are particularly labile, with potential for spuriously low levels—carefully consider abnormally low levels in clinical and laboratory context and assess the need for repeat/confirmatory testing • One-stage (aPTT-based) assays are affected by the presence of lupus anticoagulant and various anticoagulants, chromogenic assays may be preferred in these settings • Chromogenic assays should be considered in the evaluation of mild hemophilia A and are preferred for monitoring particular types of factor VIII and IX replacement therapies
Related tests	Specific factor inhibitor testing, lupus anticoagulant, mixing studies
References:	Marlar RA, Strandberg K, Shima M, Adcock DM. Clinical utility and impact of the use of the chromogenic vs one-stage factor activity assays in haemophilia A and B. *Eur J Haematol.* 2020;104(1):3–14. https://doi.org/10.1111/ejh.13339

aPTT, Activated partial thromboplastin time; *FIX*, factor IX; *FV*, factor V; *FVII*, factor VII; *FVIII*, factor VIII; *FXI*, factor XI; *FXII*, factor XII; *PT*, prothrombin time.

BETHESDA ASSAY/NIJMEGEN-BETHESDA ASSAY

Summary points	• Bethesda unit (BU) = the amount of inhibitor that will neutralize 50% factor VIII activity after 2-h incubation • Assay generally used for the identification of factor VIII inhibitors, but the methodology can be used for other factor inhibitors • Heat inactivation of residual factor activity can be used for the assessment of patients on replacement therapy
Methodology	Clot-based or chromogenic
Specimen requirements	Citrate
Indications	Assessment of patients with suspected factor inhibitors, particularly those with hemophilia A receiving factor-replacement therapy
Reference range	0 BU/mL
Interpretation	• Testing is usually performed for patients with less than the usual response to replacement therapy • Identification of inhibitor suggests patients will require increased factor-replacement or change-in-factor therapy • Recent factor therapy may affect test results depending on institutional methodology (use of heat inactivation) • This assay will detect inhibitors that affect invitro activity, inhibitors causing increased clearance of factors will not be detected by this method • While traditionally used for factor VIII inhibitors (the most commonly identified factor inhibitor), testing for other factor inhibitors can be performed using the same methodology
Related tests	Factor activity assays, aPTT, PT
Interfering substances	Recent replacement therapy may lead to invalid results Lupus anticoagulant and heparin therapy can cause false positives Hemolyzed or clotted samples
References	Duncan E, Collecutt M, Street A. Nijmegen-Bethesda Assay to measure factor VIII inhibitors. In: Monagle P, ed. *Haemostasis. Methods in Molecular Biology (Methods and Protocols).* Vol 992. Totowa, NJ: Humana Press; 2013

aPTT, Activated partial thromboplastin time; *BU*, Bethesda unit; *PT*, prothrombin time.

VON WILLEBRAND ANTIGEN/ACTIVITY

Summary points	• von Willebrand disease (vWD) is the most common inherited bleeding disorder and is caused by abnormalities in the vW protein – these may be quantitative or qualitative abnormalities • Values are affected by a variety of clinical conditions, and repeated testing may be required for diagnosis
Methodology	Immunoturbidometric/Immunoassay
Specimen requirements	Citrate
Indications	For patients with suspected vWD, family history of vWD, bleeding of unknown etiology Evaluation of patients with suspected acquired von Willebrand syndrome due to ECMO, VAD, Wilms tumor, and other settings
Reference range	50%–150%
Interpretation	• von Willebrand antigen/activity are affected by a variety of clinical conditions and may be falsely elevated in acute-phase reactions, traumatic venipuncture, menstruation, estrogen medications or oral contraceptives, stress, and pregnancy • Type 1: Quantitative deficiency of vWF (<30%), normal or mildly decreased factor VIII, normal multimers, normal activity:antigen ratio • Type 1C: Shortened half-life of vWF, level <30%, normal or mildly decreased factor VIII, normal multimers, normal activity:antigen ratio • Type 2A: Qualitative defect of vWF with low or low-normal vW antigen, low vW activity, normal or mildly decreased factor VIII, loss of high-molecular-weight multimers, low activity:antigen ratio • Type 2B: Qualitative defect of vWF with normal or low vW antigen, low vW activity, normal or mildly decreased factor VIII, loss of high-molecular-weight multimers, often with low activity:antigen ratio, thrombocytopenia, increased aggregation with low-dose ristocetin • Type 2M: Qualitative defect of vWF with normal or low vW antigen, low vW activity, normal or mildly decreased factor VIII, normal multimers, low activity:antigen ratio • Type 2N: Qualitative defect (decreased binding affinity for factor VIII) of vW with normal or low vWF antigen, normal or low vW activity, decreased factor VIII, normal multimers, normal activity:antigen ratio • Type 3: Quantitative defect of vWF with undetectable vW antigen/activity, low factor 8, and absent multimers • Acquired von Willebrand syndrome may or may not present with a low ratio, multimer analysis should be performed if there is clinical suspicion and shows loss of high-molecular-weight multimers • Additional testing may need to be performed for appropriate typing of vWD
Related tests	aPTT, factor VIII, Exon 28 sequencing, vW collagen binding assay, ristocetin-induced platelet aggregation
Interfering substances	Lipemic plasmas: may underestimate vWF Rheumatoid factor: may lead to an overestimation of vWF Anti-bovine and/or anti-rabbit antibodies: may lead to an overestimation of vWF
References	Nichols WL, Hultin MB, James AH, et al. von Willebrand disease (VWD): evidence-based diagnosis and management guidelines, the National Heart, Lung, and Blood Institute (NHLBI) Expert Panel report (USA). *Haemophilia*. 2008;14(2):171–232. doi:10.1111/j.1365-2516.2007.01643.x

aPTT, Activated partial thromboplastin time; *ECMO*, extracorporeal membrane oxygenation; *VAD*, ventricular assist device; *vWD*, von Willebrand disease; *vWF*, von Willebrand factor.

NATURAL ANTICOAGULANTS (ANTITHROMBIN, PROTEIN C, PROTEIN S, TISSUE FACTOR PATHWAY INHIBITOR)

Summary points	• Severe deficiency associated with severe thrombotic complications or lethality • Acquired deficiencies more common than inherited • Therapeutic repletion may be indicated in some deficiency states
Methodology	Clot-based (functional protein C and S), chromogenic (functional), or immunoassay (antigenic)
Specimen requirements	Citrate
Indications	Assessment of thrombotic risk, diagnosis of severe anticoagulant deficiency states, anticoagulant therapy monitoring (antithrombin status with heparin therapy), assessment of repletion need with concentrate (AT, PC)
Reference range	Tables 159.31 and 159.32
Interpretation	• Levels lower in early infancy and may be reduced in acute thrombosis, consumptive coagulopathy, liver disease • Estrogen, heparin, and asparaginase therapy, nephrotic syndrome associated with decreased AT • PC, PS vitamin K dependent—levels reduced with deficiency and vitamin K antagonist exposure • PS decreased in the setting of inflammation, coexisting activated PC resistance (factor V Leiden), pregnancy, estrogen therapy, sickle cell anemia, nephrotic syndrome • No definitive threshold for what levels constitute adequate levels protective against thrombosis, but levels below approximately 70% are often considered abnormal
Related tests	Thrombophilia evaluation, anticoagulation monitoring tests
Interfering substances	Hemolyzed sample or lipemia

AT, Antithrombin; *PC*, protein C; *PS*, protein S.

D-DIMER

Summary points	- Fibrin degradation byproduct of the fibrinolytic process after cross-linking by FXIII - Used as a biomarker in thrombosis, disseminated intravascular coagulation - Varied assay methods without clear standardization—reference values specific to method and population critical to interpretation
Methodology	Immunoassay
Specimen requirements	Citrate or EDTA
Indications	Assessment of possible venous thromboembolism, risk stratification for recurrent thrombosis, evaluation of disseminated intravascular coagulation
Reference range	Table 159.33
Interpretation	- Elevated with recent fibrin formation and subsequent fibrinolysis (assuming normal fibrinolytic function) - Elevated with inflammation, malignancy, surgery, recent trauma, bleeding, liver disease, pregnancy - Varied assay methods without clear standardization—reference values specific to method and population critical to interpretation
Related tests	Thrombophilia evaluation, anticoagulation monitoring tests
Interfering substances	Hemolyzed sample or lipemia
Reference	Adam SS, Key NS, Greenberg CS. D-dimer antigen: current concepts and future prospects. *Blood*. 2009;113:2878.

EDTA, Ethylenediaminetetraacetic acid; *FXIII*, factor XIII.

TABLE 159.33 D-Dimer Reference Values in Infants, Children, and Adults

	Day 1	Day 3	1 Month–1 Year	1–5 Years	6–10 Years	11–16 Years	Adults
D-dimer	1.47[a]	1.34[a]	0.22	0.25[a]	0.26[a]	0.27[a]	0.18
	0.41–2.47	0.58–2.74	0.11–0.42	0.09–0.53	0.1–0.56	0.16–0.39	0.05–0.42
	20	23	20	40	39	21	32

Data from Monagle P, Barnes C, Ignjatovic V, et al. Developmental haemostasis: impact for clinical haemostasis laboratories. *Thromb Haemost.* 2006;95:362. First two rows show mean and boundaries including 95% of the population. The next row shows the number of individual samples.

[a] Denotes values that are significantly different from adult values ($P < .05$).

ANTI-XA ASSAY

Summary points	• Anti-Xa assay provides a more direct method of measuring heparin effect and has less variability than the aPTT which can be affected by several interfering substances (ex. lupus anticoagulant, high factor VIII) • Assay depends on availability of antithrombin; assays that do not have an exogenous source of antithrombin may correlate better with in vivo heparin activity • May be used to exclude presence of apixaban or rivaroxaban prior to urgent surgical interventions, but not currently recommended for monitoring of these drugs
Methodology	Chromogenic
Specimen requirements	Citrate
Indications	• Used to monitor anticoagulant effect in patients receiving UFH or LMWH therapy • Can be used to assess for oral anti-Xa therapy with rivaroxaban or apixaban
Reference range	Range depends on clinical target and anticoagulant 0.35–0.7 U/mL for UFH 0.2–0.4 U/mL for prophylactic LMWH 0.5–1.0 U/mL for treatment LMWH
Interpretation	• Anti-Xa assays can be used to titrate UFH or LMWH therapy to clinical targets • When also monitoring UFH therapy with aPTT, discordant results are not uncommon • Discordant results between the aPTT and anti-Xa assays can be seen in the setting of increased factor VIII or decreased factor II • A supratherapeutic aPTT with a therapeutic anti-Xa level may be associated with increased risk for bleeding • Anti-Xa assays calibrated for LMWH can be used to assess for residual rivaroxaban or apixaban effects, particularly if urgent intervention is needed
Related tests	aPTT, thrombin time
Interfering substances	Hemolysis, high bilirubin, and release of PF4 from platelets if not appropriately processed all cause falsely decreased values
References	Guervil DJ, Rosenberg AF, Winterstein AG, Harris NS, Johns TE, Zumberg MS. aPTT, activated partial thromboplastin time; *LMWH*, low molecular weight heparin; *UFH*, unfractionated heparin.

PFA-100

Summary points	• Widely available method measuring time to platelet plug formation under high shear and in presence of platelet agonists (epinephrine and ADP) • Suboptimal sensitivity and specificity for platelet function disorders and von Willebrand disease
Methodology	Automated aspiration of whole blood
Specimen requirements	Citrate
Indications	Assessment of primary hemostasis
Reference range	Table 159.34
Interpretation	• Determination of site-specific reference ranges recommended—longer closure times have been reported • Prolonged closure times with more severe von Willebrand disease and platelet dysfunction but also with anemia, thrombocytopenia, and antiplatelet therapy • Specimen agitation and delayed time to assay may give spurious results
Related tests	Platelet aggregometry, von Willebrand disease testing
Interfering substances	Antiplatelet therapy and other drugs

ADP, Adenosine diphosphate.

TABLE 159.34 PFA-100 Closure Times in Healthy Neonates, Children, and Adults

	Collagen/Epinephrine (s)	Collagen/ADP (s)
Term neonates (*n* = 17)	81 (61–108)	56 (48–65)
Children (*n* = 57)	117 (83–163)	91 (72–111)
Adults (*n* = 31)	106 (82–142)	85 (67–111)

ADP, Adenosine diphosphate.
From Carcao MD, Blanchette VS, Dean JA, et al. The Platelet Function Analyzer (PFA-100): a novel in-vitro system for evaluation of primary haemostasis in children. *Br J Haematol.* 1998;101:70. Mean and ranges given as 5th–95th percentiles.

PLATELET AGGREGOMETRY

Summary points	• "Gold standard" for measuring platelet function • Poor interlaboratory standardization of sample collection methods, agonists, agonist concentrations, parameters of interest and other methodologic aspects can limit interpretability • Test availability often limited to specialized hemostasis laboratories due to significant technical and quality control requirements
Methodology	Turbidometric or impedance
Specimen requirements	Citrate
Indications	Assessment of platelet function
Reference range	Laboratory dependent; control specimen often required
Interpretation	• Common agonists include ADP, arachidonic acid, collagen, epinephrine, ristocetin, thrombin; pattern of aggregation and presence or absence of primary or secondary waves help to define certain rare, inherited but well-characterized platelet function disorders (e.g., Glanzmann thrombasthenia, Bernard-Soulier syndrome) • Other less specific abnormalities seen in acquired disorders: uremia, myeloproliferative neoplasms, myelodysplastic syndromes, dysproteinemia, liver disease, cardiopulmonary bypass, drug effect
Related tests	PFA-100, VerifyNow assay
Interfering substances	Antiplatelet therapy and other drugs

ADP, Adenosine diphosphate.
